SIFS	short inter-frame separation (éeparation inter-trames courte)
(U)SIM	(universal) subscriber identity module (module d'identité (universelle) d'abonné)
SINR	signal to interference plus noise ratio (rapport signal/brouillage plus bruit)
SK	clé T (symétrique) utilisée pour l'authentification et la confidentialité
SKG	secret key generation (generation de cle secrete)
SL	session layer (couche session)
SMIB	structured management information base (base d'informations de gestion structurées)
SMAP	system manager application process (processus d'application de gestionnaire de système)
SM	system manager (gestionnaire de système)
SMAP	system management application process (processus d'application de gestion de système)
SMO	system monitoring object (objet de surveillance de système)
SOE	sequence of events (séquence d'événements)

SRTT	smoothed round-trip time (temps de propagation aller-retour lisse)
STSO	system time service object (objet de service de temps système)
TAI	international atomic time (temps atomique international)
TCP	transmission control protocol (protocole de contrôle de transport)
TDMA	time division multiple access (accès multiple par répartition dans le temps)
TDE	transport layer data (sub-)entity ((sous-)entité de données de couche transport)
TDSAP	transport layer data service access point (point d'accès au service de données de couche transport)
TFRC	TCP-friendly rate control (controle de débit compatible TCP), IETF RFC 5348
TICI	transport interface control information (informations de controle d'interface de transport)
TL	transport layer (couche transport)
TLE	transport layer entity (entité de couche transport)
TME	transport layer management (sub-)entity ((sous-)entité de gestion de couche transport)
TMIB	transport layer management information base (base d'informations de gestion de couche transport)
TMIC	transport layer message integrity code (code d'intégrité de message de couche transport)
TMSAP	transport layer management service access point (point d'accès au service de gestion de couche transport)
ToS	type of service (type de service)
TPCI	transport layer protocol control information (informations de contrôle de protocole de couche transport)
TPDU	transport layer protocol data unit (unité de données de protocole de couche transport)
TSAP	transport layer service access point (point d'accès au service de couche transport)
TSC	transport layer security component (composant de sécurité de couche transport)
TSCH	time-slotted channel hopping (saut de voies en fonction du temps)
TSDU	transport layer service data unit (unité de données de service de couche transport)
TUN	tunnel object (objet tunnel)
TUN-Data	tunnel data (données tunnel)
UAL	upper application layer (couche d'application supérieure)
UAP	processus d'application utilisateur
UAPMO	user application process management object (objet de gestion de processus d'application utilisateur)
UDO	upload/download object (objet téléchargement montant/téléchargement descendant)
UDP	user datagram protocol (protocole datagramme d'utilisateur)
UFO	unified field object (objet champ unifié)
UTC (TUC)	universal coordinated time (temps universel coordonné)
WBM	wideband modulation (modulation en large bande)
WiMAX	worldwide interoperability for microwave access (système d'interopérabilité mondiale pour l'accès hyperfréquence)
WISN	wireless industrial sensor network (réseau de capteurs industriels sans fil)

3.3 Conventions

3.3.1 Interfaces de service

Des parties de la présente norme utilisent les conventions descriptives données dans l'ISO/IEC 10731.

Les primitives de service, utilisées pour représenter les interactions utilisateur de service/fournisseur de service (voir ISO/IEC 10731), acheminent des paramètres qui indiquent les informations disponibles dans l'interaction entre utilisateur et fournisseur.

La présente norme utilise un format de tableau pour décrire les paramètres de composants des primitives de NS (SAP couche N ou SAP d'entité). Les paramètres qui s'appliquent à chaque groupe de primitives de NS sont consignés en tableaux. Chaque tableau comporte jusqu'à six colonnes, contenant le nom du paramètre de service, et une colonne chacune pour les primitives et les sens de transfert de paramètres utilisés par le NS:

- les paramètres d'entrée de la primitive "request";
- les paramètres de sortie de la primitive "indication";
- les paramètres d'entrée de la primitive "response"; et
- les paramètres de sortie de la primitive "confirm".

NOTE 1 Les primitives "request", "indication", "response" et "confirm" sont aussi respectivement appelées primitives "requestor.submit", "acceptor.deliver", "acceptor.submit", et "requestor.deliver" (voir ISO/IEC 10731).

Un paramètre (ou une partie de celui-ci) est énuméré dans chaque rangée de chaque tableau. Dans les colonnes appropriées de la primitive de service, un code est utilisé pour spécifier le type d'usage du paramètre sur la primitive et le sens de paramètres spécifiés dans la colonne:

M: le paramètre est obligatoire pour la primitive;

S: une sélection dans un ensemble défini d'au moins deux paramètres;

U: le paramètre est une option de l'utilisateur et peut ou peut ne pas être fourni, cela dépendant de l'usage dynamique de l'utilisateur de NS. Lorsqu'il n'est pas fourni, une valeur par défaut est supposée pour le paramètre;

C: le paramètre est conditionné à d'autres paramètres ou à l'environnement de l'utilisateur de NS;

(blanc/vide) ou tiret cadratin ("—"): le paramètre n'est jamais présent.

Certaines entrées sont en plus qualifiées par des éléments entre parenthèses. Ceux-ci peuvent être:

- une contrainte spécifique au paramètre:

(=) indique que le paramètre équivaut du point de vue de la sémantique au paramètre dans la primitive de service située immédiatement à sa gauche dans le tableau;

- une indication qu'une certaine note s'applique à l'article:

(n) indique que la note n suivante contient des informations complémentaires relatives au paramètre et à son utilisation. Les notes énumérées avec des lettres sont normatives; les notes numérotées avec des chiffres sont informatives.

Un tableau récapitulatif est fourni pour définir l'utilisation du paramètre dans la primitive. Chaque cellule définit si chaque paramètre est obligatoire, facultatif, interdit ou conditionnel.

L'ordre des paramètres est également défini implicitement de bas en haut.

Des paramètres complexes peuvent également être montrés. Par exemple, une structure peut être obligatoire, mais certains des éléments de la structure peuvent être facultatifs. Les éléments d'une structure sont indentés proportionnellement à leur niveau de hiérarchie.

Les paramètres d'entrée pour les services sont spécifiés pour les primitives de service "request" et "response". Les paramètres de sortie pour les services sont spécifiés pour les primitives de service "indication" et "confirmation".

Les abréviations suivantes sont utilisées dans les tableaux des services:

- Demande demande de service
- Indication indication de service

- Réponse réponse de service
- Confirmation confirmation de service

NOTE 2 Le traitement dans un appareil de situations d'erreur entre couches, telles que les situations où une file d'attente de couche inférieure connaît un dépassement de capacité ou il se produit une temporisation de couche inférieure, relève d'une initiative locale et n'est donc pas abordé par la présente norme.

3.3.2 Cellules de tableau

Pour tous les tableaux, les entrées de tableau qui ne sont ni pertinentes ni spécifiées peuvent contenir un tiret cadratin ("—"). Les entrées de tableau devant être remplies par les fournisseurs peuvent contenir des points de suspension ("...").

3.3.3 Italique

Dans certains cas, les termes génériques utilisés à des fins spécifiques sont mis en italique à leur première occurrence afin d'indiquer au lecteur que des précautions d'interprétation sont suggérées. Il convient que les autres usages de l'italique, tels que décrits en 4.5.5.2.1, soient clairement explicités par leur contexte immédiat.

3.3.4 Gras

Dans certains cas, les paragraphes descriptifs sont précédés par une phrase descriptive récapitulative ou un terme en gras, la mise en gras étant utilisée pour aider le lecteur à mémoriser l'information pour plus tard.

NOTE Cet usage du gras n'est pas indispensable, c'est pourquoi la perte d'une telle distinction consécutivement au procédé de photocopie n'est pas importante.

3.3.5 Déclarations informelles de constantes nommées

D'après l'ASN.1, l'attribution de noms symboliques à des constantes numériques est permise. L'attribution de représentations numériques spécifiques à des constantes nommées d'énumérations est également permise. Dans la présente norme, les deux types de déclarations sont unifiés, lorsqu'ils sont utilisés en tant que déclarations incorporées de choix admis concernant des champs de structures de données, grâce à l'utilisation de la syntaxe suivante:

valeurNumérique ": " texte explicatif

qui vise à être équivalente à la déclaration ASN.1

texte_explicatif "(" valeurNumérique ")"

où le texte explicatif est converti en identificateur alphanumérique en remplaçant les espaces figurant entre les mots (s'il y en a) par des tirets de soulignement et en ajustant les caractères de délimitation éventuels (point, virgule ou point-virgule) figurant après le texte explicatif en fonction du séparateur d'éléments de liste ASN.1 exigé après la parenthèse fermante équivalente de la valeurNumérique.

4 Vue d'ensemble

4.1 Généralités

La présente norme utilise la méthodologie de description de couches de l'OSI (voir Annexe C) pour définir des spécifications de suite de protocoles, en plus des spécifications pour les fonctions de sécurité, de gestion, de passerelle et mise à disposition d'un réseau industriel sans fil. Les couches de protocoles prises en charge sont la couche physique (PhL), la couche liaison de données (DL), la couche réseau (NL), la couche transport (TL) et la couche d'application (AL).

NOTE 1 Bien que la présente norme utilise le concept de couches de protocoles, la conformité à la présente norme ne signifie pas que la partition des mises en œuvre ait un fonctionnement similaire à celui impliqué par ces couches. Les interfaces inter-couches ne sont généralement pas exposées dans un produit et ne sont donc pas adéquates pour les essais de conformité.

Le réseau sans fil défini par la présente norme est constitué d'appareils sans fil servant les classes d'utilisation 1 à 5 (décrites à l'Annexe C) pour les applications non critiques d'appareils fixes, portatifs et mobiles.

Les références à un réseau conforme à la présente norme seront appelées ci-après un réseau de capteurs industriels sans fil (WISN), même lorsque le réseau comporte des actionneurs et d'autres appareils qui ne sont pas logiquement classifiables en tant que capteurs.

La plupart des appareils qui participent à un WISN sont censés mettre en œuvre juste une seule PhLE sans fil et la DLE associée. Cependant, les appareils comportant plusieurs PhLE sans fil et les DLE associées ne sont pas exclus. Par conséquent, la présente norme distingue entre les exigences pour un appareil et les exigences pour une PhLE et la DLE associée, même si les deux sont habituellement jugées comme étant synonymes.

NOTE 2 Il est conseillé au lecteur d'intérioriser cette relation et donc que le terme DLE fasse penser au terme appareil, même si dans certains cas, ils ne sont pas en relation biunivoque (1:1).

4.2 Interopérabilité et problèmes associés

L'IEC TR 62390 fournit des définitions utiles pour les différents niveaux d'interopération. Les trois définitions suivantes, chacune incluant la définition précédente, sont citées telles qu'elles apparaissent dans ce rapport technique.

NOTE 1 Dans l'IEC/TR 62390:2005, la Figure 9 apporte des éclaircissements supplémentaires concernant la relation existant entre ces termes.

NOTE 2 Les notes en 4.2 ne figuraient pas dans l'IEC TR 62390.

a) **Interconnectabilité**: Deux appareils ou plus sont interconnectables s'ils utilisent les mêmes protocoles de communication, interface de communication et accès aux données.

b) **Interfonctionnabilité**: Deux appareils ou plus sont interfonctionnables s'ils peuvent transférer des paramètres entre eux; outre le protocole de communication, l'interface de communication et l'accès aux données, les types de données de paramètres sont les mêmes.

NOTE 3 L'interfonctionnabilité implique l'interconnectabilité.

c) **Interopérabilité**: Deux appareils ou plus sont interopérables s'ils peuvent fonctionner ensemble pour accomplir un rôle spécifique dans un ou plusieurs programmes d'application distribués. Les paramètres et leurs fonctionnalités applicatives s'ajustent à la fois de manière syntaxique et sémantique. L'interopérabilité est accomplie lorsque les appareils prennent en charge des ensembles complémentaires de paramètres et fonctions appartenant au même profil.

NOTE 4 L'interopérabilité implique l'interfonctionnabilité et par conséquent l'interconnectabilité aussi.

4.3 Qualité de service

Afin de prendre en charge plusieurs applications au sein d'un réseau avec des besoins divers, la présente norme prend en charge plusieurs niveaux de qualité de service (QoS). La QoS décrit les paramètres tels que la latence, le débit et la fiabilité. Une ou plusieurs application d'un appareil demande le niveau de QoS nécessaire. Si les ressources nécessaires sont mises à la disposition de l'application demandeuse, le gestionnaire du système alloue ces ressources en réponse à la QoS demandée. Voir Article 6 pour des informations complémentaires.

4.4 Applicabilité à l'échelle mondiale

La présente norme vise à se conformer à des réglementations établies dans toutes les régions du monde; cependant, son acceptabilité dans un contexte de réglementation spécifique n'est pas garantie et doit donc être évaluée. L'Annexe V traite de ce thème, y compris l'utilisation dans la CE sous l'ETSI EN 300 328.

4.5 Architecture réseau

4.5.1 Interfaces

4.5.1.1 Interfaces définies

La présente norme définit des points d'accès au service (SAP) à la frontière supérieure de chaque couche de protocoles pour découpler les spécifications ou les révisions de chacune de ces couches de protocoles par rapport aux autres couches, dans toute la mesure du possible. Par exemple, si une nouvelle PhL est définie et n'exige pas d'apporter des modifications à la DL utilisatrice, elle peut être ajoutée à la spécification avec un impact minimal (voire nul) sur les autres couches de protocoles définies par la présente norme.

Dans la plupart des cas, ces interfaces définies sont internes à une mise en œuvre. A ce titre, elles ne sont pas soumises à des vérifications de normalisation et de conformité, car ces vérifications ne peuvent être appliquées qu'à des interfaces externes d'une unité en essai (à savoir des essais de boîte noire). Par conséquent, ces interfaces internes sont descriptives et informatives, pas normatives. Cependant, les mises en œuvre qui partitionnent les logiciels selon les lignes suggérées par ces interfaces sont censées être plus faciles à maintenir et adapter à de futures révisions de la présente norme.

La conformité à la présente norme s'applique seulement au comportement observable d'une mise en œuvre, y compris la structure et le codage de toute information échangée à des interfaces observables qui sont spécifiées comme telles par la présente norme.

4.5.1.2 Interfaces non définies

Les interfaces suivantes ne sont pas traitées par la présente norme.

- Gestionnaire de système – gestionnaire de sécurité: Le gestionnaire de sécurité et le gestionnaire de système forment deux rôles centraux dans le réseau qui sont étroitement liés. Sachant que le gestionnaire de sécurité et le gestionnaire de système sont si dépendants l'un de l'autre et que le gestionnaire de sécurité communique directement seulement avec le gestionnaire de sécurité, il est attendu que le seul ou les quelques appareils fournissant ces deux rôles seront obtenus auprès d'un seul et même fournisseur, en étant réalisés sous la forme d'un seul appareil prenant en charge les deux rôles. Avec ces attentes, il est jugé inutile de normaliser cette interface.

NOTE Cette interface est une matière d'une potentielle normalisation future.

- Interfaces externes: Un important attribut de la présente norme est qu'elle est conçue pour permettre au réseau sans fil d'exercer un effet de levier sur une infrastructure de communications d'une installation ou de s'y intégrer. La présente norme définit les rôles spécifiques pour permettre à ce réseau de s'interfacer à d'autres réseaux, y compris les réseaux tant câblés que sans fil et les réseaux tant normalisés que propriétaires. Cependant, de même que ces réseaux externes spécifiques ne peuvent pas être identifiés par la présente norme, de même les interfaces à ces réseaux ne peuvent pas être identifiées ou spécifiées.

4.5.2 Structures des données

4.5.2.1 PDU définies

La présente norme définit la structure des unités de données de protocole (PDU) utilisées pour la communication entre appareils aux couches de protocoles suivantes: PhL, DL, NL, TL et AL. La plupart de celles-ci sont basées sur d'autres normes internationales: des normes ISO/IEC/IEEE pour la PhL et la DL, et des normes IETF pour la NL et la TL. Toutes ces définitions de PDU sont normatives, soumises à des essais externes d'examen et de conformité.

Du point de vue conceptuel, chaque classe distincte de PDU a:

- une syntaxe de transfert abstraite, qui décrit la structure de la PDU, y compris l'ordre des champs et la signification sémantique de chaque champ et de son contenu alternatif; et
- une ou plusieurs syntaxes de transfert concrètes, qui décrivent le codage au sein de la PDU pour chacun de ces champs et variantes de contenu.

La présente norme spécifie une syntaxe de transfert concrète *complète* ou *canonique* pour chaque PDU et, pour les DPDU, les NPDU et les TPDU, elle spécifie également une syntaxe de transfert concrète *compressée* qui réduit les exigences énergétiques pour l'émission et la réception des PDU, ainsi que le temps d'occupation de la voie sans fil lorsque la PDU est en cours d'émission.

NOTE 1 L'occupation réduite de la voie réduit l'interférence avec d'autres appareils et systèmes sans fil, tout en augmentant la probabilité de réussite de la réception de la PDU. Elle réduit également la puissance moyenne exigée pour le fonctionnement des appareils, ce qui revêt une importance particulière pour les appareils qui ne sont pas connectés à une source d'alimentation externe.

Pour les DPDU et les TPDU, une troisième syntaxe concrète (à savoir le codage) est utilisée dans le calcul d'un code d'intégrité de message pour la PDU. Le codage en question ajoute habituellement un *pseudo-en-tête* en préfixe à la PDU telle qu'émise/reçue, lequel pseudo-en-tête contient des informations spécifiques d'adressage de PDU de couche inférieure, servant ainsi à lier ces informations de couche inférieure à la PDU dont l'intégrité est couverte par le MIC calculé. Dans la présente norme, cette troisième syntaxe concrète est appelée la *syntaxe de calcul de MIC*.

NOTE 2 Les descriptions de PDU dans la présente norme réunissent souvent la syntaxe abstraite de la PDU (à savoir son contenu logique) avec la syntaxe de transfert concrète (à savoir son codage). Il est prévu qu'une édition future de la présente norme corrigera ce défaut.

4.5.2.2 Structures de données de gestion définies

La présente norme définit la structure des objets de données de gestion aux diverses couches de protocoles. Ces définitions sont normatives quant au comportement des opérations définies sur ces structures de données et quant à la présentation de ces structures de données dans la mesure, et sous la forme, où elles apparaissent lorsqu'elles sont acheminées par des PDU. Cependant, la représentation de ces structures de données internes à une mise en œuvre ne s'inscrit pas dans le domaine d'application de la normalisation, car cette représentation n'est pas observable et n'est donc pas soumise à des essais de conformité.

4.5.3 Description de réseau

La Figure 1 montre les zones de communication adressées par la présente norme, ainsi que les zones (ombrées en bleu) qui ne s'inscrivent pas dans le domaine d'application de la présente norme. Dans la Figure 1, les objets circulaires représentent les rôles pour les appareils de terrain (capteurs, robinets, actionneurs, etc.) tandis que les objets rectangulaires représentent les rôles pour les appareils d'infrastructure qui communiquent avec d'autres appareils de réseau par une interface au réseau dorsal de l'infrastructure de réseau.

NOTE La présente norme définit les rôles dont les appareils sont les modes de réalisation; pour plus d'informations sur ces rôles, voir 5.2.6.

Une dorsale est un réseau de données (préférentiellement de haut débit de données) qui n'est pas défini par la présente norme. Cette dorsale peut être un réseau Ethernet industriel, IEEE 802.11, ou tout autre réseau au sein du moyen s'interfaçant au réseau de l'installation. Voir l'Annexe E pour plus d'informations et hypothèses relatives aux caractéristiques d'une dorsale.

Figure 1 – Réseau conforme à la norme

Un réseau complet tel que défini dans la présente norme comprend tous les composants et protocoles exigés pour acheminer un trafic sécurisé, gérer des ressources réseau et s'intégrer à des systèmes hôtes. Un réseau complet est constitué d'un ou plusieurs sous-réseaux D de terrain qui peuvent être connectés par un appareil d'infrastructure à un sous-réseau d'installation.

Un sous-réseau D de terrain est constitué d'un ensemble d'appareils de terrain qui communiquent sans fil en utilisant une pile de protocoles définie par la présente norme. Comme illustré à la Figure 1, certains appareils de terrain peuvent avoir des capacités d'acheminement, leur permettant de transmettre des messages issus d'autres appareils.

Un sous-réseau de transit est constitué d'appareils d'infrastructure sur une dorsale, tels que des routeurs dorsaux, des passerelles, des gestionnaires de système et des gestionnaires de sécurité. Comme le moyen de communication physique de la dorsale et sa pile de protocoles de réseau ne relèvent pas du domaine d'application de la présente norme, ils ne sont pas spécifiés et peuvent inclure la tunnellisation des PDU conformes sur des protocoles TL ou AL externes.

Les appareils qui connectent deux sous-réseaux D disparates ont au moins deux interfaces DLE et PhLE. Un routeur dorsal connecte un sous-réseau D de terrain à un sous-réseau dorsal D. Une passerelle connecte un sous-réseau dorsal à un sous-réseau d'installation; elle peut être co-allouée à un routeur dorsal.

NOTE 1 La portée d'un sous-réseau dépend de la couche de communication supérieure utilisée dans la construction du sous-réseau, qui pourrait être la couche OSI 1, 2, 3 ou 4.

NOTE 2 Etant donné que les passerelles ne sont pas définies dans la présente norme, la nature de l'interface qu'elles fournissent à un réseau "d'installation" est strictement théorique. Ainsi, le terme "réseau d'installation" (Figure 1) désigne un réseau ou tout autre moyen de communication résidant à l'extrémité de la passerelle par rapport aux sous-réseaux D qui sont couverts par la présente norme. De même, le terme "sous-réseau de terrain" désigne le sous-réseau D composé directement des appareils de terrain.

Tout l'adressage, le routage et le transport sont limités à la portée du sous-réseau D de terrain. Chaque DLE au sein d'un tel sous-réseau D est identifié par une adresse DL16Address locale, ainsi qu'une adresse IPv6Address avec une portée globale.

4.5.4 Construction d'une unité de données de protocole générique

La présente norme de communication utilise des couches de protocole de communication modélisées selon le Modèle de référence de base OSI. Une couche de protocole encapsule généralement les données qu'elle achemine pour une couche de protocole supérieure, puis utilise à son tour une couche inférieure pour acheminer le résultat encapsulé.

Les informations acheminées sur le réseau entre des entités homologues s'appellent une unité de données de protocole (PDU). Les informations acheminées à la frontière d'une couche entre les entités de couche d'un même nœud de réseau s'appellent une unité de données de service (SDU). Une SDU se compose généralement d'une seule PDU, mais elle peut également comprendre un groupe de PDU concaténées (voir "concaténation", 3.1.1.16).

Une SDU est considérée comme une chaîne d'octets ou de bits opaque devant être acheminée de manière transparente (autrement dit sans interprétabilité ni altération) par la

couche inférieure. La SDU peut être acheminée par une unité PDU de couche inférieure, ou être segmentée (voir "segmentation", 3.1.1.58) afin d'être acheminée de manière individuelle par plusieurs PDU de couche inférieure, ou être regroupée avec d'autres SDU (voir "groupage", 3.1.1.10) afin d'être acheminée de manière groupée dans une seule PDU de couche inférieure. Dans le cas le plus courant, un en-tête et un bas de page sont ajoutés à une SDU unique pour former une PDU unique (voir Figure 2).

NOTE Le bas de page est habituellement vide ou utilisé pour une certaine forme de code d'intégrité de message (MIC), telle qu'une somme de contrôle ou une partie de code de hachage à clé sécurisé de manière cryptographique simple facile à reproduire.

L'en-tête et le bas de page sont souvent appelés surdébit (par rapport à la SDU ou aux SDU acheminées sous forme individuelle, groupée ou segmentée), la quantité de surdébit dépendant de la quantité des informations complémentaires ayant besoin d'être incluses pour que le protocole d'acheminement fonctionne correctement. Un but de la présente norme étant de réduire au maximum la consommation d'énergie et l'occupation de voie lors de l'acheminement des PDU, la réduction au maximum de la quantité de surdébit à chaque couche de protocoles est donc une méthode principale d'atteindre le but en question.

Une description complète de chaque en-tête et bas peut être consultée dans la description appropriée de la couche de protocoles. Une PDU complète à plusieurs couches comprend tous les en-têtes et tous les bas de page, tels que montrés à la Figure 3. La quantité de données (mesurée en octets) d'une PDU d'application qui peut être envoyée en une seule émission est déterminée par la différence entre la charge utile de PhL maximale autorisée ou prise en charge et le surdébit imposé par tous les en-têtes et de tous les bas de page intermédiaires.

Figure 3 – Structure de PDU complète à plusieurs couches utilisée par la présente norme

4.5.5 Données abstraites et représentations concrètes

4.5.5.1 Types de données abstraites

Chaque couche de protocoles de la présente norme définit la structure des PDU qu'elle échange avec des entités de protocole homologues sur la même couche, ainsi que des SDU et des informations de contrôle d'interface associées (ICI) qu'elle échange avec des entités de couche adjacentes au sein d'un nœud local du réseau.

Par ailleurs, chaque couche de protocoles définit les structures de données de gestion qui sont échangées par chaque entité de couche (sous la forme de données acheminées) avec des entités de gestion de systèmes distants.

Chacune de ces structures de données possède une forme abstraite qui exige une représentation concrète. Les éléments abstraits sont soit des valeurs scalaires, soit des valeurs composites composées de valeurs scalaires et d'autres valeurs composites. Les valeurs composites peuvent être homogènes, auquel cas il s'agit de groupes monodimensionnels ou multidimensionnels (souvent connues sous le nom de "vecteur" ou "matrice", respectivement), ou bien hétérogènes (souvent appelées simplement "structure de données").

Les éléments scalaires utilisés par les entités de protocole de la présente norme sont:

a) des entiers d'une plage restreinte, où chaque valeur abstraite est représentée par la valeur binaire concrète à deux compléments équivalente ou une valeur binaire concrète non signée, selon que la plage abstraite inclut des valeurs négatives;

b) des énumérations, généralement déclarées sous la forme d'une représentation UnsignedN pour $N \leq 8$, où chaque valeur abstraite est généralement représentée par l'index ordinal d'origine zéro de la valeur abstraite parmi la liste de valeurs définies;

c) des booléens, possédant deux valeurs abstraites (false, true) auxquelles les règles et les opérateurs de la logique booléenne s'appliquent, ainsi qu'une représentation concrète de false par zéro et de true par une valeur binaire différente de zéro;

NOTE 1 Les booléens tirent leur nom du logicien George Boole.

NOTE 2 Même si les booléens semblent être une classe d'énumération spéciale, les différences sont que la valeur true peut être représentée par une valeur binaire différente de zéro et que les opérateurs booléens s'appliquent à cette classe.

d) des nombres à virgule flottante IEEE d'une plage et d'une précision spécifiques, dont les valeurs sont des nombres réels approximatifs ou des constantes non-numériques spéciales;

e) des représentations du Temps atomique international (TAI) correspondant à des valeurs entières ou à des valeurs à virgule fixe à l'échelle modulo 2^{32} s.

Les éléments composites utilisés par les entités de protocole de la présente norme incluent trois classes de groupes d'origine zéro monodimensionnels, appelés chaînes (*strings*). Ce sont:

f) les caractères, appelés chaînes visibles;

g) les bits, appelés chaînes de bits; et

h) les octets non interprétés, appelés chaînes d'octets.

Les autres éléments composites incluent les groupes booléens condensés, qui sont souvent (à tort) assimilés à leur représentation sous-jacente en tant que chaînes de bits.

4.5.5.2 Déclarations des éléments de données abstraites et de leurs représentations concrètes

4.5.5.2.1 Déclarations simples

Dans le cadre de la présente norme, un type abstrait et sa représentation concrète sont souvent déclarés sous une forme unifiée qui indique à la fois la classe de 4.5.5.1 a) à h) ainsi que le nombre de bits dans la représentation binaire sous-jacente.

- Les entiers sont déclarés au sein d'une plage implicite sous la forme *unsignedN* (impliquant une plage de $0..2^N-1$) ou *signedN* (impliquant une plage de $-2^{N-1}..2^{N-1}-1$), où N représente le nombre de bits de la représentation, généralement un multiple de 8.

  Les entiers qui exigent une plage différente de celle impliquée par leur représentation sont déclarés sous la forme

  unsignedN plage min..max

  où min et max représentent respectivement les valeurs minimale et maximale de la plage de cet élément entier.

- Les booléens sont déclarés sous la forme *BooleanN*, où N représente le nombre de bits de la représentation, généralement 1 (lorsqu'ils se trouvent dans une structure de données condensée) ou 8.

- Les nombres à virgule flottante, ainsi que leurs plage et précision sont déclarés sous la forme *float32* ou *float64*.

- Les chaînes de taille fixe ainsi que leurs tailles sont déclarées sous les formes *visibleStringN*, *octetStringN* et *bitStringN*, où N représente le nombre d'éléments dans le groupe sous-jacent.

NOTE 1 Un mécanisme de codage interne dans certaines chaînes visibles, généralement une valeur nulle (0x00) utilisée en guise de délimiteur de fin de contenu, est souvent utilisé pour tronquer la taille effective de la chaîne contenue. De nombreuses bibliothèques d'opérateurs de chaîne présument un tel codage.

- Les chaînes de taille variable sont déclarées sous les formes *visibleString* et *octetString* sans taille déclarée concaténée (autrement dit la valeur N de *visibleStringN*).

- Les groupes booléens condensés ainsi que leur taille sont déclarés sous la forme *BooleanArrayN*, où N représente le nombre d'éléments dans le groupe (et par conséquent le nombre de bits de la représentation).

- Les constantes nommées, généralement issues de valeurs de champs UnsignedN, peuvent être déclarées à la manière de l'ASN.1 comme s'il s'agissait d'énumérations ASN.1, comme dans:

  UnsignedN {name-1(integer-value-1), … , name- K(integer-value-K)}

  où N représente le nombre de bits de la représentation et où une déclaration explicite des constantes est fournie sous la forme d'une liste séparée par des virgules et placée entre crochets, chaque élément étant suivi de "(K)" où K représente la valeur affectée à cet élément.

  EXEMPLE 1 Une déclaration pour les couches de protocoles définies dans la présente norme pourrait être:

  protocolLayers Unsigned3 {PhL(1), DL(2), NL(3), TL(4), AL(7)}

  NOTE 2 L'exemple 1 démontre que les noms des éléments de ce qui équivaut à une énumération peuvent ne pas être disjoints de ceux utilisés en d'autres endroits de la présente norme, comme cela pourrait être exigé dans le cadre d'une spécification de langage de programmation explicite.

  Sinon, ces constantes nommées peuvent être déclarées sous la forme

  UnsignedN {integer-value-1:description-1; … ; integer-value-K:description-K}

  où N représente le nombre de bits de la représentation et où une déclaration explicite des constantes nommées est fournie sous la forme d'une liste séparée par des points-

virgules et placée entre crochets, chaque élément étant précédé de "K" où KK représente la valeur affectée à cette constante nommée. (Voir 3.3.5.)

EXEMPLE 2 A Une déclaration pour la méthode de jointure join_method définie dans la présente norme pourrait être:

join_method Unsigned8{ 0:none; 1:join and start; 2:warm restart; 3:restart as provisioned; 4:reset to factory defaults }

Pour cette dernière forme de déclaration, la liste entre crochets peut être séparée de la déclaration de la représentation du champ.

EXEMPLE 3 join_method Unsigned8

Constantes nommées:
0: none
1: join and start
2: warm restart
3: restart as provisioned
4: reset to factory defaults

NOTE 3 On retrouve souvent cette dernière forme de déclaration dans les descriptions tabulaires de structures de données dans la présente norme où la première partie de la déclaration figure dans une colonne et la deuxième partie figure dans la même colonne ou dans une colonne différente de la même ligne.

Souvent, seuls quelques éléments de la plage d'une déclaration UnsignedN sont nommés, un tel cas pouvant survenir lorsque la valeur tout-à-zéro ou tout-à-un de la représentation a une interprétation spéciale. A certaines occasions, en particulier lorsque la description est "réservée", une plage de valeurs peut être spécifiée à la place d'une valeur unique.

4.5.5.2.2 Déclarations d'objets composés et de méthodes avec leurs arguments

Dans la présente norme, les structures de données composées sont généralement déclarées sous la forme de tables, chaque ligne (après les lignes d'en-tête) décrivant un élément constituant au sein de la structure de données.

Dans la présente norme, les descriptions de méthodes sont généralement déclarées sous la forme de tables. Chacune de ces descriptions spécifie un nom de méthode, un ID de méthode numérique ainsi qu'une description de la méthode, suivis d'une série de descriptions d'arguments d'entrée de méthode, suivis d'une série de descriptions d'arguments de sortie de méthode. Comme pour les définitions de structures de données, chaque argument est déclaré tout seul sur une ligne de la table et possède un type déclaré ainsi que, lorsque cela s'avère approprié, une déclaration des variantes pour les constantes nommées associées.

4.6 Caractéristiques de réseau

4.6.1 Généralités

Les caractéristiques d'un WISN (à savoir un réseau sans fil qui est conforme à la présente norme) sont notamment:

- évolutif;
- extensible;
- prise en charge d'un fonctionnement simple;
- exploitation sans licence;
- robustesse en présence d'interférence et avec des réseaux autres que WISN;
- déterminisme ou accès aux supports sans conflits;
- réseau auto-organisé avec prise en charge des communications redondantes de l'appareil de terrain vers le réseau d'installation;

NOTE La prise en charge de la redondance n'est pas définie dans la présente norme.

- couche réseau compatible avec IP;
- coexistence avec d'autres appareils sans fil dans l'espace de travail industriel;
- sécurité, y compris l'authenticité des données, la confidentialité des données, l'intégrité des données, la protection contre les retards et la protection contre le rejet;
- gestion de système de tous les appareils de communication;
- prise en charge des processus applicatifs utilisant des objets normalisés; et
- prise en charge de la tunnellisation (à savoir le transport) d'autres protocoles à travers le réseau sans fil.

4.6.2 Evolutivité

L'architecture prend en charge des systèmes sans fil qui s'étendent dans la plage physique allant d'un seul petit sous-réseau D isolé, tel qu'on pourrait en trouver au voisinage d'un puits de gaz ou de pétrole ou un très petit atelier d'usinage, aux systèmes intégrés de plusieurs milliers d'appareils et plusieurs sous-réseaux D qui peuvent couvrir une installation de plusieurs kilomètres carrés. Il n'y a aucune limite technique au nombre d'appareils pouvant participer à un réseau composé de plusieurs sous-réseaux D. Un sous-réseau D, à savoir un groupe de DLE partageant un certain nombre d'aspects de configuration de DL, peut contenir jusqu'à 30 000 DLE (qui est une limitation de l'espace d'adressage d'un sous-réseau D). Avec plusieurs sous-réseaux D, le nombre des DLE (et donc des appareils) dans le réseau peut évoluer linéairement.

La quantité maximale de données de couche supérieure ou de gestion pouvant être acheminées dans une seule DPDU est limitée par la PhL et la quantité de surdébit de DL exigée. Par conséquent, la présente norme prend en charge la fragmentation au sein de la DL, permettant l'émission d'une quantité de données bien plus élevée. Dans la fragmentation, les données sont segmentées en portions de dimension appropriée au niveau de la DLE émettrice, encapsulées dans des DPDU et émises à travers le sous-réseau D pour être ensuite réassemblées au niveau de la DLE destinataire. Une utilisation de ce mécanisme est la mise à jour du firmware d'appareil.

4.6.3 Extensibilité

Les protocoles définis par la présente norme ont des champs et des plages de valeurs de paramètres qui sont réservés pour usage futur et des identificateurs de version (édition) dans des en-têtes qui permettent l'identification de l'édition appropriée.

NOTE Ces fonctionnalités sont destinées à permettre de futures révisions de la présente norme pour offrir une fonctionnalité complémentaire ou améliorée sans sacrifier inutilement la compatibilité amont, ni alourdir le codage (ce qui survient généralement lors de l'utilisation du mécanisme d'extensibilité déclaré ASN.1).

4.6.4 Fonctionnement simple

A la suite de la configuration, telle que décrite à l'Article 13, une DLE peut automatiquement se rattacher au sous-réseau D et à son réseau N supérieur. Le rattachement automatique d'appareil et la formation d'un sous-réseau D permettent la configuration du système avec un besoin minimal en personnel ayant la formation spécialisée en ondes radioélectriques (RF) et en outils.

En outre, la présente norme prend en charge l'utilisation de techniques de routage D totalement redondantes et autorégénératrices pour réduire au maximum la maintenance du sous-réseau D. Voir 9.1.6 pour plus d'informations.

4.6.5 Exploitation sans licence sur site

La présente norme utilise des radios conformes à l'IEEE 802.15.4 utilisant les voies DSSS 11..26 de 2,4 GHz spécifiées dans la norme en question.

NOTE 1 La bande ISM de 2,4 GHz est disponible et exempte de licence sur site dans la plupart des pays, sous réserve que l'équipement dispose d'une licence de type pour une telle exploitation acceptée dans le pays en question.

NOTE 2 L'ISA TR100.00.01 fournit des informations complémentaires sur l'exploitation des ondes radioélectriques.

4.6.6 Robustesse en présence d'interférence, y compris en provenant d'autres systèmes sans fil

La présente norme utilise le saut de voies en fonction du temps

- pour assurer un niveau d'immunité contre les interférences issues d'autres appareils RF fonctionnant dans la même bande,
- pour atténuer les effets des interférences à chemins multiples,
- pour faciliter la coexistence avec d'autres systèmes RF, et
- pour satisfaire à des exigences réglementaires communes.

Dans certains régimes de réglementation, la coexistence peut être encore plus renforcée par une mise sélective en liste noire de voies, évitant ainsi des voies autrement occupées dans la bande. La mise sélective en liste noire de voies peut aussi renforcer la fiabilité en évitant l'utilisation des voies avec une performance constamment médiocre.

4.6.7 Déterminisme et accès sans conflits aux supports

La présente norme définit un mécanisme d'accès multiple par répartition dans le temps (AMRT) qui permet à un appareil d'accéder au support RF sur un programme et, de ce fait, la majeure partie de la concurrence pour l'utilisation de la voie aura été préalablement résolue par l'agent de programmation. Les communications synchronisées sont fondées sur des intervalles de temps consécutifs qui ont des durées configurables, généralement dans la plage de 10 ms à 12 ms. La programmation et le fonctionnement des DLE sont grandement simplifiés lorsque tous les intervalles de temps ont une seule et même durée et, donc, les WISN sont en général configurés pour n'avoir qu'une seule durée d'intervalle de temps utilisée pour tous les intervalles de temps.

NOTE 1 Etant donné que les intervalles de temps sont attribués à des voies logiques qui sont ensuite associées de manière cyclique à des voies physiques, l'utilisation d'une seule durée d'intervalle de temps commune signifie que l'évitement de contention sur les voies logiques élimine automatiquement cette contention sur les voies physiques. Des intervalles de temps de durées différentes font perdre cette simplification de planification.

Une DLE expéditrice reçoit un intervalle de temps et une voie qui lui sont assignés et qui sont propres à l'appareil en question et à l'appareil avec lequel elle communique. Ces durées d'intervalle de temps sont configurables sur une base supertrame par supertrame. Une supertrame est un ensemble cyclique d'intervalles de temps. L'aptitude de configurer la durée d'intervalle de temps permet

- de plus courts intervalles de temps pour tirer pleinement profit de mises en œuvre optimisées;
- de plus longs intervalles de temps pour prendre en charge
  - des durées prolongées d'attente de DPDU,
  - un acquittement sériel de deux ou plusieurs appareils configurés (par exemple, duodiffusion), et
  - un accès CSMA/CA au début d'un intervalle de temps (par exemple, pour mettre en œuvre le protocole Listen Before Talk ou pour bénéficier d'un accès priorisé à des intervalles de temps partagés); et
- des périodes de durée prolongée pour les sauts de voie lents.

NOTE 2 La réglementation locale peut contraindre la durée maximale d'une telle période de saut de voie lent.

La prise en charge est assurée aussi bien pour les intervalles de temps dédiés au trafic prévisible et régulier que pour les intervalles de temps partagés pour le trafic par salves tel que les alarmes. L'édition/abonnement, les communications client/serveur, les rapports d'alerte et le transfert en masse de données sont également pris en charge.

4.6.8 Mise en réseau auto-organisé avec prise en charge de redondance

Les techniques de routage pleinement redondantes et autorégénératrices, telles que le routage maillé (voir 9.1.6), prennent en charge la fiabilité de réseau de bout en bout face à des conditions changeantes d'ondes RF et d'environnement. Les caractéristiques spéciales qui permettent au réseau d'adapter les fréquences utilisées (saut de voie adaptatif, par exemple) avec le routage maillé peuvent automatiquement atténuer les problèmes de coexistence sans intervention de l'utilisateur.

4.6.9 NL compatible avec le protocole IP

La NL de la présente norme utilise des formats d'en-tête qui se conforment aux normes 6LoWPAN de l'Internet Engineering Task Force, facilitant ainsi l'utilisation potentielle des réseaux compatibles à l'IPv6 comme réseaux dorsaux en appui à la présente norme. L'utilisation d'en-têtes qui se conforment à la 6LoWPAN n'implique ni

- qu'un réseau dorsal a besoin être basé sur la 6LoWPAN ou l'IPv6, ni
- qu'un réseau basé sur la présente norme est ouvert au piratage par Internet.

En fait, un grand nombre des réseaux basés sur la présente norme ne sont pas directement connectés à Internet. Les autres peuvent utiliser la vielle norme IPv4, au moins pendant les premières années d'exploitation.

NOTE L'utilisation d'IPv6 permet l'utilisation de logiciels et d'outils réseau normalisés, ainsi que la possibilité d'utiliser une large gamme de normes IETF dans les révisions ou extensions futures de la présente norme.

4.6.10 Coexistence avec d'autres systèmes de fréquences radioélectriques

4.6.10.1 Vue d'ensemble de la coexistence

L'architecture de système spécifiée par la présente norme est spécifiquement conçue pour prendre en charge la coexistence avec d'autres

- WISN (à savoir des systèmes sans fil conformes à la présente norme);
- d'autres réseaux de communication opérant à 2,4 GHz qui utilisent différentes versions des normes IEEE 802.11, IEEE 802.15.1 et IEEE 802.15.4; et
- d'autres appareils qui utilisent le même spectre de fréquences radioélectriques.

Le fonctionnement avec de très courtes communications synchronisées tend à réduire l'encombrement des bandes RF et à permettre à des systèmes voisins de récupérer rapidement de leurs PhPDU perdues ou corrompues.

En raison du temps de séjour réduit sur une voie quelconque au moment d'un saut de voie, l'impact sur les autres systèmes radioélectriques est réduit et la fiabilité face à des interférences est accrue. Par exemple, les DPDU peuvent être renvoyées sur d'autres voies non perturbées. La mise sélective en liste noire de voies augmente encore plus la coexistence en évitant les voies qui sont prédéterminées comme étant inutilisables ou trop encombrées.

La présente norme prend en charge (mais n'exige pas) l'utilisation de l'évaluation de voie libre (CCA) pour réduire au maximum les collisions avec des systèmes non synchronisés et aussi pour fournir la fonctionnalité CSMA/CA au sein de systèmes synchronisés.

NOTE Certaines juridictions réglementaires exigent l'utilisation de la CCA dans certains modes d'exploitation. Une telle utilisation exigée est fournie par la présente norme lorsqu'un appareil est configuré dans le but d'être exploité dans ces juridictions.

L'architecture des WISN est conçue pour prendre en charge le fonctionnement en présence d'interférences issues de radiateurs intempestifs, tels que les fours micro-ondes, en utilisant le saut de voie et un protocole de demande automatique de répétition (ARQ. L'ARQ est une méthode courante de contrôle d'erreurs pour l'émission de données qui utilise des acquittements pour la réception réussie des messages, couplée avec la réémission différée en cas de réception erronée, pour assurer l'acheminement fiable des données.

Pour des informations complémentaires relatives à la diversité des techniques qui maximalisent la coexistence, voir 9.1.2.

4.6.10.2 Stratégies de coexistence

4.6.10.2.1 Généralités

Ci-après sont donnés des exemples de techniques de coexistence qui ne sont spécifiques à aucun protocole. Ils améliorent la coexistence avec une large gamme d'appareils partageant la bande de 2,4 GHz tout en optimisant le succès de chaque tentative de communication.

NOTE Voir l'IEC 62657-2 pour un débat plus complet sur la coexistence sans fil.

4.6.10.2.2 Infrastructure à effet de levier pour les liaisons de communications à haut débit de données

Les réseaux à sauts multiples acheminent plusieurs fois, une fois (au moins) par saut, les mêmes données de couche supérieure. Une capacité fondamentale de la présente norme est l'aptitude à acheminer aussi directement que possible les données à une DLE connectée à un sous-réseau dorsal (préférentiellement un réunissant un haut débit de données et un faible taux d'erreurs). Cela réduit souvent l'utilisation de la PhL spécifiée par la présente norme à un(e) ou deux transactions D et sauts de sous-réseau D pour chaque PDU de couche supérieure acheminée.

4.6.10.2.3 Fonctionnement par intervalles de temps

Le fonctionnement par intervalles de temps et les émissions programmées servent à réduire au maximum les collisions au sein du sous-réseau D et, de ce fait, à éviter l'inutile utilisation de la voie pour les répétitions de tentative.

4.6.10.2.4 Sélection du type d'ondes radioélectriques

Le sous-ensemble 2,4 GHz de l'IEEE 802.15.4 a été sélectionnée comme PhL pour la présente norme, car, dans un grand nombre de conditions, des ondes radioélectriques semblables se chevauchant, ainsi que les ondes radioélectriques de l'IEEE 802.11, peuvent être actives simultanément sans perte des données acheminées.

NOTE La présente norme s'intéresse essentiellement à la coexistence avec les versions plus récentes de ces normes, alors qu'on tend à rencontrer les anciennes versions de moins en moins souvent avec le temps

4.6.10.2.5 Faible facteur d'utilisation

L'acheminement de données pour les applications focus décrites en 0.1 est rare, alors que le surdébit ajouté issu des couches de protocoles d'envoi est réduit au maximum.

4.6.10.2.6 Emissions saccadées

Les émissions attendues sont très courtes, ce qui est une caractéristique de la PhL sélectionnée. Cela permet à des réseaux IEEE 802.11 co-implantés de récupérer rapidement en cas d'interférences provenant du WISN.

4.6.10.2.7 Diversité temporelle

Plusieurs des applications focus ont des exigences relatives à la latence moins strictes que les autres utilisateurs du spectre, fournissant plus d'opportunité d'utiliser la diversité temporelle pour la coexistence. Des périodes configurables de répétitions de tentatives, s'étendant potentiellement sur des centaines de millisecondes, permettent au système de coexister avec d'autres utilisateurs qui peuvent exiger l'utilisation du même spectre au cours des salves d'activité de plus haute priorité.

4.6.10.2.8 Diversité de voie

Le faible facteur d'utilisation des ondes radioélectriques est étalé sur seize voies IEEE 802.15.4, ce qui réduit encore plus le potentiel de cas le plus défavorable pour les interférences à 1 % du temps voire moins dans un grand nombre de scénarios réalistes.

4.6.10.2.9 Gestion de spectre

L'utilisateur peut configurer des supertrames dans le sous-réseau D afin de limiter le fonctionnement de certaines voies radioélectriques.

4.6.10.2.10 Utilisation sélective de voie

Lorsque le régime de réglementation le permet, la gestion D peut éviter les voies problématiques sur une base liaison par liaison, telles que les voies qui présentent une interférence croisée IEEE 802.11 ou des évanouissements persistants sur des trajets multiples.

4.6.10.2.11 Evitement des collisions

Toutes les DLE prennent en charge l'accès CSMA/CA, qui permet à une DLE de mettre en œuvre le protocole Listen Before Talk pour permettre la détection en temps réel de l'utilisation de la voie et retarder sa propre émission, réduisant les interférences à ces autres utilisateurs.

NOTE Un tel évitement est exigé dans certains régimes de réglementation, du moins dans certains modes d'exploitation.

4.6.10.2.12 PhPDU variables

En raison des mesures de sécurité intégrées de la DL, qui incluent la défense contre des attaques de rejet dans la même voie et à travers les voies, les PhPDU varient d'une émission à l'autre même pendant la réémission des mêmes informations de DPDU nominales. Avec la modulation à étalement de spectre, cela engendre des interférences de durée variable même lorsque des messages sinon identiques sont en cours de transmission.

4.6.11 Transactions D par intervalles de temps à voie assignée comme base pour la communication

4.6.11.1 Vue d'ensemble

Excepté pendant l'intervalle où une DLE sollicite l'occasion de rejoindre un sous-réseau D, chaque instance de la communication de DLE selon la présente norme se produit

a) dans une fenêtre temporelle spécifiée au préalable, par rapport au sens du temps TAI de la DLE;

b) sur une voie spécifique de PhL, à un niveau de puissance qui respecte les réglementations locales;

c) en utilisant un modèle d'intervalle de temps spécifique pour l'initiateur d'une transaction D, qui spécifie

   1) l'acquisition de voie, configurée en accord avec les réglementations locales et le modèle d'intervalle de temps;

2) l'émission d'une DPDU Data (à savoir la DPDU initiale d'une transaction) contenant soit des données de couche supérieure, soit des données de gestion, à destination d'un ensemble de correspondants prévus; et

3) lorsque cela est ainsi spécifié par le modèle d'intervalle de temps, la réception tentée d'une ou plusieurs DPDU ACK/NAK (à savoir le message SCS) envoyées par des correspondants prévus;

NOTE 1 La réception intentionnelle de plus d'une DPDU ACK/NAK est utile pour évaluer le fonctionnement d'un réseau, mais n'est pas essentielle pour l'acheminement réussi d'une DPDU.

d) en utilisant un différent modèle d'intervalle de temps spécifique pour un correspondant prévu d'une transaction D, qui spécifie

1) la durée de la phase d'acquisition de voie, relative à c)1);

2) la réception tentée d'une DPDU Data contenant soit des données de couche supérieure, soit des données de gestion, adressées soit à la DLE elle-même, soit à une autre adresse DL16Address spécifiée; et

NOTE 2 Cette dernière capacité est utilisée pour la multidiffusion/diffusion et la duodiffusion/N-diffusion.

3) lorsque la réception d)2) s'est effectivement produite et était exempte d'erreur à la PhL avec une FCS de DLE sans erreur, et lorsque le modèle d'intervalle de temps le spécifie ainsi, l'émission d'une seule DPDU ACK/NAK (à savoir le message SCS) envoyée à l'adresse DL16Address d'expédition de la DPDU reçue en d)2), se produisant soit

i) à un retard spécifié après la fin de la réception de la DPDU Data d)2), soit

ii) à un instant spécifié avant la fin programmée de l'intervalle de temps,

comme le spécifie le modèle d'intervalle de temps.

Lorsque le modèle d'intervalle de temps correspondant pour l'initiateur de transaction spécifie plus d'un intervalle pour la réception de DPDU ACK/NAK en c)3), les modèles d'intervalle de temps pour les répondeurs de la transaction diffèrent en leurs valeurs assignées pour d)3)i) ou d)3)ii), assignant de ce fait ces réponses potentielles pour disjoindre les durées dans l'intervalle de temps.

Les appareils auxquels s'applique c)2) sont appelés des *initiateurs de transaction*; les appareils auxquels s'applique d)2) sont appelés des *destinataires de transaction* (qui constituent les destinataires prévus, et pas seulement des intermédiaires); les appareils auxquels s'applique d)3) sont appelés préférentiellement des *répondeurs de transaction* (même s'il s'agit également de *destinataires de transaction*).

NOTE 3 L'IEEE 802.15.4e spécifie des mécanismes qui sont similaires, mais pas identiques, à plusieurs des mécanismes DL spécifiés dans la présente norme.

4.6.11.2 Phase d'acquisition de voie

La phase d'acquisition de voie d'une transaction a deux utilisations.

a) **Listen Before Talk (LBT)**: Un mode de fonctionnement qui est exigé dans certaines juridictions de réglementation et facultatif dans d'autres, dont le but est de réduire l'interférence avec d'autres appareils émettant dans la même gamme de fréquences, que ces appareils utilisent des PhL semblables (d'autres systèmes IEEE 802.15.4 sur la même voie, par exemple) ou des PhL différentes qui se chevauchent dans leur utilisation de la fréquence (IEEE 802.11, par exemple,). Dans ce mode de fonctionnement, les initiateurs de transaction prévus échantillonnent la voie d'une manière spécifiée (par exemple, mode 1 de CCA) pendant une durée spécifiée, conformément aux exigences réglementaires locales, et arrêtent l'utilisation prévue de l'intervalle de temps si cet échantillonnage implique que le canal soit en cours d'utilisation par un autre courant appareil.

b) **CSMA/CA**: Un moyen par lequel plusieurs DLE conformes à la présente norme tentent de réclamer l'utilisation d'un intervalle de temps d'utilisation partagée. Dans ce mode de fonctionnement, chaque initiateur de transaction compétiteur fonctionne comme en a) pendant une durée qui est uniformément choisie dans une distribution de durées

d'intervalle qui augmente exponentiellement avec les échecs successifs (jusqu'à une certaine limite prédéterminée), fournissant de ce fait le repli exponentiel en cas d'encombrement pour l'utilisation de l'intervalle de temps. Quand la plus petite valeur de l'intervalle sélectionné est supérieure à zéro, un tel fonctionnement prend en charge l'accès priorisé, car les DLE qui mettent en œuvre le mode CSMA/CA tendent à différer à celles qui ne le font pas.

Les deux modes a) et b) peuvent être combinés pour satisfaire aux deux ensembles d'objectifs. Les modèles d'intervalle de temps utilisés par les destinataires prévus ont besoin de rendre compte de ces retards initiaux, comme en 4.6.11.1, d)1), afin que de tels destinataires ne mettent pas prématurément fin à la réception dans une tentative de réduire au maximum l'énergie utilisée par leurs récepteurs de PhL lorsqu'ils sont actifs.

En raison des propriétés bien connues de la propagation RF, les processus Listen Before Talk et CSMA/CA ci-dessus ne sont pas fiables quant à leur aptitude à détecter soit l'utilisation de voie par d'autres appareils, soit le potentiel que l'utilisation de voie pour une transaction donnée interfère avec d'autres communications distantes en cours. Cette question porte de nombreux noms, notamment celui fréquent de problème de "nœud caché". Ainsi le différé des transactions en raison de a) et/ou b) est toujours pessimiste en ce qui concerne l'interférence projetée, pourtant le non-différé est inadéquat pour éviter l'interférence (qui se produit aux récepteurs) causée par des émetteurs RF concourants qui échouent à se détecter les uns les autres.

4.6.11.3 Phase de communication

La phase de communication d'une transaction est utilisée pour trois classes de base de transactions, à savoir:

a) **Multicast/broadcast** (multidiffusion/diffusion): Le modèle d'intervalle de temps pour l'initiateur de transaction est constitué de 4.6.11.1, c)1) et c)2), avec omission de c)3), alors que le modèle d'intervalle de temps pour les destinataires de transaction est constitué de 4.6.11.1, d)1) et d)2), avec omission de d)3). Pour ces transactions, il n'y a pas de répondeur de transaction, car aucune occasion de réponse immédiate de message SCS n'est fournie dans le modèle.

b) **Unicast** (monodiffusion): Le modèle d'intervalle de temps pour l'initiateur de transaction est constitué de toutes les parties de 4.6.11.1, c), alors que le modèle pour les destinataires est constitué de toutes les parties de 4.6.11.1, d). Pour ces transactions, il y a exactement un répondeur de transaction prévu, avec une seule occasion de réponse immédiate ACK/NAK fournie dans le modèle.

c) **Duocast/N-cast** (duodiffusion/N-diffusion): Le modèle d'intervalle de temps pour l'initiateur de transaction est constitué de toutes les parties de 4.6.11.1, c), alors que le modèle pour les destinataires est constitué de toutes les parties de 4.6.11.1, d). Pour ces transactions, il y a un nombre désigné (respectivement 2 ou n pour la duodiffusion et la N-diffusion) de répondeurs de transaction prévus, chacun avec un modèle d'intervalle de temps différent qui spécifie une seule occasion de réponse pour une DPDU ACK/NAK disjointe de toutes les autres occasions de réponse pour la même transaction.

   Dans cette classe de transaction, tous les répondeurs de transaction ou tous les répondeurs (sauf le premier) se sensibilisent eux-mêmes pour recevoir une DPDU dont l'adresse DL16Address de destination n'est pas la propre adresse DL16Address de la DLE. Dans de tels cas, le modèle d'intervalle de temps spécifie également l'adresse DL16Address devant être utilisée à cet effet. Cette utilisation d'une adresse DL16Address distincte s'applique seulement aux DPDU Data de la transaction; toute DPDU ACK/NAK utilise les adresses DL16Address réelles explicites ou implicites du répondeur et de l'initiateur de la transaction.

4.6.12 Sécurité robuste et flexible

Tous les réseaux conformes ont un gestionnaire de sécurité pour gérer et authentifier des clés cryptographiques en transit. Des primitives de sécurité définies par l'IEEE 802.15.4 sont

utilisées par la DLE et la TLE, fournissant l'authentification de l'émetteur du message, l'intégrité du message, et la confidentialité facultative du contenu du message.

L'authentification de l'appareil est activée par l'utilisation de clés symétriques et d'identificateurs (ID) uniques d'appareil, avec une option pour l'utilisation de clés asymétriques pendant le processus de configuration de l'appareil et un certain nombre d'autres processus relatifs à la sécurité.

Au cours du fonctionnement normal, l'authenticité des données reçues et l'intégrité des données sont vérifiables par le biais de l'utilisation des clés symétriques secrètes connues à la fois de l'émetteur et du ou des destinataires.

Pendant la configuration, l'authenticité des authentifiants d'appareil reçus provenant d'un nouvel appareil peuvent être vérifiés par un gestionnaire de système par le biais de l'utilisation facultative de clés publiques ouvertement partagées par le nouvel appareil, et une clé privée asymétrique correspondante tenue secrète au sein du nouvel appareil.

Les PDU sont protégées en utilisant le chiffrement par défaut AES à blocs de 128 bits ou un autre chiffrement par blocs mandaté localement, en utilisant des modes cryptographiques normalisés. Des clés symétriques secrètes qui sont connues des entités en communication sont utilisées pour sécuriser la communication d'un appareil vers un autre.

4.6.13 Gestion de système

La présente norme inclut des fonctions pour gérer des ressources de communication sur chaque appareil individuel, ainsi que des ressources système qui ont un impact sur la performance de bout en bout. La gestion de système permet la prise en charge de la gestion politique de la configuration en temps d'exécution et elle effectue une surveillance et fournit des rapports sur la configuration, la performance, les conditions de défauts et le statut opérationnel. Les fonctions de gestion de système participent à des activités telles que:

- le rattachement à un réseau et départ d'un réseau pour un appareil;
- les rapports relatifs aux défauts qui se produisent dans le réseau;
- la configuration de communication;
- la configuration de la distribution d'horloges et le réglage du temps système;
- la surveillance d'appareil;
- la surveillance et l'optimisation de performances.

La gestion de sécurité du système travaille conjointement avec la fonction de gestion du système et, potentiellement, avec des systèmes externes de sécurité pour permettre l'exploitation sécurisée du système.

Toutes les fonctions de gestion sont accessibles à distance par l'intermédiaire de la passerelle.

4.6.14 Processus applicatif utilisant des objets normalisés

Le processus applicatif de la présente norme est représenté sous la forme d'un objet normalisé qui contient un ou plusieurs composants en communication puisant dans un ensemble d'objets d'application définis normalisés. Ces objets fournissent le stockage pour les données d'un processus applicatif et accèdent à celles-ci.

Le fait de définir des objets normalisés fournit d'une manière définitive une représentation des capacités d'une application distribuée, permettant de ce fait à des mises en œuvre indépendantes d'interfonctionner. Des objets sont définis pour permettre non seulement l'interaction parmi des appareils de terrain, mais aussi l'interfonctionnement avec des systèmes hôtes différents.

Les objets et services normalisés de la présente norme peuvent être utilisés pour établir un mapping direct des communications d'appareils de terrain héritées existantes à des objets normalisés et à des services de communication de sous-couche d'application, fournissant ainsi un moyen d'adapter des appareils hérités pour communiquer sur le réseau WISN.

4.6.15 Tunnellisation

Les protocoles natifs définis par la présente norme permettent à des appareils d'encapsuler des PDU étrangères et de transporter ces PDU étrangères, par le réseau WISN, vers un appareil de destination au sein du WISN, qui est habituellement une passerelle vers des protocoles hérités. Ce mécanisme d'encapsulation est appelé "tunnellisation". L'application réussie de la tunnellisation dépend de la bonne qualité avec laquelle les exigences techniques du protocole étranger (temporisation, latence, etc., par exemple) sont respectées par l'instanciation du WISN.

5 Système

5.1 Généralités

Dans la présente norme, un système est défini pour avoir un axe application et adresser des applications et leurs besoins. Les réseaux, d'autre part, ont un axe communication et sont consacrés à la tâche de communication d'un appareil à un autre. Pour les besoins de la présente norme, un réseau est un composant d'un système plus grand.

L'Article 5 décrit comment les diverses couches de protocoles et fonctions de la présente norme travaillent ensemble pour former un système qui atteint les buts de la présente norme. Spécifiquement, l'Article 5 décrit les aspects système des appareils, réseaux, suite de protocoles, flux de données, une base de temps partagée, et le besoin des applications pour les révisions de firmware.

5.2 Appareils

5.2.1 Généralités

Les appareils mettent en œuvre une combinaison des couches de protocoles, y compris habituellement une PhLE, une DLE, une NLE, une TLE et une ALE, et peut inclure des fonctions telles que le rôle de gestionnaire de système, le rôle de gestionnaire de sécurité, un ou plusieurs rôles de passerelle, et la prise en charge de configuration d'autres appareils dans le réseau.

NOTE Seuls les comportements de système sont spécifiés à l'Article 5.

5.2.2 Interfonctionnabilité d'appareils

L'interfonctionnabilité d'appareils est l'aptitude d'appareils issus de plusieurs fournisseurs à communiquer et maintenir le réseau complet. L'interfonctionnabilité d'appareils requiert la maîtrise sur les diverses options, valeurs de réglage de configuration et capacités de l'appareil:

a) **Options**: Pour permettre à tous les appareils d'interfonctionner, et d'interopérer dans un domaine restreint d'application, indépendamment des options mises en œuvre (celles définies dans la présente norme), les appareils doivent être capables de désactiver (c'est-à-dire de ne pas utiliser) toute option qui n'est pas obligatoire pour le ou les rôles configurés de l'appareil, tel que spécifié dans les profils de rôles à l'Annexe B.

b) **Valeurs de réglage de configuration**: Le gestionnaire de système est responsable de configurer les appareils du WISN et les rôles mis en œuvre par les appareils du WISN. Le gestionnaire de système est décrit à l'Article 6. Certains aspects de configuration sont décrits à l'Annexe D.

c) **Capacités**: Il existe des capacités minimales qui doivent être remplies pour les appareils en fonction de leur rôle dans le système. L'Annexe B définit les capacités de base exigées pour tous les appareils.

5.2.3 Profils

Un profil peut être décrit comme étant une tranche verticale à travers les couches de protocoles. Il définit les options dans chaque couche de protocoles qui sont obligatoires pour le profil en question. Il définit également les configurations et les plages de paramètres pour chaque protocole. Le concept de profil est utilisé pour réduire le risque de problèmes d'interfonctionnabilité et d'interopérabilité d'appareils entre les produits de différents fabricants. L'interopérabilité dans les zones figurant hors du domaine d'application de la présente norme exige soit l'utilisation de profils allant au-delà de la présente norme, soit d'autres dispositions complémentaires à la présente norme

Un profil de rôles est défini comme représentant les capacités de base, y compris toutes les caractéristiques facultatives, valeurs de réglages et configurations, qui sont exigées d'un appareil pour accomplir correctement le rôle en question. Les rôles sont définis en 5.2.6.2.

5.2.4 Qualité de service

Une application au sein d'un appareil est censée connaître le niveau du service qui est nécessaire pour son fonctionnement correct. Le niveau de la qualité du service (QoS) est convenu par un contrat entre le gestionnaire de système et l'appareil demandeur. Lorsque l'application au sein d'un appareil désire communiquer à un certain niveau de QoS, elle envoie une demande au gestionnaire de système lui notifiant qu'elle souhaite communiquer avec une destination spécifique et qu'elle désire un niveau donné de QoS. Ce niveau désiré de QoS est indiqué par une priorité désirée de contrat et de message. En outre, un certain niveau de fiabilité, une périodicité, une phase, et une date limite pour les messages périodiques, et une fréquence de salve de court terme, une fréquence de salve de long terme, et le nombre maximal de demandes en cours pour des client/serveur, peuvent être indiqués. Voir 6.3.11.2.7 pour des informations spécifiques relatives à la QoS.

5.2.5 Applicabilité mondiale d'appareil

5.2.5.1 Généralités

La présente norme est conçue pour prendre en charge le fonctionnement au sein d'une zone géographique fixe qui fonctionne sous des réglementations uniformes. A ce titre, elle est censée prendre en charge le fonctionnement dans la bande de 2,4 GHz n'importe où dans le monde (voir le débat en 9.1.15.6). Par exemple, l'Annexe V explique comment les systèmes et appareils peuvent être configurés pour satisfaire aux contraintes réglementaires de l'UE.

La présente norme est également conçue pour prendre en charge les systèmes d'automation sans fil fonctionnant sur des plateformes mobiles, telles que les navires marins (par exemple, les navires porte-conteneurs et les navires-citernes de produits pétrochimiques) et les trains, qui peuvent se déplacer entre des régions géographiques (des pays, par exemple) où s'appliquent des réglementations différentes voire conflictuelles. Par exemple, un navire porte-conteneurs serait habituellement soumis à des réglementations locales lorsqu'il est au port, et pourrait donc avoir des exigences de conformité différentes lorsqu'il est à Rotterdam de celles en vigueur dans la Baie de Tokyo, car les réglementations qui s'appliquent aux systèmes sans fil lorsqu'ils fonctionnent sous la juridiction de l'UE diffèrent de celles qui s'appliquent lorsqu'ils fonctionnent sous juridiction japonaise.

Les règlements des radiocommunications exigent souvent des appareils de fonctionner à des niveaux contraints de puissance, et ce, à tout moment, y compris pendant la configuration par liaison radio. Certaines limites de densité EIRP et EIRP identifiées sont: 10 mW/MHz (Japon); 10 dBm (Chine); 10 dBm, 10 mW/MHz et 20 dBm (UE); 36 dBm avec au maximum un gain d'antenne de 6 dBi (US FCC).

Dans certains pays, tels que la France, les niveaux d'émission sur certaines voies peuvent avoir besoin d'être affaiblis. Dans d'autres pays, tels que la Corée, le nombre et la gamme de voies ont besoin d'être contraints.

5.2.5.2 Fonctionnement au sein d'un régime de réglementation fixe

Le champ dlmo.CountryCode, décrit en 9.1.15.6, est utilisé pour spécifier le régime de réglementation. Il peut également être utilisé pour spécifier un certain nombre de contraintes de réglementation dérogatoires.

Ce champ inclut un mécanisme "autobloquant" qui permet de mettre ce champ à une valeur de sorte que le champ complet ne puisse pas être modifié pendant que l'appareil est opérationnel. Une fois la valeur définie, seule la reconfiguration de l'appareil, comme après une réparation ou un transfert de propriété, est capable de désactiver ce verrou.

Cette caractéristique "mettre et oublier" a été incluse pour prendre en charge des régimes de réglementation, tels que certains au sein de l'UE, où aucune méthode opérationnelle ne peut déroger aux limites d'émission RF établies par réglementation. Néanmoins, la caractéristique est fournie d'une manière qui prend également en charge la réparation et la revente d'appareils dans d'autres juridictions de réglementation, dont les exigences pourraient être différer de celles de la juridiction dans laquelle l'appareil a été déployé précédemment.

5.2.5.3 Fonctionnement sur une plateforme qui se déplace entre des régimes de réglementation

Certains systèmes d'automation sans fil peuvent être situés sur une plateforme mobile telle qu'un navire porte-conteneurs ou navire-citerne de produits pétrochimiques qui se déplace entre des régimes de réglementation, en fonctionnant temporairement dans chacun de ceux-ci. Cette transition entre régimes peut se produire rapidement, comme lorsqu'un train franchit une frontière, ou lentement, comme lorsqu'un bateau passe des eaux nationales aux eaux internationales.

La présente norme est conçue pour prendre en charge le fonctionnement de systèmes sans fil dans de telles situations de transport mobile, en fournissant un moyen par lequel un seul paramètre d'équipement peut être changé dans chaque appareil, par exemple par une action synchronisée téléchargée à l'avance vers chaque appareil, pour conduire tous les appareils affectés à changer de régimes de réglementation, après quoi leurs fonctionnements seront contraints par les réglementations des régimes de réglementation nouvellement pénétrés.

NOTE Un tel changement des caractéristiques d'émission sans fil sera souvent accompagné d'un changement des programmes de liaisons, par exemple, pour utiliser plus ou moins de routeurs dans un chemin à sauts multiples, ou pour avoir à disposition plus d'intervalles de temps pour la répétition des transactions qui ont été abandonnées en raison de l'activité détectée par le mécanisme LBT dans la voie, pour mieux faire concorder le fonctionnement du système avec les exigences plus strictes (ou assouplies) du nouveau régime de réglementation.

5.2.6 Description d'appareil

5.2.6.1 Généralités

Dans la présente norme, les appareils constituent le mode de réalisation physique des comportements, des valeurs de réglage de configuration et des capacités qui sont nécessaires pour mettre en œuvre et exploiter un réseau. Il existe un grand nombre de différents types d'appareils selon l'application, l'environnement, et leur fonction dans le réseau. Pour pouvoir décrire complètement le comportement nécessaire de réseau sans définir des mises en œuvre spécifiques d'appareil, la présente norme définit des rôles, des couches de protocoles, et un moyen de terrain dont les appareils peuvent être le mode de réalisation.

Un rôle définit un ensemble de fonctions et de capacités. La présente norme définit tous les rôles nécessaires au fonctionnement correct du réseau, y compris le gestionnaire de système, le gestionnaire de sécurité, la passerelle, le routeur dorsal, la source de temps système, la

configuration, le routeur, et l'appareil E/S. Tous les appareils conformes à la présente norme doivent mettre en œuvre au moins un rôle; cependant, un appareil peut mettre en œuvre plusieurs rôles. Un appareil mettant en œuvre un rôle doit mettre en œuvre toutes les fonctions exigées pour ce rôle en 5.3.

Les couches de protocoles décrivent les comportements exigés. Tous les appareils ne sont pas tenus mettre en œuvre toutes les couches de protocoles définies dans la présente norme. Par contre, tous les appareils conformes à la présente norme doivent mettre en œuvre les couches réseau et transport en plus de la fonctionnalité de DMAP telle que décrite en 6.2. Chaque appareil doit contenir une fonction de gestion d'appareil et une fonction de gestion de sécurité d'appareil qui coopèrent avec les processus du système pour permettre une gestion sécurisée des ressources d'un appareil et l'utilisation par l'appareil des ressources de système.

Un moyen de terrain est représenté au sein d'un appareil par une combinaison d'une PhLE et d'une DLE, toutes les deux telles que décrites dans la présente norme. Alors que tous les appareils n'ont pas nécessairement besoin de mettre en œuvre un moyen de terrain, tout appareil qui met en œuvre les rôles E/S, de routage ou de routage dorsal doit prendre directement en charge au moins un moyen de terrain tel que spécifié par la présente norme.

La Figure 4 montre la distinction entre appareils physiques (par exemple, tels que fournis par un fabricant) et les rôles que ces appareils peuvent assumer.

Figure 4 – Appareils physiques versus rôles

La Figure 4 montre un réseau représentatif et pourtant complet conforme à la présente norme. Ce réseau contient plusieurs types d'appareils, y compris des capteurs, des actionneurs, des routeurs, un calculateur à main et une station de travail. Comme montré à la Figure 4, chacun de ces appareils peut assumer différents rôles au sein du réseau. Dans cet exemple:

- la station de travail a assumé les rôles de passerelle, de gestionnaire de système et de gestionnaire de sécurité, ces rôles étant respectivement décrits en 5.2.6.10, en 5.2.6.11 et en 5.2.6.12;
- deux appareils ont assumé le rôle des routeurs dorsaux (décrit en 5.2.6.9) alors que sept autres appareils ont assumé le rôle de routeurs (décrit en 5.2.6.7);
- trois capteurs, un actionneur et un ordinateur portable ont assumé le rôle singulier d'un appareil E/S (5.2.6.6);
- le routeur en bas à gauche de la Figure 4 a assumé un rôle de configuration, tel que décrit en 5.2.6.8, et configurera le nouvel appareil en train d'être introduit; et
- deux appareils actionneurs ont assumé les rôles à la fois de routeur et de E/S.

NOTE 1 Bien que la Figure 4 montre l'utilisation d'un réseau dorsal, la fonctionnalité du réseau dorsal n'est pas spécifiée dans la présente norme.

NOTE 2 Les appareils physiques et les rôles montrés à la Figure 4 sont censés être seulement des exemples.

5.2.6.2 Moyen de terrain

5.2.6.3 Généralités

La présente norme définit un moyen de terrain spécifique, le Type A. Un type de moyen de terrain définit le protocole pour la PhL et la DL inférieure (à savoir la MAC). Les futures révisions de la présente norme peuvent prendre en charge plusieurs types de moyens de terrain.

5.2.6.4 Type A

Le moyen de terrain de Type A comprend la PhL et la DL telles que spécifiées par l'Article 8 et l'Article 9 de la présente norme.

Les appareils mettant en œuvre le moyen de terrain de Type A et la DL doivent mettre en œuvre valeurs de réglage pour le silence radio (Radio Silence). La configuration Radio Silence est utilisée pour empêcher la radio d'émettre pendant des périodes inadéquates, telles que quand l'émission est peu sûre ou quand des réglementations interdisent les émissions radio. Les valeurs de réglage de la configuration Radio Silence sont définies en 9.1.15.4.

5.2.6.5 Définitions des rôles

5.2.6.6 Entrée/sortie

Un appareil avec le rôle E/S (entrée/sortie) doit fournir des données (de source) à d'autres appareils ou utiliser (consommer) des données en provenance de ceux-ci (et peut aussi bien fournir qu'utiliser des données) et doit avoir au moins un objet processus d'application utilisateur (UAP). Un appareil avec seulement un rôle E/S est un appareil qui a les caractéristiques minimales exigées pour participer à un réseau conforme à la présente norme. Le rôle E/S ne fournit de mécanisme de transmission de messages ou de routage pour aucun autre appareil. Cela permet la construction d'appareils avec la plus faible complexité et le potentiel pour une faible consommation d'énergie, car ils n'ont pas besoin de dépenser de l'énergie pour acheminer les messages d'autres appareils et ils ne sont pas non plus tenus d'accepter et de configurer de nouveaux appareils souhaitant rejoindre le réseau.

NOTE Une source de données fournit des données. Un actionneur serait un exemple d'un consommateur de données (c'est-à-dire: un puits), alors qu'un capteur fournirait des données (c'est-à-dire: une source).

Les appareils qui mettent en œuvre le rôle E/S doivent mettre en œuvre le moyen de terrain de Type A.

5.2.6.7 Routeur

Un appareil avec le rôle de routeur doit avoir une capacité de routage, doit agir comme un proxy ("un mandataire") et doit avoir une capacité de propagation d'horloges. Ces appareils peuvent fournir une extension de portée pour un réseau et une redondance de chemin et peuvent fournir différents niveaux de QoS sur une base message par message. Le gestionnaire de système peut désactiver les capacités de routage du rôle de routeur pour optimiser des exigences relatives aux performances du système telles que la latence des messages ou la consommation de batterie.

Les appareils qui mettent en œuvre le rôle de routeur doivent mettre en œuvre le moyen de terrain de Type A.

5.2.6.8 Configuration

Un appareil avec le rôle de configuration (appareil de configuration) doit être capable de configurer un appareil mis aux valeurs par défaut d'usine et doit mettre en œuvre l'objet service de configuration d'appareil (DPSO; voir Article 13). L'appareil de configuration insère les données de configuration exigées dans un appareil pour permettre à un appareil de rejoindre un réseau spécifique. Les appareils mettant en œuvre la PhL doivent être capables d'être configurés en utilisant l'interface physique définie. Cette capacité peut être désactivée (voir Article 13).

Les appareils qui mettent en œuvre le rôle de configuration doivent mettre en œuvre le moyen de terrain de Type A.

5.2.6.9 Routeur dorsal

Un appareil avec le rôle de routeur dorsal doit avoir une capacité de routage, par l'intermédiaire de la dorsale, et doit agir comme un proxy en utilisant la dorsale. Les routeurs dorsaux permettent aux réseaux externes de porter le protocole natif en encapsulant les PDU pour le transport. Cela permet à un réseau décrit par la présente norme d'utiliser d'autres

réseaux, y compris des réseaux ayant une plus longue portée ou de plus hautes performances.

Alors que les supports et les suites de protocole des réseaux dorsaux ne sont pas définis dans la présente norme, il est jugé que de nombreuses instanciations du routeur dorsal le seront avec les réseaux IP (protocole internet). Plusieurs de ces réseaux dorsaux peuvent se conformer à IPv4 par opposition au plus nouvel IPv6. L'Article 10 décrit comment une NPDU WISN reçue par un BBR à l'interface DLE WISN du BBR est convertie en une NDPU pleinement conforme à l'IPv6. Si l'interface dorsale du BBR met en œuvre IPv6, alors la NPDU peut simplement être acheminée en utilisant la norme IPv6. Si l'interface dorsale du BBR met en œuvre IPv4, alors le BBR doit prendre en charge l'utilisation de l'IETF RFC 2529 pour acheminer la NPDU à la dorsale IPv4.

Les appareils mettant en œuvre le rôle de routeur dorsal doivent mettre en œuvre le moyen de terrain de Type A en plus de l'interface réseau dorsale du BBR.

5.2.6.10 Passerelle

Un appareil avec le rôle de passerelle met en œuvre une interface du côté haut. Un exemple d'un GIAP interne prenant en charge une telle interface de côté haut est donné en Annexe U. La passerelle communique sur le WISN par l'accès natif et/ou la tunnellisation. Un tel appareil doit avoir un UAP. Le rôle de passerelle fournit une interface entre le WISN et le réseau d'installation, ou directement à une application finale sur un réseau d'installation. Plus généralement, une passerelle marque la transition entre les communications conformes à la présente norme et les autres communications et agit comme convertisseur de protocole entre une AE décrite par la présente norme et les autres AE. Il peut y avoir plusieurs passerelles dans un système.

5.2.6.11 Gestionnaire de système

Un appareil mettant en œuvre le rôle de gestionnaire de système doit mettre en œuvre le SMAP (6.3.2) et doit positionner l'arbre de source de temps.

Le gestionnaire de système est une fonction spécialisée qui régit le réseau, les appareils, et les communications. Le gestionnaire de système accomplit la commande politique de la configuration en temps d'exécution du réseau, effectue une surveillance et fournit des rapports sur la configuration, la performance, le statut opérationnel et fournit des services relatifs au temps.

Lorsque deux appareils ont besoin de communiquer, ils le font en utilisant un contrat. Un contrat est un accord entre le gestionnaire de système et un appareil dans le réseau qui implique l'allocation de ressources du réseau par le gestionnaire de système pour prendre en charge un besoin particulier de communication de cet appareil. Ce contrat est conclu entre les applications tant dans les appareils que dans le gestionnaire de système. Le gestionnaire de système assignera au contrat un identificateur de contrat, et l'application dans l'appareil utilisera le contrat pour des communications. Une application peut seulement demander la création, la modification, ou la résiliation d'un contrat. Il est de la seule responsabilité du gestionnaire de système de créer, maintenir, modifier et résilier le contrat.

Pour plus d'informations sur la gestion de système, voir Article 6.

5.2.6.12 Gestionnaire de sécurité

La fonction de gestion de sécurité de système, ou le gestionnaire de sécurité, est une fonction spécialisée qui travaille conjointement avec le gestionnaire de système et, potentiellement, des systèmes externes de sécurité pour permettre l'exploitation sécurisée du système. Le gestionnaire de sécurité est logiquement séparable du gestionnaire de système et, dans certains cas d'utilisation, sera résident sur un appareil séparé et dans un lieu séparé. Chaque système conforme à la présente norme doit avoir un gestionnaire de sécurité. Pour plus d'informations sur le gestionnaire de sécurité, voir Article 7.

NOTE Le protocole de transmission utilisé entre le gestionnaire de système et le gestionnaire de sécurité n'est pas défini par la présente norme parce que de tels composants sont habituellement fournis par un fournisseur sous la forme d'un jeu/d'une paire assorti(e).

Pour plus d'informations sur la fonctionnalité de gestion de sécurité, voir 7.7.

5.2.6.13 Source de temps système

Un appareil mettant en œuvre le rôle de source de temps système doit mettre en œuvre la source de base de temps pour le système. Un sens de temps est un aspect important de la présente norme; il est utilisé pour gérer le fonctionnement de l'appareil. La source de temps système fournit un sens de temps pour le système entier. Cela est décrit en plus de détails en 6.3.10.1.

Les appareils mettant en œuvre le rôle de source de temps système doivent mettre en œuvre les rôles E/S, de routeur, de routeur dorsal, de gestionnaire de système, ou de passerelle.

5.2.7 Adressage d'appareil

Chaque appareil qui met en œuvre le moyen de terrain de Type A doit avoir une adresse DL16Address de sous-réseau D qui lui est assignée en vue de l'adressage local. Chaque appareil doit avoir une adresse EUI64Address qui lui est propre. Voir Article 9 pour de plus amples informations.

Chaque appareil doit également avoir une adresseIPv6Address qui est assignée par le gestionnaire de système telle que décrite en 6.3.5. Le gestionnaire de système peut choisir d'assigner l'adresse IPv6Address comme une adresse logique pour maintenir la liaison d'ALE en cas de remplacement d'appareil. L'adresse IPv6Address peut être employée par l'application pour atteindre un appareil particulier au sein d'un système après que le processus de rattachement du sous-réseau se sera achevé. Voir Article 10 pour de plus amples informations.

5.2.8 Phases d'appareil

5.2.8.1 Généralités

Un appareil peut passer par plusieurs phases pendant sa durée de vie opérationnelle. Chacune de ces phases contient plusieurs états. Une représentation hypothétique des phases de la vie d'un appareil est montrée à la Figure 5. Voir la Figure 136 et la Figure 137 pour le détail normatif.

Item not yet complete	Elément pas encore complet
Item complete	Elément complet

Figure 5 – Représentation hypothétique des phases d'un appareil

Un appareil peut passer plusieurs fois par ces phases pendant qu'il est mis en service et utilisé, puis retiré du service et remis en service pour une application différente. Après avoir rejoint le réseau, les appareils doivent être capables de rapporter leur statut afin que les applications sachent si un appareil est accessible et s'il est rattaché à une application.

5.2.8.2 Valeur par défaut d'usine

Un appareil est considéré comme étant non configuré s'il n'a été configuré ou mis en service avec aucune information spécifique à une application ou spécifique à un réseau. Un appareil non configuré peut provenir d'un fabricant ou peut entrer dans un état non configuré à la suite de son retrait du service.

5.2.8.3 Configuré pour application

Un appareil est considéré comme étant configuré pour une application lorsqu'il a reçu sa propre programmation spécifique à une application et lorsque toutes les valeurs par défaut appropriées ont été ont été appliquées. Un appareil configuré pour application peut provenir d'un fabricant ou peut être fourni par un intégrateur de systèmes ou un autre revendeur à valeur ajoutée, en étant déjà configuré pour l'application prévue. Des mises à jour de programmes d'application en liaison radio peuvent avoir lieu, mais sont traitées par l'ALE de l'appareil.

5.2.8.4 Configuré pour rejoindre le réseau

Un appareil est configuré pour rejoindre le réseau lorsqu'il a obtenu les authentifiants de sécurité et les informations spécifiques au réseau qui sont appropriés. Un appareil entre habituellement dans cette phase lorsqu'il a été préparé pour l'installation dans une application d'automation. Souvent, l'appareil ne communiquera pas directement avec le gestionnaire de sécurité; à la place, le gestionnaire de système sert de relais pour toute la communication avec le gestionnaire de sécurité.

5.2.8.5 Appareil accessible

Un appareil est considéré comme étant accessible lorsqu'il a rejoint le réseau et a été authentifié par le gestionnaire de système. Un appareil accessible peut communiquer avec le gestionnaire de système.

5.2.8.6 Rattaché à une application

Dans cette phase, un objet d'application sur l'appareil peut envoyer ou recevoir de l'information à destination ou en provenance des objets d'application désirés sur des appareils homologues. Voir 7.4 pour plus d'infirmations sur le processus de rattachement du sous-réseau.

NOTE Les objets d'application dans deux appareils quelconques sur le réseau peuvent communiquer l'un avec l'autre. Se référer à l'Article 12 pour plus de détails.

5.2.9 Sources d'énergie d'appareil

La présente norme ne limite pas les types de sources d'énergie qu'un appareil peut utiliser. La norme permet le comportement de haut rendement énergétique d'un appareil qui adapte le fonctionnement de l'appareil pendant de longues périodes (cinq à dix ans, par exemple) en utilisant les accumulateurs appropriés.

Les types de sources d'énergie peuvent être groupés en cinq catégories:

- secteur;
- accumulateur limité (élément bouton, par exemple);
- accumulateur modéré (au plomb-bioxyde de plomb, par exemple);
- batterie rechargeable;
- environnemental ou récupérateur d'énergie.

Les appareils mettant en œuvre les rôles E/S ou de routeur peuvent être censés utiliser n'importe quelle catégorie de source d'énergie. Les rôles du gestionnaire de sécurité, de gestionnaire de système, de passerelle, et de routeur dorsal sont habituellement intensifs en performances; il convient donc que les appareils mettant en œuvre ces rôles aient des sources d'énergie plus capables, comme les catégories secteur ou accumulateur modéré.

Le statut de la source d'énergie des appareils est critique pour la gestion correcte du système. Tous les appareils doivent fournir au gestionnaire de système les informations relatives à l'alimentation en énergie. Ces informations peuvent être utilisées pour prendre des décisions de routage. Voir Article 9 pour plus d'informations.

5.3 Réseaux

5.3.1 Généralités

L'axe sur lequel les réseaux sont centrés est la communication d'un appareil vers un autre. Il existe de nombreux aspects de la capacité des réseaux à communiquer. Ces aspects incluent le réseau atomique (c'est-à-dire minimal ou irréductible), les topologies de réseau, les

relations des appareils au sein d'un réseau, la structure de la suite de protocoles, et le concept de temps partagé.

5.3.2 Réseau minimal

Un réseau minimal est un réseau avec la quantité minimale d'appareils mettant en œuvre le nombre minimal de rôles. Bien qu'un système minimal puisse être construit avec juste un gestionnaire de système et un gestionnaire de sécurité, un système minimum plus pratique inclut les rôles de gestionnaire de système, de gestionnaire de sécurité, de configuration, de source de temps système et d'E/S. Le gestionnaire de système et le gestionnaire de sécurité constituent deux rôles distincts; ils peuvent résider dans le même appareil ou être divisés entre deux appareils physiques. Un même appareil physique peut assumer plusieurs rôles. Par conséquent, un réseau minimal doit être constitué de deux appareils communiquant l'un avec l'autre, où un appareil met en œuvre les rôles de gestionnaire de système et de gestionnaire de sécurité; les rôles de configuration, de source de temps système et E/S sont mis en œuvre par l'un ou l'autre des appareils.

Un petit réseau représentatif de quatre appareils de terrain et d'un appareil d'infrastructure est montré à la Figure 6. Bien qu'un tel réseau soit atypique, il représente un petit système conforme. Dans ce réseau, un même appareil physique a assumé les rôles de passerelle, de gestionnaire de système et de gestionnaire de sécurité.

5.3.3 Topologies réseau de base prises en charge

5.3.3.1 Généralités

Les Figures 6 à 9 en 5.3.3 fournissent plusieurs exemples informatifs et illustrent la flexibilité de l'architecture d'un système. L'ensemble d'exemples n'est pas censé être exhaustif. Ces exemples sont présentés ici pour permettre seulement une meilleure compréhension éléments d'un système.

5.3.3.2 Topologie en étoile

La présente norme prend en charge une topologie en étoile simple, telle que montrée à la Figure 6.

Figure 6 – Topologie en étoile simple

Cette configuration de système peut donner la plus faible latence possible à travers la couche physique. Elle est très simple du point de vue de l'architecture, mais se limite à la portée d'un seul saut.

Dans les Figures 6 à 9 en 5.3.3, chaque zone étiquetée G,M,S représente un ensemble de trois rôles séparés combinés dans un seul appareil physique dans les réseaux relativement simples illustrés:

- une passerelle;
- un gestionnaire de système; et

- un gestionnaire de sécurité.

5.3.3.3 Topologie concentrateur-rayons

Le fait d'étendre le réseau en utilisant des routeurs dorsaux permet à l'utilisateur de construire un réseau concentrateur-rayons (ou réseau en étoile) (voir Figure 7) dans lequel les appareils sont placés en grappes autour de chaque routeur dorsal, fournissant l'accès à la dorsale à grande vitesse.

Figure 7 – Topologie concentrateur-rayons simple

Dans ce cas, la latence est légèrement dégradée par rapport à la topologie en étoile simple, mais le débit global peut augmenter, et dans de plus gros systèmes, la latence moyenne peut diminuer en raison des multiples tubes de données disponibles (un à travers chaque routeur dorsal). Bien que le réseau puisse s'étendre encore plus loin de la passerelle, il est néanmoins limité à la portée d'un seul saut autour d'un routeur dorsal.

5.3.3.4 Topologie maillée

La présente norme prend en charge les topologies de mise en réseau maillé, telles que montrées à la Figure 8.

Figure 8 – Topologie maillée

Dans certains cas, le nombre d'itinéraires qu'un appareil peut prendre en charge peut être limité. La portée s'allonge à mesure que plusieurs sauts sont pris en charge. La latence est plus grande, mais peut être réduite au maximum par une programmation correcte des émissions. Le débit se dégrade à mesure que les ressources de l'appareil sont utilisées dans des messages répétitifs. La fiabilité peut être améliorée par l'utilisation d'une diversité de chemins.

Pour plus d'informations sur la topologie maillée, voir 9.1.14.

5.3.3.5 Topologie maillée en étoile

La combinaison de la topologie en étoile avec la topologie maillée est montrée à la Figure 9.

Figure 9 – Topologie en étoile-maillée simple

Cette configuration a l'avantage de limiter le nombre de sauts dans un réseau. Elle n'a pas la fiabilité ajoutée que la pleine mise en réseau maillé peut fournir.

5.3.3.6 Combinaisons de topologies

La présente norme permet la combinaison de n'importe lesquelles des topologies mentionnées précédemment afin que puisse être construite une configuration qui satisfait le mieux aux besoins de l'application. Par exemple, des systèmes de surveillance qui couvrent de grandes zones physiques au sein d'une installation peuvent utiliser la topologie en étoile maillée ou une combinaison de topologies concentrateur-rayons et en étoile maillée, alors que certaines applications de contrôle où la latence est critique peuvent tirer bénéfice d'une topologie en étoile ou concentrateur-rayons. La flexibilité du système permet à toutes ces topologies de fonctionner en harmonie, sous n'importe quelle combinaison.

5.3.4 Configurations de réseau

5.3.4.1 Généralités

Le sous-réseau D dans la présente norme comprend un ou plusieurs groupes d'appareils sans fil, avec un gestionnaire de système partagé et (si applicable) une dorsale partagée. Alors qu'un sous-réseau D s'arrête au niveau du routeur dorsal (voir 5.5.6), le routage de réseau peut s'étendre dans la dorsale et le réseau d'installation. Un réseau complet inclut tous les sous-réseaux D connexes, ainsi que d'autres appareils reliés par l'intermédiaire de la dorsale, tels qu'une passerelle, un gestionnaire de système, ou un gestionnaire de sécurité. La Figure 10 et la Figure 11 montrent la distinction entre un sous-réseau D et un réseau.

Figure 10 – Exemple où le réseau et le sous-réseau D se chevauchent

La Figure 10 montre un réseau simple constitué d'un ensemble d'appareils sans fil appelés un sous-réseau D et d'appareils complémentaires qui gèrent le sous-réseau D et le relient à d'autres réseaux. Dans la Figure 10, le réseau et le sous-réseau de D sont les mêmes.

Le sous-réseau D est composé d'appareils de routage et d'appareils E/S. Les lignes en traits pleins entre les appareils désignent le premier itinéraire établi entre les appareils, alors que les lignes pointillées désignent le deuxième itinéraire, le troisième itinéraire, et ainsi de suite. Des messages peuvent être acheminés en utilisant n'importe lequel des itinéraires connus.

Dans la Figure 11, le sous-réseau D inclut un ensemble d'appareils de terrain jusqu'aux routeurs dorsaux (boîtes étiquetées B). Les routeurs dorsaux utilisent des connexions à une dorsale de réseau pour réduire le nombre de sauts que les messages exigeraient autrement, ce qui peut améliorer la fiabilité, réduire la latence et étendre la couverture du réseau.

Le réseau dans la Figure 11 inclut le sous-réseau D, ainsi que la dorsale et une passerelle, un gestionnaire de système, et un gestionnaire de sécurité, qui sont colocalisés sur la dorsale.

Les appareils passerelles peuvent être identiques (c'est-à-dire: reproduits en miroir, pour la redondance) ou uniques, par exemple, avec chaque passerelle mettant en œuvre une

application de logiciel pour traiter les communications entre une classe particulière d'appareil et un système de contrôle rattaché au réseau d'installation.

5.3.4.3 Plusieurs passerelles – Désignation d'une passerelle comme secours

NOTE La présente norme ne définit ni la fonctionnalité d'un passerelle de secours ni les mécanismes pour la synchronisation des passerelles de secours.

La Figure 13 est semblable à la Figure 10, mais avec un second appareil G,M,S (passerelle, gestionnaire de système, et gestionnaire de sécurité).

Figure 13 – Réseau de base avec passerelle de secours

Les deux appareils G,M,S offrent une fonctionnalité identique et peuvent coordonner leur fonctionnement par l'intermédiaire de messages de synchronisation échangés par un mécanisme de backchannel non spécifié par la présente norme. Un seul appareil G,M,S peut être responsable de toutes les fonctions de passerelle, de gestionnaire de système et de gestionnaire de sécurité, avec un second appareil G,M,S agissant comme appareil de réserve active qui reste au repos en attendant qu'on en ait besoin. En variante, les deux appareils G,M,S peuvent diviser la charge de travail entre eux jusqu'à ce que l'un d'eux ait une défaillance.

5.3.4.4 Ajout de routeurs dorsaux

Au réseau de base représenté à la Figure 13, la Figure 14 ajoute des routeurs dorsaux (boîtes étiquetées B), qui facilitent l'extension des réseaux conformes à la présente norme, en termes de nombre d'appareils et de surface que le réseau occupe.

La passerelle, le gestionnaire de système, et le gestionnaire de sécurité physiquement séparés qui sont représentés à la Figure 15 ne peuvent être mis en œuvre que dans les réseaux avec une dorsale de réseau.

5.4 Structure de suite de protocoles

Les couches de protocoles pour un appareil conforme à la présente norme sont décrites en termes du Modèle de référence de base OSI, qui est adapté tel que montré à la Figure 16. Tous les rôles et types d'appareils conformes à la présente norme peuvent être dérivés de ce modèle par extension ou restriction des éléments communs montrés à la Figure 16.

Figure 16 – Modèle de référence utilisé par la présente norme

Comme montré à la Figure 16, chaque couche fournit un point d'accès de service (SAP). Les services d'une couche sont définis comme étant les fonctions et les capacités de la couche en question qui sont exposées par l'intermédiaire du SAP aux couches environnantes. En général, deux types de SAP sont définis: les SAP de données, qui sont utilisés pour le transfert de données opérationnelles, et les SAP de gestion, qui sont utilisés pour la gestion de couche. Les services fournis par une couche sont définis par les données circulant par les SAP de données et, dans certains cas, par les états qu'une couche fournit et les transitions d'état qui sont pilotées par l'interaction à travers ces SAP. Le gestionnaire d'appareil est l'entité au sein de chaque appareil qui accomplit la fonction de gestion; dans la plupart des cas, il est accessible par l'intermédiaire d'un SAP de gestion de couche. Le gestionnaire

d'appareil a un chemin consacré menant à plusieurs des couches de protocoles inférieures au sein d'un appareil, pour fournir la maîtrise directe en temps réel sur le fonctionnement de ces couches ainsi que l'accès direct à des informations relatives aux diagnostics et aux statuts.

Dans la Figure 16, l'appareil assure la fonctionnalité de chaque SAP de gestion utilisé par le DMAP pour chaque couche de protocoles mise en œuvre.

Etant donné que la conformité peut être évaluée uniquement sur les interfaces externes, notamment le contenu des structures de données acheminées sur ces interfaces, toutes les descriptions théoriques portant sur la manière dont les fonctionnalités spécifiques pourraient être mises en œuvre ont uniquement un but informatif, et pas normatif.

5.5 Flot de données

5.5.1 Généralités

Les descriptions en 5.5 sont censées fournir des exemples de la manière dont les données peuvent circuler à travers le système. L'ensemble d'exemples n'est pas censé être exhaustif.

5.5.2 Communications natives

Un appareil communique sur le réseau en utilisant seulement des services définis par ASL tels que définis à l'Article 12; les charges utiles sont classifiées comme étant natives ou non natives. Les charges utiles natives sont définies à l'Article 12; les charges utiles non natives ne sont pas définies dans la présente norme.

5.5.3 Flot de données de base

La Figure 17 illustre le flot de données en régime établi pour un réseau de base conforme à la présente norme, tel que celui montré à la Figure 10.

Figure 17 – Flot de données de base

L'appareil E/S est un appareil capteur ou actionneur au sein du sous-réseau D qui contient des couches physiques, liaison de données, réseau et transport telles que définies par la présente norme et exécute une application qui traite la fonction de capteur ou d'actionneur.

Le routeur achemine des messages pour le compte de l'appareil E/S. Le routage au sein du sous-réseau D est entièrement accompli au sein de la DL, et pas au sein de la NL (voir Article 9). Dans un réseau du monde réel, il y aura un routeur pour chaque saut supplémentaire entre l'appareil et le routeur relié au WISN ou le routeur dorsal.

La passerelle traduit les messages entre le sous-réseau D et le réseau d'installation. L'application tournant sur la passerelle est constituée d'une composante qui communique avec l'ALE de l'appareil E/S, plus une composante qui communique avec une ALE au sein du système de contrôle, plus toutes les éventuelles composantes qui facilitent la traduction entre les deux, telles qu'une mémoire cache.

5.5.4 Flot de données entre appareils E/S

La Figure 18 montre le flot de données pour la communication entre les appareils E/S au sein d'un sous-réseau D. Le routage au sein du sous-réseau D est entièrement accompli au sein de la DL, et pas au sein de la NL.

Figure 21 – Flot de données entre appareils E/S par un sous-réseau dorsal

5.5.6 Flot de donnée avec dorsale

La Figure 20 introduit un routeur dorsal dans le flot de données.

Le routeur dorsal encapsule des NPDU et les relaie à travers les couches physiques, liaison de données, réseau et transport de la dorsale. La passerelle utilise les mêmes couches de dorsale pour récupérer les NPDU. Bien que cela ne soit pas montré à la Figure 20, la passerelle peut inclure à la fois une PhLE et une DLE telles que définies par la présente norme, permettant à la passerelle de traiter des messages directement issus d'un sous-réseau D, en plus des messages relayés par une interface dorsale.

5.5.7 Flot de données entre appareils E/S par une dorsale

La Figure 21 montre comment un réseau dorsal traite le transfert de messages conforme à la présente norme lorsqu'un appareil E/S communique directement avec un autre appareil E/S dans un sous-réseau D différent.

5.5.8 Flot de données vers un système de contrôle ou appareil compatible à la norme

Un système de commande compatible avec la norme est un système de commande qui comprend la messagerie définie par la présente norme et n'a pas besoin d'une passerelle pour accomplir la conversion de protocole. La Figure 22 montre le flux de données à destination d'un système de commande compatible avec la norme.

NOTE La conversion de protocole générique est traitée à l'Annexe O.

Figure 22 – Flux de données à destination d'un système de commande compatible avec la norme

En général, pour qu'un appareil soit compatible avec la norme, il a seulement besoin de prendre en charge l'interface d'application définie par la présente norme et de mettre en œuvre les couches application, transport et réseau définies par la présente norme. Cela permet à deux appareils compatibles avec la norme de communiquer par l'intermédiaire d'un réseau d'installation sans utiliser ou requérir de sous-couches.

5.6 Référence temporelle

5.6.1 Généralités

Le temps selon la présente norme est basé sur le temps atomique international (TAI) comme référence temporelle; voir 6.3.10. Le temps selon la présente norme est communiqué sous la forme de secondes écoulées depuis l'instant TAI de 00:00 le 1er janvier 1958 (c'est-à-dire 1958/01/01 00:00).

Il n'est pas possible ou même souhaitable que chaque réseau suive précisément une horloge atomique. Au contraire, chaque réseau doit avoir un sens du temps qui:

- est à croissance monotone à une fréquence qui coïncide étroitement avec le temps réel;
- ne dépasse pas une erreur de plus de 1 s par rapport à la source du temps système; et
- est livré aux diverses couches dans des appareils de terrain en unités de TAI cohérentes.

Il existe des modes de communication tels que définis à l'Article 9 qui exigent une exactitude d'horloge meilleure que 1 s par rapport à la source de temps système.

Pour le fonctionnement du protocole, la séquence de rapports relatifs aux événements, et autres besoins, il est habituellement nécessaire de diviser le temps en incréments de moins d'une seconde. Par exemple, les incréments peuvent être représentés de plusieurs façons:

Tops d'horloge de WISN: Deux octets pour marquer le temps en incréments de 2^{-15} s (32 768 Hz, ou ~30,52 μs par top).

Précision en microsecondes: Trois octets pour marquer le temps en incréments de 2^{-20} s (~0,95 μs par incrément).

Précision en nanosecondes: Quatre octets pour marquer le temps en incréments de 2^{-30} s (~0,93 ns par incrément).

Les appareils ayant besoin de convertir le temps TAI vers le format hh:mm:ss, tel que sur un écran utilisateur, peuvent rendre compte d'un réajustement de secondes intercalaires accumulées en temps universel coordonné (TUC). Ce réajustement est disponible pour les appareils de terrain auprès du gestionnaire de système. Si le réajustement TUC est utilisé par un appareil de terrain, il convient qu'il rafraîchisse le réajustement au début de chaque mois.

NOTE Une liste de tels réajustements TUC est maintenue à l'adresse ftp://maia.usno.navy.mil/ser7/tai-utc.dat.

Les demandes de mise à jour TUC faites simultanément par un grand nombre d'appareils peuvent causer un orage d'activité dans la DL. Il convient de prendre cet élément en compte dans la conception du DMAP; son évitement n'est pas couverte par la courante spécification de la DL.

Tous les appareils dans un réseau partagent la référence temporelle TAI avec des degrés variables d'exactitude. Chaque appareil au sein d'un réseau doit maintenir le temps avec une exactitude à 1 s près.

Le gestionnaire de système dirige des appareils sur le système vers un appareil mettant en œuvre le rôle de la source de temps système. Dans la plupart des cas, cet appareil remplira également le rôle de gestionnaire de système. Cependant, la responsabilité de la source de temps peut être redirigée vers n'importe quel appareil ayant une source de temps plus capable.

La passerelle doit être responsable de convertir entre le temps TAI nominal du réseau et une référence temporelle externe autre que TAI, s'il en est utilisée une.

Pour plus d'informations sur les exigences relatives à la source de temps, voir 6.3.10.

5.6.2 Synchronisation du temps

Pour propager le temps d'hôte, une passerelle peut périodiquement synchroniser le sens du temps dans un sous-réseau D rattaché à une source de temps externe en demandant des changements de temps par l'intermédiaire des DLMO.

Le WISN fournit une synchronisation pour des applications afin que, au niveau de l'appareil, elles puissent utiliser le temps pour coordonner des activités ou horodater des données, une activité qui pourrait améliorer l'utilisation de l'énergie et augmenter la fiabilité. Le temps système doit être disponible auprès d'au moins un appareil (une source de temps système) sur chaque WISN. Voir Article 9.

5.7 Mises à niveau de firmware

Le système global, et chaque appareil sur le WISN, doivent fournir la capacité de mettre à niveau le firmware d'appareil qui met en œuvre la présente norme par l'intermédiaire du réseau sans fil (voir 6.3.6). Le système doit prendre en charge un mécanisme commun, tel qu'un déclencheur basé sur le temps, pour informer tous les appareils de commuter simultanément vers un nouveau firmware; ce mécanisme peut être employé pour réduire au maximum le nombre d'appareils qui sont laissés bloqués avec une suite incompatible de protocoles réseau. Les mécanismes de sécurité intégrés dans la présente norme sont utilisés au cours de la mise à niveau d'un firmware.

Chaque version du protocole doit prendre en charge les versions antérieures dans toute la mesure nécessaire pour permettre la mise à niveau du firmware via le réseau sans fil.

5.8 Dorsales sans fil et autres infrastructures

Les appareils conformes à la présente norme sont des appareils gérés. Tous les appareils conformes à la présente norme doivent mettre en œuvre les interfaces de gestion d'appareil à chaque couche, mais ils peuvent ne mettre en œuvre que la fonctionnalité de leurs couches fonctionnelles exigées.

Le système prend en charge les réseaux dorsaux tant câblés que sans fil par l'utilisation des routeurs dorsaux. Le fonctionnement des réseaux dorsaux n'est pas traité par la présente norme.

Plus d'informations relatives aux réseaux dorsaux et à leurs caractéristiques impliquées peuvent être consultées à l'Annexe E.

6 Rôle de gestion de système

6.1 Généralités

6.1.1 Vue d'ensemble

Le rôle de gestion de système prend en charge la gestion de réseau du réseau comme un tout, ainsi que la gestion d'appareil des appareils fonctionnant au sein du réseau. La gestion de réseau inclut la gestion des diverses ressources de communications à travers le réseau et à travers toutes les couches de protocoles de l'architecture. La gestion d'appareil prend en charge la gestion localisée des ressources de communications, et potentiellement d'autres ressources, d'un appareil.

Les fonctions de gestion décrites par la présente norme prennent en charge:

- le rattachement au réseau et départ du réseau;
- les rapports relatifs aux défauts qui se produisent au sein du réseau;
- la configuration de communication;
- la configuration de la distribution d'horloges et le réglage du temps système;
- la surveillance d'appareil;
- la surveillance et optimisation de performances; et
- la configuration et surveillance de la sécurité.

6.1.2 Composantes et architecture

Les composantes primaires du service de gestion incluent un processus d'application de gestion d'appareil (DMAP) qui réside sur chaque appareil conforme à la présente norme, ainsi qu'un processus d'application de gestion de système (SMAP) qui doit résider sur un appareil qui met en œuvre le rôle de gestionnaire de système. Les rôles sont décrits en 5.2.6.5. Le DMAP est un type spécial de processus d'application utilisateur (UAP) qui est consacré à gérer l'appareil et ses services de communications, décrits en 12.4.3 et 12.4.4. Le DMAP et le gestionnaire de système doivent être capables de communiquer l'un avec l'autre sur le réseau en utilisant les services de sous-couche d'application définis par la présente norme et doivent fournir ensemble un moyen d'accéder aux informations de gestion à distance et gérer le système et ses appareils. La gestion de système est accomplie par l'intermédiaire d'une messagerie entre appareils (inter-appareil), alors que la gestion d'appareil est accomplie par des communications locales internes à un appareil (intra-appareil).

L'architecture de gestion selon la présente norme est montrée à la Figure 23.

Figure 23 – Architecture de gestion

Les appareils conformes à la présente norme doivent être gérés par l'intermédiaire de deux classes distinctes de processus applicatifs, à savoir les UAP et le DMAP. Les UAP sont configurés et surveillés par des applications d'hôtes, telles que les systèmes de gestion automatisés, ou par des applications de proxys d'hôtes dans les passerelles. Le DMAP dans l'appareil doit être géré par le gestionnaire de système.

La Figure 23 montre les relations des modèles de gestion selon la présente norme. Pour les chemins montrés à la Figure 23, la présente norme fournit une description normative des protocoles de communication pour les chemins 2 et 3. Les protocoles de communication pour les chemins 1, 4, 5 et 6 sont des exemples informatifs des mises en œuvre dans la présente norme.

La présente norme définit les protocoles de communication de gestion de système qui doivent être utilisés pour commander et surveiller les DMAP dans le réseau et les chemins de communication correspondants. Dans ce cas, ces communications parcourent le chemin 3 à la Figure 23.

Le gestionnaire de système inclut les chemins de communication à l'extérieur du réseau conforme à la présente norme qui permettent à d'autres appareils d'interagir avec lui. A la Figure 23, le chemin 5 montre une connexion entre le gestionnaire de système et l'application d'hôte. Ce chemin permet à l'application d'hôte de récupérer le statut de réseau et de demander des services de réseau. Le gestionnaire de système communique également avec le gestionnaire de sécurité sur le chemin 6 pour configurer la sécurité dans le réseau et pour rapporter le statut.

Les applications d'utilisateur sur des appareils conformes à la présente norme communiquent avec des passerelles et des applications d'hôte en utilisant les protocoles normalisés montrés sur le chemin 2 à la Figure 23. Cela est décrit à l'Article 12 et Annexe U.

L'application d'hôte basée dans l'installation communique avec la passerelle en utilisant des protocoles d'installation qui parcourent le chemin 4. Le gestionnaire de système ne communique pas directement avec les UAP. Il y a un chemin de communication intra-appareil qui permet aux processus DMAP et UAP d'interagir par l'intermédiaire du chemin de

communication intra-appareil 1 à la Figure 23 entre le gestionnaire de système et une passerelle. Cela est accompli sur une interface virtuelle 1 à la Figure 23, UAPME-SAP, utilisant l'objet de gestion UAP (UAPMO) qui est décrit en 12.15.2.2.

6.1.3 Fonctions de gestion

Chaque réseau qui est conforme à la présente norme doit inclure au moins un rôle de gestion de système et un rôle de gestion de sécurité. Ces rôles doivent être accessibles à tous les appareils conformes à la norme sur ce réseau.

La gestion de système est un rôle spécialisé qui régit le réseau, le fonctionnement des appareils sur le réseau, et les communications du réseau. Les fonctions définies dans ce rôle sont accomplies par le gestionnaire de système, fournissant la commande politique de la configuration des communications en temps d'exécution. Le gestionnaire de système accomplit une surveillance et des rapports sur la configuration des communications, les performances, les conditions de défauts, et le statut opérationnel. Cela est décrit en 6.3.7. Le gestionnaire de système fournit également des services relatifs au temps. Certaines fonctions de gestion de système peuvent être complètement automatisées, alors que d'autres peuvent être assistées par l'homme.

Le gestionnaire de système prend en charge la configuration du réseau conforme à la présente norme, y compris les attributs de la suite de protocoles de la DL vers l'AL pour des applications de gestion de système. Il gère l'établissement, la modification et la résiliation de contrats qui sont utilisés par les appareils conformes à la présente norme pour communiquer les uns avec les autres. Les fonctions du gestionnaire de système n'incluent pas la commande, la configuration, et la surveillance des UAP sur l'appareil. Ces fonctions de gestion sont commandées par des applications d'hôtes sur des réseaux d'installation ou dans des outils de maintenance tenus à la main.

La gestion de sécurité du système est une fonction spécialisée qui est réalisée en une entité et qui travaille conjointement avec la fonction de gestion de système pour permettre l'exploitation sécurisée du système. Cette fonction est accomplie par le gestionnaire de sécurité. Certaines fonctions de gestion de sécurité peuvent être complètement automatisées, alors que d'autres peuvent être assistées par l'homme.

Chaque appareil conforme à la présente norme doit contenir un DMAP. Le DMAP inclut une fonction locale de gestion de degré de sécurité d'appareil. Le DMAP coopère avec le gestionnaire de système et le gestionnaire de sécurité pour permettre l'utilisation des ressources du système par l'appareil et la gestion sécurisée des ressources d'un appareil. Par exemple, le DMAP peut demander à rejoindre le réseau, demander de la largeur de bande de communication, demander une configuration de communication, et rapporter sa santé. Le gestionnaire de système et le gestionnaire de sécurité autorisent l'appareil à rejoindre le réseau, allouent la largeur de bande de communication, configurent l'appareil, et rassemblent les rapports de santé. Ces rapports de santé sont stockés dans le gestionnaire de système et sont utilisés pour prendre des décisions de configuration de communication.

Afin de compartimenter les fonctions de sécurité, l'architecture de gestion définie par la présente norme prend en charge des fonctions séparables de gestion de système et de gestion de sécurité tant au niveau du système qu'au niveau de l'appareil. Ainsi, le gestionnaire de sécurité est logiquement séparable du gestionnaire de système. Plus de détails relatifs au gestionnaire de sécurité sont fournis à l'Article 7.

NOTE Les fonctions de gestion de système et de gestion de sécurité sont souvent incluses au sein d'une seule et même entité physique.

6.2 DMAP

6.2.1 Généralités

Le DMAP est un type spécial de processus d'application consacré à gérer l'appareil conforme à la présente norme et ses services de communications. Un DMAP réside sur chaque appareil conforme à la présente norme.

6.2.2 Architecture de la gestion d'appareil

Telle que montrée à Figure 16, la structure de suite de protocoles d'un appareil inclut les couches de protocoles de mise en réseau et les UAP.

Le DMAP est montré en relation aux autres composants de la suite de protocoles sur la droite de la structure de la suite de protocoles, y compris des flèches décrivant l'accès aux SAP de gestion pour plusieurs des couches de protocoles. Les composantes dans le DMAP sont modélisées sous la forme d'objets, appelés objets de gestion, qui ont des caractéristiques qui sont accessibles sur le réseau. Le DMAP, comme tous les processus d'application, est capable d'utiliser la sous-couche d'application pour communiquer. Le DMAP doit utiliser le SAP de sous-couche d'application ASLDE-0 SAP pour des communications de données normales. Ce SAP de sous-couche d'application doit correspondre au SAP de TL TDSAP-0 qui doit correspondre au numéro de port 0xF0B0. La sous-couche d'application fournit des services de communication pour permettre aux objets au sein du DMAP d'interagir avec le gestionnaire de système du réseau. Ces services de communication sont décrits en 12.17.

6.2.3 Définition des objets de gestion

Les objets définis dans le DMAP suivent la spécification qui est utilisée pour définir les objets UAP. Les modèles pour définir les types d'objet, les attributs d'objet, les méthodes d'objet et les alertes d'objet sont spécifiés à l'Annexe I.

Les objets de gestion sont extensibles par les fabricants d'appareils et les développeurs d'appareils/suites de protocoles de réseau. Cela est décrit en 12.5. L'espace d'identification d'attributs et de méthodes est mis de côté pour les objets spécifiques à un appareil définis par un fabricant. Le gestionnaire de système ne doit pas être tenu de mettre en œuvre la prise en charge pour des extensions propriétaires pour que l'appareil en question interfonctionne et accomplisse sa fonction principale.

6.2.4 Objets de gestion dans le DMAP

Le DMAP doit contenir un certain nombre d'objets de gestion qui prennent en charge les opérations de gestion d'appareil. Ces objets doivent accomplir collectivement deux types de fonctions de gestion d'appareil. En premier lieu, ces objets doivent gérer l'appareil localement en manipulant des attributs et en invoquant des méthodes sur les SAP de gestion de couche. En second lieu, les objets de gestion doivent être accessibles à distance en utilisant les services d'ASL afin qu'un gestionnaire de système puisse manipuler des attributs et invoquer des méthodes sur les objets de gestion d'appareil ou capturer des alertes issues des objets. Ces objets sont conceptuels en ce qu'il n'existe pas d'exigences de mises en œuvre orientées objet dans l'appareil, excepté que le comportement visible extérieurement en termes de messagerie d'ASL par liaison radio doit être compatible avec le modèle de communications d'objets ayant les attributs, les méthodes, et les alertes spécifiés.

Comme montré à la Figure 24, le DMAP doit inclure un ensemble d'objets de gestion de couche, un objet de gestion d'appareil, un objet de gestion de sécurité d'appareil, un objet de gestion de rapports d'alertes, un objet de téléchargement montant/téléchargement descendant, et d'autres objets de gestion.

Réservé pour les éditions futures de la présente norme	119..114	-	-

6.2.5 Services de communication fournis aux objets de gestion d'appareil

Les services de niveau application fournis aux objets de DMAP sont les mêmes que ceux fournis par la sous-couche d'application aux objets d'UAP. Ces services incluent le client/serveur (C/S), éditeur/abonné (P/S), source/puits (S/S), et rapports d'alertes (AR). Les détails de ces services, fournis par la sous-couche d'application, sont donnés en 12.17.

Comme montré à la Figure 25, TDSAP-0, qui correspond au numéro de port 0xF0B0, doit être utilisé pour accéder aux objets de gestion dans le DMAP, qui accèdent à leur tour aux attributs de gestion de couche par l'intermédiaire du SAP de gestion de couche.

L'accès aux objets de gestion d'appareil est protégé par les mécanismes de sécurité de TL décrits en 11.3.

L'accès aux objets du DMAP est limité au SMAP avec les exceptions suivantes:

- L'objet ARMO peut également être accessible par les maîtres d'alertes qui reçoivent des alertes provenant de l'appareil. Voir 6.2.7.2.3.
- Un appareil candidat au rattachement est autorisé à accéder aux méthodes de l'objet de gestion d'appareil utilisées au cours du processus de rattachement à un sous-réseau. Voir 6.3.9.2.2.

Figure 25 – Exemple de flux de SAP de gestion à travers une suite de protocoles normalisée

Les interactions de C/S (y compris la lecture et l'écriture d'attributs, l'exécution de méthodes, le rattachement, la demande et la fourniture de contrats) sont les principaux outils utilisés pour la gestion de système. En outre, le DMAP peut utiliser les services de rapports d'alertes de l'ASL pour faire un rapport au gestionnaire de système lorsque certaines conditions relatives à la gestion sont détectées. Les concepteurs des objets de gestion peuvent utiliser des alertes à divers niveaux de priorité pour aider à accomplir des fonctions de gestion de système et d'appareil.

6.2.6 Attributs des objets de gestion

6.2.6.1 Généralités

Les SAP de gestion de couche montrées à la Figure 25 fournissent l'accès à des informations de gestion dans les diverses couches de la suite de protocoles.

Ces informations sont représentées par des attributs définis dans les objets de gestion du DMAP, qui peuvent être contrôlés et exploités par le gestionnaire de système. Les détails des objets de gestion sont donnés en 6.2.3. Les attributs dans les objets de gestion de couche sont utilisés pour configurer les couches de protocoles et pour surveiller leur statut. Le modèle pour décrire les attributs dans tous les objets de gestion est fourni dans l'Annexe I, pour utilisation dans des extensions propriétaires et dans de futures éditions de la présente norme.

Les attributs doivent avoir un type de données qui est soit un type scalaire défini par une norme, ou une structure de données définie par une norme. Plus de détails relatifs aux attributs sont donnés en 12.6.2.

Un attribut structuré est un type spécial d'attribut qui a un type de données constitué d'une matrice de structures de données définies par une norme. Le modèle de matrice est utilisé pour permettre l'accès d'objet par le biais d'une indexation, où l'index est l'attribut clé pour l'accès à l'objet.

Les informations de gestion qu'il est nécessaire de visualiser comme étant un ensemble d'une ou plusieurs tables sont modélisées sous la forme d'attributs structurés définis dans les objets de gestion.

Les attributs définis dans des objets de gestion peuvent être accessibles en utilisant les services normalisés de lecture ou d'écriture fournis par l'ASL. De telles opérations permettent la configuration de chaque couche et la surveillance de son statut. Elles peuvent être utilisées pour récupérer, établir/modifier, et réinitialiser les valeurs des attributs. Les opérations sur des attributs sont décrites dans l'Annexe J.

6.2.6.2 Champ d'indice d'attribut structuré

Sachant que les attributs structurés sont décrits sous la forme de matrices de structures de données, il est nécessaire d'indiquer un ou plusieurs champs d'indices pour ces matrices dans la définition de chacun de ces attributs structurés. Cela se fait en incluant un * (astérisque) après le(s) nom(s) d'élément dans la table décrivant la structure des données. Le modèle pour définir une structure des données est présenté à l'Annexe I.

6.2.6.3 Métadonnées d'attribut structuré

Les attributs structurés représentent des tables d'information. Pour fournir l'accès externe au nombre d'objets contenus dans une telle table et à la capacité de cette table, des méta-attributs supplémentaires qui contiennent de telles informations sont définis pour les objets de gestion. De tels attributs représentent les métadonnées des attributs structurés correspondants.

Le type de données normalisé pour un attribut de métadonnées est présenté dans le Tableau 2.

Tableau 2 – Structure de données Metadata_attribute

Nom du type de données normalisé: Metadata_attribute		
Code du type de données normalisé: 406		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
Compte (nombre de rangées à indices actuellement présentes dans l'attribut)	1	Type: Unsigned16 Classification: Static Accessibilité: Read only
Capacité (nombre de rangées que l'attribut peut contenir)	2	Type: Unsigned16 Classification: Static Accessibilité: Read only

6.2.7 Définitions des objets de gestion dans le DMAP

6.2.7.1 Device management object (objet de gestion d'appareil)

Comme montré à la Figure 24, le DMAP inclut un ensemble d'objets de gestion. L'objet de gestion d'appareil (DMO) dans le DMAP doit fournir l'accès aux attributs ayant une portée à l'échelle de l'appareil. Les attributs du DMO doivent inclure l'adresse EUI64Address principale de la DLE, un ID de fournisseur, un numéro de série, une identification de la révision courante du logiciel de communication, et la classe de source d'énergie de l'appareil. Plus de détails relatifs au DMO sont fournis en 6.2.8.1.

6.2.7.2 Alert reporting management object (objet de gestion des rapports d'alertes)

6.2.7.2.1 Généralités

L'objet de gestion de rapports d'alertes (ARMO) est utilisé pour gérer tous les rapports d'alertes de l'appareil. **Alert** (alerte) est le terme utilisé pour décrire l'action consistant à rapporter une condition d'événement ou une condition d'alarme. **Event** (événement) est le terme pour une condition transitoire (c'est-à-dire sans état), utilisé pour rapporter lorsque quelque chose s'est produit. **Alarme** est le terme utilisé pour une condition qui maintient l'état jusqu'à ce que la condition soit éliminée, qui est rapportée à la suite d'un changement d'état. Les alertes, y compris les événements et les alarmes, sont envisagées être d'une grande utilité pour gérer un réseau conforme à la présente norme.

Il doit y avoir tout au plus un seul ARMO par appareil. Les alarmes et les événements doivent être rapportés au moyen de l'ARMO. Lorsqu'une alerte est déclenchée, elle indique une situation significative qui a besoin d'être rapportée. L'ARMO doit encapsuler le rapport, gérer les temporisations et les répétitions de tentative et étrangler les rapports d'alertes issus de l'appareil.

L'ARMO fonctionne comme un proxy d'alertes pour les objets présents dans l'appareil. Toutes les alertes générées par n'importe quel objet présent dans un appareil doivent être envoyées seulement par l'ARMO qui est un objet de gestion qui est une partie intégrante du DMAP. L'APDU de données Alert doit indiquer dans son en-tête d'APDU que l'initiateur de la communication est l'objet ARMO et le DMAP de l'appareil rapportant l'alerte. L'objet et l'UAP qui sont à l'origine de l'APDU d'alerte réelle doivent être identifiés dans le contenu du rapport Alert plutôt que dans les en-têtes des APDU.

Chaque alerte doit être acquittée par l'appareil recevant l'alerte. Chaque acquittement d'alerte doit être adressée à l'ARMO de l'appareil qui était à l'origine de l'alerte. Les alertes sont promptement rapportées et précisément horodatées en utilisant des rapports d'alertes en file d'attente. Les rapports d'alertes en file d'attente impliquent que l'appareil détectant l'alerte rapporte la condition en utilisant le flux de communication S/S et reçoive en retour une DPDU ACK/NAK.

NOTE L'intention du fait de spécifier l'ARMO dans la présente norme est de séparer la détection d'alerte de la gestion des rapports relatifs à la condition d'alerte. A la différence de certains protocoles hérités orientés filaires, la présente norme consolide les alertes localement afin de réduire au maximum la messagerie externalisée et la consommation d'énergie.

Le modèle d'alerte utilisé dans la présente norme est décrit en 12.8.

Les interfaces entre l'ARMO et tous les autres objets, tant dans les UAP que dans le DMAP, sont internes à un appareil et ne sont pas spécifiées dans la présente norme

6.2.7.2.2 Types d'alertes

Les classes d'alertes, les sens d'alertes et les priorités d'alertes sont définies en 12.11. La catégorie d'alertes indique si l'alerte est une alerte de diagnostics d'appareil, une alerte de diagnostics de communication, une alerte de sécurité ou une alerte de processus. Le type d'alerte fournit des informations complémentaires relatives à l'alerte, spécifiques à la catégorie d'alertes et spécifiques à l'objet d'application générant l'alerte.

Le Tableau 3 fournit les types d'alertes pour les catégories d'alertes de la catégorie d'alertes de diagnostics de communication. Le Tableau 4 fournit les types d'alertes pour la catégorie d'alertes de sécurité. Le Tableau 5 fournit les types d'alertes pour la catégorie d'alertes de diagnostics d'appareil. Le Tableau 6 fournit les types d'alertes pour la catégorie d'alertes de processus.

6.2.7.2.3 Maître d'alertes

Les alertes doivent être envoyées à des objets récepteurs d'alertes. Les objets récepteurs d'alertes sont définis en 12.15.2.3. Chaque catégorie d'alertes peut avoir un objet récepteur d'alertes différent résidant dans un appareil différent. Les appareils qui reçoivent ces alertes sont appelés maîtres d'alertes.

L'accès de DMAP est souvent limité au SMAP présent dans le gestionnaire de système. Dans une exception à ce principe général, les maîtres d'alertes sont autorisés à accéder à l'objet ARMO présent dans le DMAP. L'accès de DMAP par les maîtres d'alertes doit être limité à l'ARMO, à moins que le maître d'alertes n'utilise la session DMAP-SMAP établie lorsque l'appareil avait rejoint le réseau. Les maîtres d'alertes auxquels l'appareil est configuré pour envoyer des alertes sont énumérés dans le Tableau 7.

6.2.7.2.4 File d'attente d'alertes

Les alertes appartenant à chaque catégorie sont supposées être placées dans une file d'attente interne fournie par catégorie dans l'appareil. Les deux types d'alertes, événements (sans état) et alarmes (à états), seront placés dans la même file d'attente, filtrée par catégorie. La file d'attente est nécessaire pour assurer une livraison garantie des alertes au maître d'alertes. Chaque alerte devant être rapportée au maître d'alertes est placée dans cette file d'attente de rapports.

Il convient que la taille de la file d'attente soit assez grande pour contenir simultanément tous les événements ainsi que toutes les conditions d'alarme possibles afin d'aider à la récupération d'alarmes sans perdre la moindre alarme.

Bien que placés dans la même file d'attente, les événements et les alarmes auront des priorités différentes. L'appareil doit rapporter un événement de plus haute priorité avant un événement de plus basse priorité. Pour les alarmes, la file d'attente est vidée séquentiellement; l'alarme la plus ancienne est rapportée en premier. Lorsque la file d'attente est pleine et une nouvelle alarme est présentée, l'alarme la plus ancienne est exclue de la file d'attente indépendamment de son état de rapport.

6.2.7.2.5 Modèles d'états d'alertes

Les tableaux d'états et transitions d'états pour les alarmes et les événements sont donnés en 12.9 et en 12.10.

6.2.7.2.6 Récupération d'alarme

Il est souvent utile d'être capable de récupérer toutes les alarmes actuellement actives au sein d'un appareil. Le besoin de récupération d'alarme se fait sentir toutes les fois qu'une connexion à l'appareil est perdue pendant une durée ou toutes les fois qu'un maître d'alertes ordonne une récupération d'alarme.

La récupération d'alarme est constituée de l'ensemble suivant d'activités:

- Le maître d'alertes ordonne une récupération d'alarme en utilisant la méthode Alarm_Recovery de l'ARMO. Cette méthode est décrite dans le Tableau 9.
- L'ARMO envoie une alerte de début de récupération au maître d'alertes, qui indique que l'ARMO a reçu une commande de récupérer des alarmes et que ces alarmes actives suivront.

NOTE Le processus pour envoyer de nouveau ces alarmes actives au sein d'un appareil n'est pas spécifié.

- L'ARMO envoie une alerte de fin de récupération au maître d'alertes.

L'ARMO est chargé de générer des alertes de début et de fin de récupération d'alarme et de coordonner le processus de récupération d'alarme avec les objets d'application résidant au sein de l'appareil.

6.2.7.2.7 Attributs, alertes et méthodes de l'objet de gestion de rapports d'alertes

Les attributs de l'ARMO sont définis dans le Tableau 7.

Tableau 7 – Attributs ARMO *(1 de 4)*

Nom du type d'objet normalisé: Alert reporting management object (ARMO, objet de gestion des rapports d'alertes)				
Identificateur du type d'objet normalisé: 126				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Alert_Master_Device_ Diagnostics	1	Maître d'alertes pour les alertes appartenant à la catégorie d'alertes de diagnostics d'appareil	Type: Point d'extrémité de communication d'alertes Classification: Static Accessibilité: Read/write Plage valide: Voir 12.16.3.5	Généralement défini sur une passerelle correspondant aux informations de l'appareil, mais peut être remplacé par tout autre appareil conforme à la norme doté d'une adresse IPv6Address valide [a]
Confirmation_Timeout _ Device_Diagnostics	2	Temporisation d'attente pour l'acquittement d'une alarme de diagnostics d'appareil qui a été envoyée au maître d'alertes	Type: Integer16 Classification: Static Accessibilité: Read/write Valeur par défaut: 10	Temporisation indépendante vis-à-vis de la proximité au maître d'alertes. Une valeur de $N > 0$ spécifie une durée de N s tandis qu'une valeur de $N < 0$ spécifie une durée de -1/N s. $N = 0$ n'est pas permise [b]
Alerts_Disable_Devic e_ Diagnostics	3	Commande permettant d'activer et de désactiver toutes les alertes de diagnostics d'appareil	Type: Boolean8 Classification: Static Accessibilité: Read/write Valeur par défaut: false	false = activer, true = désactiver

Nom du type d'objet normalisé: Alert reporting management object (ARMO, objet de gestion des rapports d'alertes)				
Identificateur du type d'objet normalisé: 126				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Alert_Master_Comm_ Diagnostics	4	Maître d'alertes pour les alertes appartenant à la catégorie d'alertes de diagnostics de communication	Type: Point d'extrémité de communication d'alertes Classification: Static Accessibilité: Read/write Plage valide: Voir 12.16.3.5	Généralement défini sur le gestionnaire de système correspondant à l'appareil, mais peut être remplacé par tout autre appareil conforme à la norme doté d'une adresse IPv6Address valide. L'appareil doit définir cet attribut sur son gestionnaire de système après avoir rejoint le réseau; voir 6.3.7.2
Confirmation_Timeout _ Comm_Diagnostics	5	Temporisation d'attente pour l'acquittement d'une alarme de diagnostics de communication qui a été envoyée au maître d'alertes	Identique à l'attribut 2	Identique à l'attribut 2
Alerts_Disable_Comm _ Diagnostics	6	Commande permettant d'activer et de désactiver toutes les alertes de diagnostics de communication	Type: Boolean8 Classification: Static Accessibilité: Read/write Valeur par défaut: false	false = activer, true = désactiver
Alert_Master_Security	7	Maître d'alertes pour les alertes appartenant à la catégorie d'alertes de sécurité	Type: Point d'extrémité de communication d'alertes Classification: Static Accessibilité: Read/write Plage valide: Voir 12.16.3.5	Généralement défini sur le gestionnaire de système/sécurité correspondant à l'appareil, mais peut être remplacé par tout autre appareil conforme à la norme doté d'une adresse IPv6Address valide. L'appareil doit définir cet attribut sur son gestionnaire de sécurité après avoir rejoint le réseau; voir 6.3.7.2
Confirmation_Timeout _Security	8	Temporisation d'attente pour l'acquittement d'une alarme de sécurité qui a été envoyée au maître d'alertes	Identique à l'attribut 2	Identique à l'attribut 2

Tableau 7 *(3 de 4)*

Nom du type d'objet normalisé: Alert reporting management object (ARMO, objet de gestion des rapports d'alertes)				
Identificateur du type d'objet normalisé: 126				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Alerts_Disable_Security	9	Commande permettant d'activer et de désactiver toutes les alertes de sécurité	Type: Boolean8 Classification: Static Accessibilité: Read/write Valeur par défaut: false	false = activer, true = désactiver
Alert_Master_Process	10	Maître d'alertes pour les alertes appartenant à la catégorie d'alertes de processus	Type: Point d'extrémité de communication d'alertes Classification: Static Accessibilité: Read/write Plage valide: Voir 12.16.3.5	Généralement défini sur une passerelle correspondant aux informations de l'appareil, mais peut être remplacé par tout autre appareil conforme à la norme doté d'une adresse IPv6Address valide[a]
Confirmation_Timeout_Process	11	Temporisation d'attente pour l'acquittement d'une alarme de processus qui a été envoyée au maître d'alertes	Identique à l'attribut 2	Identique à l'attribut 2
Alerts_Disable_Process	12	Commande permettant d'activer et de désactiver toutes les alertes de processus	Type: Boolean8 Classification: Static Accessibilité: Read/write Valeur par défaut: false	false = activer, true = désactiver
Comm_Diagnostics_Alarm_Recovery_AlertDescriptor	13	Utilisé pour changer la priorité des événements d'alertes de début et de fin de récupération d'alarme (Tableau 8) appartenant à la catégorie d'alertes de diagnostics de communication; ces événements peuvent également être activés ou désactivés	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 3] Plage valide: Voir 12.16.3.7	—

Tableau 7 *(4 de 4)*

Nom du type d'objet normalisé: Alert reporting management object (ARMO, objet de gestion des rapports d'alertes)				
Identificateur du type d'objet normalisé: 126				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Security_Alarm_Recovery_ AlertDescriptor	14	Utilisé pour changer la priorité des événements d'alertes de début et de fin de récupération d'alarme (Tableau 8) appartenant à la catégorie d'alertes de sécurité; ces événements peuvent également être activés ou désactivés	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 3] Plage valide: Voir 12.16.3.7	—
Device_Diagnostics_Alarm_ Recovery_AlertDescriptor	15	Utilisé pour changer la priorité des événements d'alertes de début et de fin de récupération d'alarme (Tableau 8) appartenant à la catégorie d'alertes de diagnostics d'appareil; ces événements peuvent également être activés ou désactivés	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 3] Plage valide: Voir 12.16.3.7	—
Process_Alarm_Recovery_ AlertDescriptor	16	Utilisé pour changer la priorité des événements d'alertes de début et de fin de récupération d'alarme (Tableau 8) appartenant à la catégorie d'alertes de processus; ces événements peuvent également être activés ou désactivés	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 3] Plage valide: Voir 12.16.3.7	—
Réservé pour les éditions futures de la présente norme	17..63	-	-	—
[a] Ces informations sont censées être configurées par l'application hôte après que l'appareil a rejoint le réseau. [b] Toutes les alarmes exigent un acquittement.				

Les alertes de l'ARMO sont définies dans le Tableau 8.

Tableau 8 – Alertes de l'ARMO

Nom du type d'objet normalisé: Alert reporting management object (ARMO, objet de gestion des rapports d'alertes)				
Identificateur du type d'objet normalisé: 126				
Description de l'alerte: Evénements d'alertes de début et de fin de récupération d'alarmes appartenant à toutes les catégories				
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alertes (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: urgent, haut, moyen, faible, journal)**	**Description de la valeur incluse avec l'alerte**
0 = Event	1 = Comm. diagnostics	0 = Alarm_Recovery_Start	3 = Low	Générée par l'ARMO pour le maître d'alertes de diagnostics de communication indiquant que la commande de récupération d'alarme a été reçue; toutes les alarmes de diagnostics de communication en cours sont rapportées après que cet événement a été déclenché
0 = Event	1 = Comm. diagnostics	1 = Alarm_Recovery_End	3 = Low	Générée par l'ARMO pour le maître d'alertes de diagnostics de communication indiquant que le processus de récupération d'alarme est terminé
0 = Event	2 = Security	0 = Alarm_Recovery_Start	3 = Low	Générée par l'ARMO pour le maître d'alertes de sécurité indiquant que la commande de récupération d'alarme a été reçue; toutes les alarmes de sécurité en cours sont rapportées après que cet événement a été déclenché
0 = Event	2 = Security	1 = Alarm_Recovery_End	3 = Low	Générée par l'ARMO pour le maître d'alertes de sécurité indiquant que le processus de récupération d'alarme est terminé
0 = Event	0 = Device diagnostics	0 = Alarm_Recovery_Start	3 = Low	Générée par l'ARMO pour le maître d'alertes de diagnostics d'appareil indiquant que la commande de récupération d'alarme a été reçue; toutes les alarmes de diagnostics d'appareil en cours sont rapportées après que cet événement a été déclenché
0 = Event	0 = Device diagnostics	1 = Alarm_Recovery_End	3 = Low	Générée par l'ARMO pour le maître d'alertes de diagnostics d'appareil indiquant que le processus de récupération d'alarme est terminé
0 = Event	3 = Process	0 = Alarm_Recovery_Start	3 = Low	Générée par l'ARMO pour le maître d'alertes de processus indiquant que la commande de récupération d'alarme a été reçue; toutes les alarmes de processus en cours sont rapportées après que cet événement a été déclenché

Nom du type d'objet normalisé: Alert reporting management object (ARMO, objet de gestion des rapports d'alertes)				
Identificateur du type d'objet normalisé: 126				
Description de l'alerte: Evénements d'alertes de début et de fin de récupération d'alarmes appartenant à toutes les catégories				
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alertes (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: urgent, haut, moyen, faible, journal)**	**Description de la valeur incluse avec l'alerte**
0 = Event	3 = Process	1 = Alarm_Recovery_End	3 = Low	Générée par l'ARMO pour le maître d'alertes de processus indiquant que le processus de récupération d'alarme est terminé

La méthode de l'ARMO utilisée pour récupérer des alarmes des différentes catégories doit être telle que définie dans le Tableau 9.

Tableau 9 – Méthode Alarm_Recovery

Nom du type d'objet normalisé: Alert reporting management object (ARMO, objet de gestion des rapports d'alertes)				
Identificateur du type d'objet normalisé: 126				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
Alarm_Recovery	1	Méthode pour récupérer des alarmes qui appartiennent à la catégorie mentionnée dans l'argument d'entrée		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Alert_Category	Data type: Unsigned8	Valeurs nommées: 0: diagnostic d'appareil; 1: diagnostic de communication; 2: sécurité; 3: processus.
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**

6.2.7.3 Upload/download object (objet téléchargement montant/téléchargement descendant)

Les attributs, les méthodes et les diagrammes d'état de l'UDO dans le DMAP doivent être selon la définition donnée en 12.15.2.4. L'identificateur d'objet de l'UDO dans le DMAP doit être 8.

Un objet de téléchargement montant/téléchargement descendant(UDO) est utilisé pour télécharger, en montant ou en descendant, de grands blocs d'informations vers/depuis un appareil. L'UDO peut être utilisé pour prendre en charge le téléchargement descendant d'une nouvelle version du firmware de communications ou des données. L'UDO maintient des informations de contrôle de révision. L'UDO est décrit en 12.15.2.4.

Le processus de mise à niveau de firmware utilisé par le gestionnaire de système pour les mises à niveau de firmware par liaison radio est décrit en 6.3.6. Les méthodes et les attributs de l'objet de téléchargement montant/téléchargement descendant dans le DMAP de l'appareil peuvent être utilisés pour envoyer des mises à jour de firmware vers l'appareil.

Le processus de mise à niveau de firmware peut inclure un mécanisme de basculement qui spécifie l'heure de basculement (après livraison de la mise à jour), point auquel les appareils

commencent à utiliser le nouveau firmware. L'attribut CutoverTime dans l'UDO doit être utilisé pour indiquer cette heure de basculement ("cut-over time"). L'heure de basculement utilise le sens partagé de temps qui a été configuré par le gestionnaire de système.

Un support est fourni pour les mises à jour spécifiques à un fournisseur, spécifiques à un modèle d'appareil et spécifiques à une instance d'appareil. Avant le basculement, l'objet de téléchargement montant/téléchargement descendant de l'appareil peut accomplir des vérifications de sécurité sur une mise à jour reçue pour s'assurer qu'une mise à jour est appropriée pour un type d'appareil spécifique. Etant donné que toute la communication a lieu entre des objets d'application, une telle mise à jour est protégée par le mécanisme de sécurité de bout en bout de la TL. En outre, la mise à jour de firmware peut utiliser des mécanismes de sécurité pour authentifier la mise à jour. Comme partie intégrante du processus de mise à niveau de firmware, l'objet de téléchargement montant/téléchargement descendant de l'appareil peut être équipé des informations appropriées relatives à l'étiquetage, au contrôle des versions et à la sécurité normalisés pour ces vérifications par l'application de mise à jour d'hôte. Ces vérifications peuvent être spécifiques à un fournisseur et ne sont pas spécifiées par la présente norme.

NOTE L'UDO dans le DMAP pour mettre à jour un firmware est décrit ici. Les détails relatifs aux objets généraux de téléchargement montant/téléchargement descendant qui sont disponibles pour une utilisation par des procédés applicatifs généraux sont donnés en 12.15.2.4.

6.2.7.4 Layer management objects (objets de gestion de couche)

L'ensemble d'objets au sein du DMAP doit inclure des objets représentant l'accès à chacun des SAP de gestion de couche. Ces objets comprennent:

- L'objet de gestion de sous-couche d'application (ASLMO), qui fournit l'accès à l'ASMSAP.
- L'objet de gestion de TL (TLMO), qui fournit l'accès au TMSAP.
- L'objet de gestion de NL (NLMO), qui fournit l'accès au NMSAP.
- L'objet de gestion de liaison de données (DLMO), qui fournit l'accès au DMSAP.

Les services, définis par les définitions de SAP de couche, sont reflétés dans les caractéristiques des objets de gestion afin qu'effectivement, les services rendus disponibles au niveau des SAP de gestion deviennent accessibles à distance en utilisant des mécanismes normalisés de communication sécurisés. Génériquement, les SAP de gestion permettent de lire et écrire des attributs, d'invoquer des méthodes, et de rapporter des événements. Les diverses spécifications de couche spécifient les caractéristiques exactes qui sont disponibles sur chacune de ces SAP. En effet, ces spécifications définissent les objets de gestion de couche. Voir 6.2.8.2 pour plus de détails relatifs aux objets de gestion de couche.

6.2.7.5 Device security management object (objet de gestion de sécurité d'appareil)

Le DMAP doit inclure un objet de gestion de sécurité d'appareil (DSMO) qui fournit l'accès judicieusement limité aux fonctions de gestion de degré de sécurité d'appareil. Le DSMO gère le support de clé de sécurité et les opérations cryptographiques. Les détails de cet objet sont fournis en 7.11.

6.2.7.6 Device provisioning object (objet de configuration d'appareil)

Le DMAP doit inclure un objet de configuration d'appareil (DPO) qui est accessible au cours du processus de configuration de l'appareil. Plus de détails relatifs aux attributs, aux méthodes et aux alertes du DPO sont fournis en 13.9.

6.2.7.7 Health reports concentrator object (objet concentrateur de bulletins de santé)

Le DMAP doit inclure un objet concentrateur de rapports de santé (HRCO) qui peut être configuré par le gestionnaire de système pour permettre la publication périodique de rapports

de santé d'appareil. Les rapports de santé d'appareil peuvent consister en une publication périodique d'un ou plusieurs attributs issus d'objets de gestion dans le DMAP.

Les attributs du HRCO sont conformes à la définition de l'objet concentrateur donnée en 12.15.2.5. L'identificateur d'objet du HRCO dans le DMAP doit être 10. Les attributs CommunicationEndPoint et Array of ObjectAttributeIndexAndSize du HRCO sont utilisés par le gestionnaire de système pour établir des publications périodiques de rapports de santé à partir de l'appareil. Le gestionnaire de système peut choisir d'inclure n'importe quel attribut de n'importe quel objet de gestion dans de tels rapports de santé qui sont utilisés pour la surveillance des performances du système. La surveillance des performances du système est décrite en 6.3.7.

6.2.8 Fonctions de gestion d'appareil et de gestion de couche

6.2.8.1 Fonctions de gestion d'appareil

6.2.8.1.1 Généralités

Des capacités de gestion d'appareil sont fournies principalement par l'intermédiaire de l'accès aux attributs de DMO et à l'invocation des méthodes. Le DMO contient les attributs critiques de portée à l'échelle de l'appareil qui doivent être disponibles dans des tous les appareils. Les réalisateurs de produit peuvent étendre la liste d'attributs au-delà des attributs exigés qui sont décrits ci-dessous.

Certains attributs disponibles par l'intermédiaire du DMO peuvent également être disponibles comme attribut d'un objet de gestion de couche particulier. Dans ce cas, une modification de la valeur d'un tel attribut doit être reflété dans l'attribut correspondant.

Le DMO doit fournir des informations de temps système à d'autres objets de gestion; le DMO peut obtenir ces informations de temps système en interagissant avec la DL de l'appareil et/ou du gestionnaire de système ou à partir d'une autre source, telle qu'un récepteur GPS au sein de l'appareil. Le chronométrage par la DL est décrit en 9.1.9. Le rôle du gestionnaire de système dans le maintien du temps à travers le réseau est décrit en 6.3.10.

L'établissement, la modification et la résiliation de contrats pour un appareil doivent être gérés par son DMO. Les contrats sont décrits en 6.3.11.2.

Les attributs du DMO sont définis dans le Tableau 10.

Tableau 10 – Attributs du DMO *(1 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
EUI64	1	Identificateur de 64 bits de l'appareil	Type: EUI64Address Classification: Constant Accessibilité: Read only Valeur par défaut: 0x0000 0000 0000 0001	Il doit s'agir d'une adresse EUI64Address globale unique. Cet attribut est un doublon des attributs correspondants dans le DLMO et le NLMO.
DL16Address	2	Identificateur de 16 bits de l'appareil, unique dans son sous-réseau D	Type: DL16Address Classification: Static Accessibilité: Read/write Valeur par défaut: 0 Plage valide: 0: adresse non affectée; 1..0x7FFF: adresse de monodiffusion	Adresse unique dans le sous-réseau D de l'appareil; assignée par le gestionnaire de système. Cet attribut est un doublon de l'attribut correspondant dans le DLMO et le NLMO. Cet attribut est configuré par le gestionnaire de système au cours du processus de rattachement de l'appareil au sous-réseau.
IPv6Address	3	Adresse IPv6Address assignée par le gestionnaire de système	Type: IPv6Address Classification: Static Accessibilité: Read/write Valeur par défaut: 0 Plage valide: 0: adresse non affectée; autre valeur avec réglage sur bit de poids fort: adresse de monodiffusion.	Adresse de réseau de l'appareil unique dans le réseau et utilisée par l'application pour identifier des appareils à travers le réseau. Cet attribut est un doublon des attributs correspondants dans le DLMO et le NLMO. Cet attribut est configuré par le gestionnaire de système au cours du processus de rattachement de l'appareil au sous-réseau.

Tableau 10 *(2 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Device_Role_Capability	4	Rôle(s) que l'appareil est capable de jouer dans le réseau; les rôles sont définis en 5.2.6.2	Type: BitArray16 Classification: Constant Accessibilité: Read only	Cet attribut doit être envoyé au gestionnaire de système au cours du processus de rattachement de l'appareil au sous-réseau; voir 6.3.9.2. Voir 5.2.6.2 pour les rôles acceptables et leurs descriptions. Indices nommés: 0: E/S; 1: routeur; 2: routeur dorsal; 3: passerelle; 4: gestionnaire de système; 5: gestionnaire de sécurité; 6: source de temps système; 7: appareil de configuration; 8..15: réservés (doivent être mis à 0)
Assigned_Device_Role	5	Rôle(s) de l'appareil tel(s) qu'assigné(s) par le gestionnaire de système; les rôles sont définis en 5.2.6.2	Type: BitArray16 Classification: Static Accessibilité: Read/write	Cet attribut doit être écrit par le gestionnaire de système au cours du processus de rattachement de l'appareil au sous-réseau; voir 6.3.9.2. Voir 5.2.6.2 pour les rôles acceptables et leurs descriptions. Le rôle assigné à un appareil ne doit pas dépasser ses capacités, telles que spécifiées dans l'attribut 4. Les indices de la matrice de bits sont identiques à ceux de l'attribut 4.
Vendor_ID	6	Identification du fournisseur de l'appareil lisible par l'homme	Type: VisibleString16 Classification: Constant Accessibilité: Read only	Assigné par le fournisseur au cours de la fabrication de l'appareil
Model_ID	7	Identification du modèle de l'appareil lisible par l'homme	Type: VisibleString16 Classification: Constant Accessibilité: Read only	Assigné par le fournisseur au cours de la fabrication de l'appareil
Tag_Name	8	Nom TAG de l'appareil	Type: VisibleString16 Classification: Static Accessibilité: Read/write	Attribué par l'utilisateur

Tableau 10 *(3 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Serial_Number	9	Numéro de série de l'appareil	Type: VisibleString16 Classification: Constant Accessibilité: Read only	Assigné par le fournisseur au cours de la fabrication de l'appareil
Power_Supply_Status	10	Informations de statut de l'alimentation en énergie de l'appareil	Type: Unsigned8 Classification: Dynamic Accessibilité: Read/write	Valeurs nommées: 0: alimenté par secteur; 1: alimenté par pile, plus de 75 % de capacité restante; 2: alimenté par pile, entre 25 % et 75 % de capacité restante; 3: alimenté par pile, moins de 25 % de capacité restante
Device_Power_Status_Check_AlertDescriptor	11	Utilisé pour changer la priorité d'alerte Device_Power_Status_Check (décrit dans le Tableau 11); cette alerte peut également être activée ou désactivée	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 8]	—
DMAP_State	12	Statut de DMAP	Type: Unsigned8 Classification: Dynamic Accessibilité: Read only Valeur par défaut: 1: actif	Le diagramme d'états de DMAP est le même que le diagramme d'états d'UAP donné en 12.15.2.2.3. Valeurs nommées: 0: inactif; 1: actif; 2: en panne

Tableau 10 *(4 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Join_Command	13	Commande informant l'appareil de rejoindre le système, de se redémarrer lui-même et de se rattacher de nouveau, ou se réinitialiser aux valeurs d'usine par défaut	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 0: none	L'utilisation de cet attribut est décrite en 6.3.9. La valeur 0 ne doit pas être indiquée dans une demande d'écriture. Seul l'appareil de configuration est censé être capable d'émettre la commande Join_Command = 1 (join and start), car l'appareil n'a pas encore rejoint le réseau et n'est donc accessible par aucun autre appareil. WarmRestart doit préserver les données des attributs statiques et constants, y compris les contrats et les clés T. RestartAsProvisioned correspond à l'état configuré de l'appareil dans lequel l'appareil retient seulement les informations qui sont reçues pendant son étape de configuration. La réinitialisation aux valeurs d'usine par défaut correspond à la phase d'appareil configuré montrée à la Figure 5. Valeurs nommées: 0: aucun choix; 1: “join and start”; 2: WarmRestart; 3: RestartAsProvisioned; 4: réinitialisation aux valeurs d’usine par défaut

Tableau 10 *(5 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Static_Revision_Level	14	Niveau de révision des données statiques associées à tous les objets de gestion	Type: Unsigned32 Classification: Dynamic Accessibilité: Read only Valeur par défaut: 0: none	Le niveau de révision est incrémenté chaque fois qu'une valeur d'attribut statique dans n'importe quel objet de gestion change; la valeur repasse par zéro lorsque la limite est atteinte; la valeur se réinitialise chaque fois que l'appareil est réinitialisé aux valeurs d'usine par défaut, soit Join_Command = 4 (reset to factory defaults)
Restart_Count	15	Nombre de fois que l'appareil est redémarré	Type: Unsigned16 Classification: Static Accessibilité: Read only Valeur par défaut: 0	Le redémarrage de l'appareil peut être dû à un remplacement de batterie, une commande de redémarrage à chaud, un téléchargement descendant de firmware, une défaillance de liaison; la valeur repasse par zéro si la valeur maximale est atteinte; la valeur se réinitialise à 0 lorsque l'appareil est réinitialisé aux valeurs d'usine par défaut
Uptime	16	Compteur de faible exactitude pour compter les secondes écoulées depuis le dernier redémarrage de l'appareil	Type: Unsigned32 Classification: Dynamic Accessibilité: Read only Valeur par défaut: 0	Unités en secondes; la valeur se réinitialise à 0 si l'appareil redémarre
Device_Memory_Total	17	Mémoire totale de l'appareil exprimée en octets	Type: Unsigned32 Classification: Constant Accessibilité: Read only	Unités en octets
Device_Memory_Used	18	Mémoire actuellement utilisée dans l'appareil exprimée en octets	Type: Unsigned32 Classification: Dynamic Accessibilité: Read only	Unités en octets
TAI_Time	19	Temps TAI actuel	Type: TAINetworkTime Classification: Dynamic Accessibilité: Read only	La valeur est obtenue soit à partir de la DL (si l'appareil n'est pas source de temps système), soit la dorsale/source externe (si l'appareil est source de temps système ou est sur la dorsale et n'a pas une DL)

Tableau 10 *(6 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Comm_SW_Major_Version	20	Version majeure du logiciel de communications actuellement utilisée dans l'appareil	Type: Unsigned8 Classification: Constant Accessibilité: Read only Valeur par défaut: 0	Le numéro de version majeure de 8 bits du logiciel de communications, assigné par la présente norme, est égal à 0
Comm_SW_Minor_Version	21	Version mineure du logiciel de communications actuellement utilisée dans l'appareil	Type: Unsigned8 Classification: Constant Accessibilité: Read only	Le numéro de version mineure de 8 bits du logiciel de communications, assigné par la présente norme, est égal à 1
Software_Revision_ Information	22	Informations de révision relatives au logiciel de communications pour les numéros particuliers des versions majeure et mineure	Type: VisibleString16 Classification: Constant Accessibilité: Read only	Informations de révision assignées par le fournisseur
System_Manager_ IPv6Address	23	Adresse réseau de gestionnaire de système	Type: IPv6Address Classification: Static Accessibilité: Read/write Valeur par défaut: 0	Ces informations doivent être fournies à l'appareil soit au cours du processus de configuration, soit au cours du processus de rattachement de l'appareil au sous-réseau.
System_Manager_ EUI64Address	24	Adresse EUI64Address du gestionnaire de système	Type: EUI64Address Classification: Static Accessibilité: Read/write Valeur par défaut: 0	Ces informations doivent être fournies à l'appareil soit au cours du processus de configuration, soit au cours du processus de rattachement de l'appareil.
System_Manager_ DL16Address	25	Adresse DL16Address du gestionnaire de système dans le sous-réseau D de l'appareil	Type: DL16Address Classification: Static Accessibilité: Read/write Valeur par défaut: 0	Cet attribut doit être configuré par le gestionnaire de système au cours du processus de rattachement de l'appareil.

Tableau 10 *(7 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Contracts_Table	26	Tableau qui inclut les informations relatives à tous les contrats existants de l'appareil	Type: Array of Contract_Data Classification: Static Accessibilité: Read/write	Cet attribut est mis à jour lorsqu'un contrat correspondant est établi, modifié, renouvelé ou résilié; voir 6.3.11.2 pour plus de détails relatifs aux contrats et au type de données Contract_Data. Une nouvelle entrée dans la Contracts_Table doit être créée chaque fois qu'une réponse de contrat associée à la création réussie d'un nouveau contrat est reçue en provenance du gestionnaire de système. Pour plus de détails, voir 6.3.11
Contract_Request_ Timeout	27	Temporisation pour DMO avant la demande de contrat ne soit répétée	Type: Unsigned16 Classification: Static Accessibilité: Read/write	Le gestionnaire du système établit cette valeur de temporisation après que l'appareil a rejoint le réseau. Unité: s
Max_ClientServer_Retries	28	Nombre maximal de répétitions de tentative de demande client que le DMAP doit envoyer afin d'avoir une communication C/S réussie	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 3 Plage valide: 0..8	Le nombre de répétitions de tentative envoyées pour un message particulier peut varier par message sur la base de la détermination du processus applicatif de l'importance du message. Par exemple, certains messages ne peuvent pas du tout faire l'objet de répétitions de tentative, et d'autres peuvent être répétés le nombre maximal de fois.
Max_Retry_Timeout_ Interval	29	Intervalle de temporisation maximal pour une demande client avant qu'elle ne soit envoyée à nouveau	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 30 s	Le gestionnaire du système établit cette valeur de temporisation après que l'appareil a rejoint le réseau. Unité: s

Tableau 10 *(8 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
DMAP_Objects_Count	30	Nombre d'objets de gestion dans le DMAP, y compris ce DMO	Type: Unsigned8 Classification: Static Accessibilité: Read only Valeur par défaut: 1 Plage valide: > 0	Compte total d'objets de gestion tels que DLMO, NLMO, etc. dans le DMAP de cet appareil; tous les processus applicatifs dans l'appareil doivent inclure un attribut avec de telles informations
DMAP_Objects_List	31	Liste de tous les objets de gestion dans le DMAP	Type: Array of ObjectIDandType Classification: Static Accessibilité: Read Only	Liste permettant d'identifier tous les objets de gestion qui sont disponibles dans le DMAP; tous les processus applicatifs dans l'appareil doivent inclure un attribut avec de telles informations. Voir 12.16.3.10 pour les détails relatifs à ce type de données
Metadata_Contracts_Table	32	Métadonnées (compte et capacité) de l'attribut Contracts_Table	Type: Metadata_attribute	Métadonnées contenant un compte du nombre d'entrées dans le tableau et la capacité (nombre total de rangées autorisées) pour le tableau; voir 6.2.6.3 pour les détails relatifs à ce type de données
Non_Volatile_Memory_ Capability	33	Indique si l'appareil est capable de maintenir toutes les informations de DMAP qui s'inscrivent dans la classification Static en mémoire non volatile sur un cycle de mise sous/hors tension	Type: Boolean8 Classification: Constant Accessibilité: Read only	Voir 6.3.9.4.2 pour plus d'informations
Warm_Restart_Attempts_ Timeout	34	Temporisation après laquelle un appareil qui essaie de rejoindre à nouveau le réseau par un warmRestart passe à une commande restartAsProvisioned	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 60	Unités en minutes; voir 6.3.9.4.2 pour plus d'informations

Tableau 10 *(9 de 9)*

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Device_Restart_AlertDescriptor	35	Utilisé pour changer la priorité d'alerte Device_Restart (décrit dans le Tableau 11); cette alerte peut également être activée ou désactivée	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 8]	-
Proxy_Join_Request_Rate	36	Utilisé pour commander la fréquence maximale à laquelle un routeur proxy prendra en charge des demandes de rattachement	Type: Integer8 Classification: Static Accessibilité: Read/write Valeur par défaut: 6 Plage valide: -4..127	Intervalle exigé minimal entre les demandes de rattachement que le routeur proxy est autorisé à accepter. Une valeur de $N > 0$ spécifie une période de N s tandis qu'une valeur de $N < 0$ spécifie une période de $-1/N$ s. $N = 0$ désactive l'attribut. Ce paramètre est utilisé pour réduire l'impact des attaques de déni de service (DoS).
Réservé pour les éditions futures de la présente norme	37..63	—	—	—

6.2.8.1.2 Alertes de l'objet de gestion d'appareil

Le DMO de l'appareil doit envoyer une alerte pour indiquer un changement de son statut de puissance. Le DMO de l'appareil doit envoyer une alerte chaque fois qu'il passe par un redémarrage d'appareil. Le redémarrage d'appareil est décrit en 6.3.9.4.2.

Les alertes du DMO sont définies dans le Tableau 11.

Tableau 11 – Alertes de DMO

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)					
Identificateur du type d'objet normalisé: 127					
Description de l'alerte: Alertes de diagnostic de communication pour indiquer que le statut d'alimentation en énergie de l'appareil a changé et pour indiquer que l'appareil a redémarré					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alertes (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: urgent, haut, moyen, faible, journal)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = Event	1 = Comm. diagnostics	0 = Device_Power_ Status_Check	8 = Medium	Type: Unsigned8	La valeur courante de l'attribut Power_Supply_ Status dans le Tableau 10 est incluse dans cette alerte
0 = Event	1 = Comm. diagnostics	1 = Device_Restart	8 = Medium	Type: N/A	Seul un appareil qui a l'attribut de DMO Non_Volatile_M emory_Capabilit y = 1 peut envoyer cette alerte pour indiquer qu'il est passé par un redémarrage à chaud

6.2.8.1.3 Méthodes de l'objet de gestion d'appareil

Les méthodes du DMO sont décrites en 6.3.9.2.2, en 6.3.11.2.10.5 et en 6.3.11.2.11.3.

6.2.8.2 Gestion de couche

6.2.8.2.1 Généralités

Chaque couche de communication au sein de la suite de protocoles a une fonctionnalité autonome de gestion de couche. Chaque fonction de gestion de couche fournit un SAP de gestion. La gestion d'appareil des couches est accomplie par l'intermédiaire de l'accès aux SAP de gestion sur chacune des couches, conformément à la Figure 25. La gestion des couches au sein d'un appareil peut être faite localement par la fonctionnalité qui réside au sein du DMO, car le DMO a accès aux SAP de gestion. En outre (voir le débat en 6.2.4), la gestion de couche peut être accomplie à distance par un gestionnaire de système.

La définition formelle de chacun des objets de gestion de couche est incluse ci-dessous. La définition des objets de gestion de couche au sein du DMAP correspond directement à la définition du SAP de gestion de couche. Cependant, il peut y avoir un besoin de limiter

l'accès distant à des caractéristiques spécifiques d'un SAP de gestion de couche donné. Ainsi, il convient que certains attributs ou certaines méthodes, bien qu'accessibles au DMO local, ne soient pas accessibles à distance. De telles restrictions, toutes les fois que nécessaires, sont spécifiées dans les spécifications de la couche. Les opérations décrites dans l'Annexe J peuvent être utilisées pour accéder à des attributs dans ces objets de gestion de couche.

6.2.8.2.2 Objet de gestion de DL

6.2.8.2.2.1 Généralités

Dans l'architecture définie par la présente norme, tous les services de gestion de couche DL, MAC et PhL sont fournis par l'intermédiaire d'un point d'accès au service de gestion de liaison de données (DMSAP) unifié. Il n'y a pas de SAP de gestion directement accessible pour la couche physique et la couche MAC, car ces couches exigent parfois que les actions de gestion soient synchrones avec le flot de données. Ainsi, le DLMO fournit les attributs des couches qui sont accessibles à distance.

6.2.8.2.2.2 Gestion de la couche physique

Les entités de gestion de couche physique sont manipulées indirectement par l'intermédiaire du DMSAP. Les attributs de DL sont relatifs à un sous-ensemble de celles qui sont définies dans l'IEEE 802.15.4, telles que décrites en 9.1.5.

6.2.8.2.2.3 Gestion de la sous-couche de commande d'accès au support

Les entités de gestion de la sous-couche MAC sont manipulées indirectement par l'intermédiaire du DMSAP. Les attributs de DL sont relatifs à un sous-ensemble de celles qui sont définies dans l'IEEE 802.15.4, telles que décrites en 9.1.5.

6.2.8.2.2.4 Gestion de DL

Les attributs et méthodes de gestion de la DL sont disponibles par l'intermédiaire du DMSAP. Les attributs, les méthodes et les alertes du DLMO sont définis en 9.4 et en 9.6.

6.2.8.2.2.5 Gestion de NL

Les attributs et méthodes de gestion de la NL sont disponibles par l'intermédiaire du NMSAP. Les attributs, les méthodes et les alertes du NLMO sont définis en 10.4.

6.2.8.2.2.6 Gestion de TL

Les attributs et méthodes de gestion de la TL sont disponibles par l'intermédiaire du TMSAP. Les attributs, les méthodes et les alertes du TLMO sont définis en 11.6.

6.2.8.2.2.7 Gestion de sécurité

Les attributs et les méthodes de gestion de sécurité d'appareil sont disponibles par l'intermédiaire du DMSAP et du TMSAP. Les attributs, les méthodes et les alertes du DSMO sont définis en 7.11.

6.2.8.2.2.8 Gestion de la sous-couche d'application

Les attributs et méthodes de gestion de la sous-couche d'application sont disponibles par l'intermédiaire de l'ASMSAP. Les attributs, les méthodes et les alertes de L'ASLMO sont définis en 12.19.

6.3 Gestionnaire de système

6.3.1 Généralités

Les fonctions du gestionnaire de système incluent la gestion de sécurité, l'allocation d'adresse, la mise à jour de logiciel, la surveillance des performances du système, la gestion d'appareil, les services de temps système et la configuration de communications incluant les services de contrat, et la gestion de redondance.

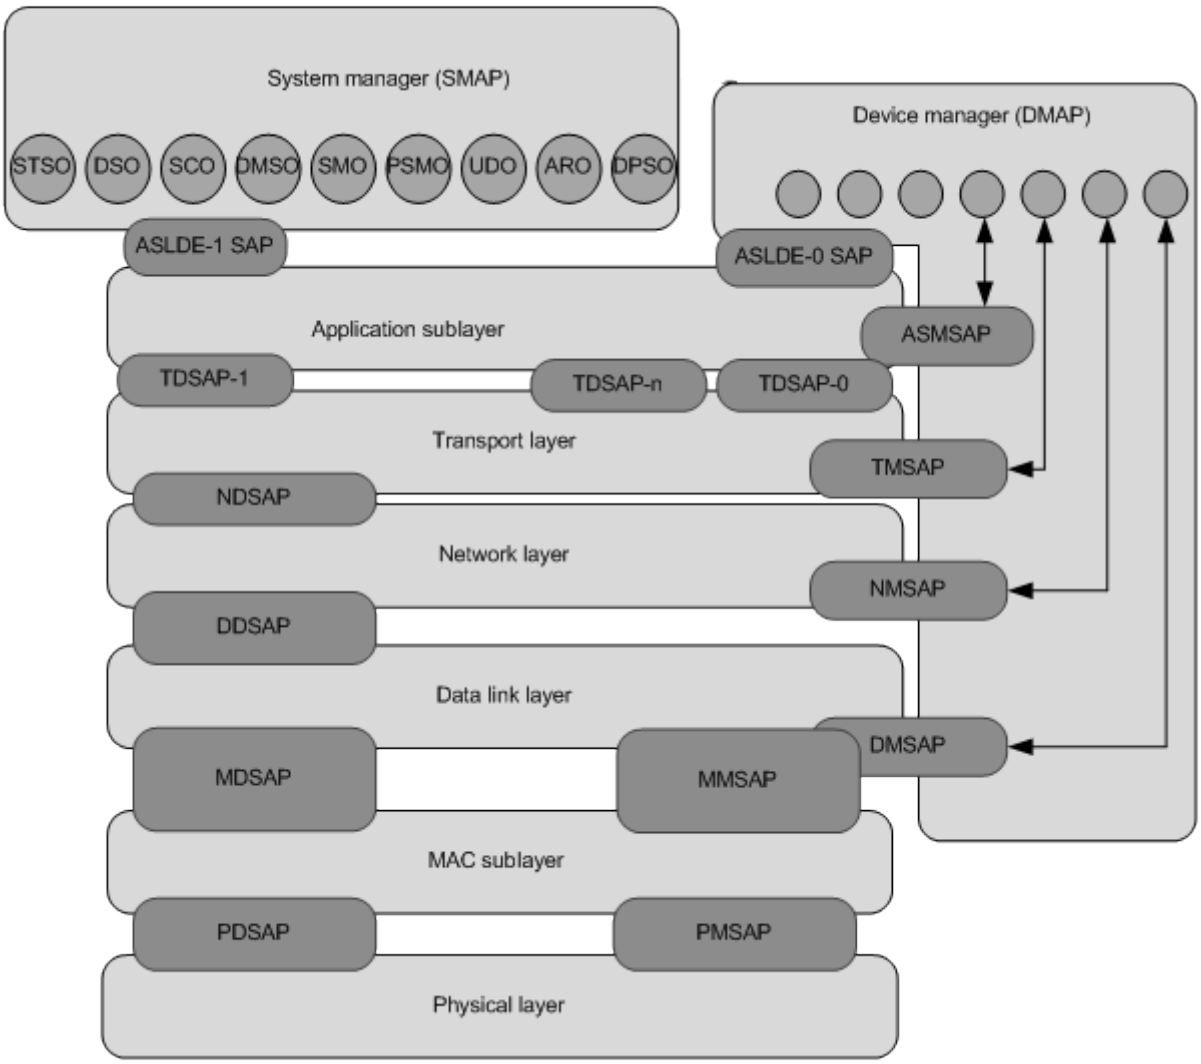
Le gestionnaire de système doit utiliser les services de l'ASL pour accéder à distance à des objets de gestion dans les DMAP des appareils conformes à la présente norme.

Le gestionnaire de système est un rôle et n'est pas attaché à une adresse physique fixe spécifique.

6.3.2 Architecture de la gestion de système

Du point de vue conceptuel, le gestionnaire de système peut être vu comme un processus applicatif tournant sur n'importe quel appareil du réseau. Un tel appareil doit être capable de prendre en charge le rôle de gestionnaire de système. Le SMAP est accessible uniquement sur un tel appareil. Le SMAP doit utiliser le SAP de la sous-couche d'application, à savoir le SAP ASLDE-1, pour communiquer avec les appareils. Ce SAP de sous-couche d'application doit correspondre au SAP de TL TDSAP-1 qui doit correspondre au numéro de port 0xF0B1.

La Figure 26 montre le gestionnaire de système qui réside dans un appareil de terrain conforme à la présente norme.



Légende

Anglais	Français
System manager (SMAP)	Gestionnaire de système (SMAP)
Device manager (DMAP)	Gestionnaire d'appareil (DMAP)
Application sub-layer	Sous-couche d'application
Transport layer	Couche transport
Network layer	Couche réseau
Data link layer	Couche liaison de données
MAC sub-layer	Sous-couche MAC
Physical layer	Couche physique

Figure 26 – Concept de l'architecture de gestionnaire de système

Comme montré à la Figure 26, TDSAP-1 doit être utilisé pour accéder aux objets de gestion dans le SMAP. La définition de ces objets de gestion de système est nécessaire pour fournir l'accès distant à ces fonctions pour les appareils dans le réseau qui sont conformes à la présente norme.

6.3.3 Types normalisés des objets de gestion de système

Le Tableau 12 inclut une liste des types d'objet de gestion de système qui sont spécifiés dans la présente norme.

Tableau 12 – Types des objets de gestion de système

Nom du type d'objet normalisé	Identificateur du type d'objet normalisé	Identificateur de l'objet normalisé	Description de l'objet
System time service object (STSO)	100	1	Cet objet facilite la gestion des informations de temps dans tout le système; voir 6.3.10
Directory service object (DSO)	101	2	Cet objet facilite la gestion des adresses de tous les appareils existants dans le réseau; voir 6.3.5
Objet de configuration de communications système (SCO)	102	3	Cet objet facilite la configuration des communications du système, y compris l'établissement, la modification et la fin de contrat; voir 6.3.11
Device management service object (DMSO)	103	4	Cet objet facilite l'attachement d'appareil, la fermeture d'appareil et la configuration des communications d'appareil; voir 6.3.9
System monitoring object (SMO)	104	5	Cet objet facilite la surveillance des performances du système; voir 6.3.7
Proxy security management object (PSMO)	105	6	Cet objet agit en tant que proxy pour le gestionnaire de sécurité; voir 6.3.4
Upload/download object (UDO)	3	7	Cet objet facilite le téléchargement de firmware/de données vers les appareils et le chargement de données à partir des appareils; voir 6.3.6
Alert-receiving object (ARO)	2	8	Cet objet reçoit toutes les alertes destinées au gestionnaire de système; voir 6.3.7
Device provisioning object (DPO)	106	9	Cet objet facilite la configuration d'appareil; voir 6.3.8
Réservé pour les éditions futures de la présente norme	107..113	—	—

Les appareils qui exigent des services de gestion de système communiquent avec les objets appropriés donnés ci-dessus.

6.3.4 Gestion de sécurité

Le gestionnaire de système s'interface avec le gestionnaire de sécurité pour générer des clés et authentifier des appareils. Le gestionnaire de sécurité est fonctionnellement séparé du gestionnaire de système afin que les politiques de sécurité puissent être communes à travers les réseaux de l'administrateur et d'autres types de réseaux. Le fait de placer le gestionnaire de sécurité fonctionnellement derrière le gestionnaire de système cache également aux appareils les divers protocoles, tels que le Kerberos, qui peuvent être utilisés par une fonction de gestion de sécurité. Plus de détails sont fournis à l'Article 7.

L'interface entre le gestionnaire de système et le gestionnaire de sécurité n'est pas spécifiée dans la présente norme. Du point de vue conceptuel, le gestionnaire de système peut être vu comme incluant un objet proxy de gestion de sécurité (PSMO). Ce PSMO transmet tous les messages relatifs à la sécurité entre le gestionnaire de sécurité et les appareils dans le réseau qui sont conformes à la présente norme. Ce PSMO peut être utilisé par le gestionnaire de sécurité pour accéder à des informations issues d'autres objets de gestion de système, telles que le temps TAI courant, s'il y a lieu. Le gestionnaire de sécurité n'a pas une adresse valide telle que définie par la présente norme; donc, les appareils qui souhaitent communiquer avec le gestionnaire de sécurité ne peuvent le faire qu'en communiquant avec le PSMO.

Les attributs, les méthodes et les alertes du PSMO sont définis à l'Article 7.

6.3.5 Adresses et allocation d'adresse

6.3.5.1 Généralités

Le gestionnaire de système a la responsabilité d'assigner des adresses aux appareils lorsqu'ils rejoignent le réseau.

6.3.5.2 Types d'adresse

Chaque appareil conforme à la présente norme doit avoir un identificateur et deux adresses comme suit:

- Chaque appareil conforme à la présente norme doit avoir un identificateur EUI64Address qui est présumé être unique au niveau global (les fournisseurs sont censés assurer l'unicité globale de ces identificateurs). Des mécanismes de reprise sur défaillance pour les rôles de passerelle, de gestionnaire de système et de gestionnaire de sécurité sont habituellement fournis par le biais de la redondance. La redondance pour les besoins de la reprise sur défaillance peut impliquer la duplication de l'identificateur EUI64Address pour les entités redondantes. Une telle duplication d'identificateur EUI64Address ne relève pas du domaine d'application de la présente norme.
- Chaque appareil conforme à la présente norme doit avoir une adresse IPv6Address par le gestionnaire de système lorsqu'il rejoint le réseau; cette adresse IPv6Address doit être unique à travers le réseau.
- Chaque appareil conforme à la présente norme qui est accessible par un sous-réseau doit avoir une adresse DL16Address dans le sous-réseau D pour son adresse IPv6Address. Cette adresse DL16Address doit être assignée par le gestionnaire de système. La portée de toute adresse DL16Address est limitée à un sous-réseau D particulier.

Plages et usages des adresses D de 16 bits:

– 0x0000: réservée par la présente norme pour indiquer qu'une adresse DL16Address n'a pas été affectée à l'appareil;

– 0x0001..0x7FFF: réservées par l'IETF RFC 4944 pour les adresses de monodiffusion 6LoWPAN;

– 0x8000..0xBFFF: réservées par l'IETF RFC 4944 pour les adresses de multidiffusion 6LoWPAN;

– 0xC000..0xCFFF: réservées par la présente norme pour les identificateurs de graphe;

– 0xD000..0xFFFD: réservées;

– 0xFFFE: réservée par l'IEEE 802.15.4e pour le coordinateur PAN local; et

– 0xFFFF: réservée par l'IEEE 802.15.4 pour la diffusion locale.

Dans la présente norme, l'adressage DL16Addressing est toujours utilisé au sein d'un sous-réseau D, excepté que les identificateurs EUI64Address sont utilisés d'une manière limitée au cours du processus de rattachement tant que l'appareil se rattachant n'a pas reçu une adresse DL16Address locale au sous-réseau D de la part du gestionnaire de système. Le processus de rattachement est décrit en 7.4.

6.3.5.3 Allocation d'adresse

Le gestionnaire de système doit allouer l'adresse IPv6Address, ainsi que l'adresse DL16Address dans le sous-réseau D, à un appareil lorsqu'il rejoint le réseau. Cela est décrit en 7.4.

Lorsqu'un appareil source qui appartient à un sous-réseau D particulier communique sur la dorsale avec un appareil de destination qui appartient à un sous-réseau D différent, le gestionnaire de système doit assigner des adresses DL16Addresses locales uniques à un sous-réseau D aux deux appareils dans les sous-réseaux D de l'un et de l'autre. De telles

adresses DL16Addresses locales pour des appareils distants (à savoir des appareils résidant dans un autre sous-réseau D) peuvent être établies par le gestionnaire de système sur une demande de contrat. (Les contrats sont décrits en 6.3.11.2.)

Lorsque la source envoie un message vers la destination, l'adresse DL16Address de la destination doit être utilisée à la NL et à la DL pour construire la NPDU et la DPDU. Ces couches peuvent utiliser le service de consultation d'annuaire fourni par le gestionnaire de système pour obtenir l'adresse DL16Address de la destination, si elle n'est pas déjà connue. Ce service est décrit en 6.3.5.4.

Les routeurs dorsaux doivent effectuer les conversions d'adresses entre l'adresse DL16Address (par sous-réseau D) et l'adresse IPv6Address pour un appareil donné. Noter que l'adresse DL16Address est utilisée seulement au sein de la DL. Une fois qu'un message atteint la dorsale, l'adresse IPv6Address complète doit être utilisée. Des exemples informatifs pour de tels scénarios sont donnés en 10.2.7.

La présente norme ne spécifie aucun mécanisme pour la façon dont le gestionnaire de système alloue les adresses IPv6Address et les adresses DL16Address. Le paragraphe 10.2.7 contient des exemples pour le routage basé sur Ethernet et le routage basé sur le bus de terrain. L'exemple du routage basé sur Ethernet décrit l'utilisation d'adresses IPv6Address basées sur IPv6. L'exemple du routage basé sur le bus de terrain décrit l'utilisation d'adresses IPv6Address qui ne sont pas basées sur IPv6.

Les appareils doivent seulement avoir une adresse IPv6Address valide. Les appareils à rattachement multiple qui exigent plusieurs adresses IPv6Address ne sont pas couverts dans la présente norme.

Les entités adressées sur la dorsale, telles que les gestionnaires de système et les passerelles, doivent également avoir des adresses DL16Address qui leur sont assignées en vue d'une utilisation dans un sous-réseau D Par conséquent, la plupart des adresses utilisées dans un sous-réseau D seront des adresses DL16Address.

6.3.5.4 Service d'annuaire

L'objet de service d'annuaire (DSO) dans le gestionnaire de système fournit les attributs nécessaires pour rechercher la conversion d'adresses entre l'adresse EUI64Address, l'adresse IPv6Address et la ou les adresses DL16Address d'un appareil donné. Des Identificateurs de sous-réseau D sont également maintenus par le DSO, mais l'allocation de ces ID de sous-réseau D n'est pas spécifiée dans la présente norme.

Les attributs du DSO sont définis dans le Tableau 13.

Tableau 13 – Attributs du DSO

Nom du type d'objet normalisé: Directory service object (DSO, objet de service d'annuaire)				
Identificateur du type d'objet normalisé: 101				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Address_Translation_Table	1	Table de conversion d'adresses contenant l'adresse EUI64Address, l'adresse IPv6Address, le ou les ID de sous-réseau D ainsi que la ou les adresses DL16Address de tous les appareils dans le réseau	Type: Array of Address_Translation_Row Classification: Dynamic Accessibilité: Read only	Attribut structuré utilisé pour consulter les conversions d'adresses; voir Tableau 14
Réservé pour les éditions futures de la présente norme	2..63	-	-	-

La structure de données Address_Translation_Row est définie dans le Tableau 14.

Tableau 14 – Structure de données Address_Translation_Row

Nom du type de données normalisé: Address_Translation_Row		
Code du type de données normalisé: 402		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
EUI64Address	1	Adresse EUI64Address de l'appareil unique au niveau global; Type: EUI64Address Classification: Static Accessibilité: Read only
IPv6Address	2	Adresse IPv6Address de l'appareil assignée par le gestionnaire de système; Type: IPv6Address Classification: Static Accessibilité: Read only
DL_Subnet_ID	3	Sous-réseau D dans lequel ou à partir duquel cet appareil est accessible; un appareil peut être accessible à partir de plusieurs sous-réseaux D, auquel cas cet élément correspond à un tel sous-réseau D; Type: Unsigned16 Classification: Static Accessibilité: Read Only
DL16Address	4	Adresse DL16Address de l'appareil dans le sous-réseau D indiquée par l'élément DL_Subnet_ID donné ci-dessus; Type: Unsigned16 Classification: Static Accessibilité: Read Only

Le service de consultation de conversions d'adresses est fourni par la méthode Read_Address_Row définie dans le Tableau 15.

Tableau 15 – Méthode Read_Address_Row

Nom du type d'objet normalisé: Directory service object (DSO, objet de service d'annuaire)				
Identificateur du type d'objet normalisé: 101				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
Read_Address_Row	1	Méthode permettant d'utiliser le service de consultation de conversions d'adresses pour lire les valeurs d'autres adresses/identificateurs d'un appareil ayant reçu un indice (l'un de ses identificateurs ou l'une de ses adresses)		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Attribute_ID	Data type: Unsigned8	Valeur = 1 (attribut Address_Translation_Table du DSO)
	2	Index_Info	Data type: Unsigned8	Indices nommés: 0: seule l'adresse EUI64Address est fournie; 1: seule l'adresse IPv6Address est fournie; 2: l'adresse EUI64Address et l'ID de sous-réseau D sont fournis; 3: l'adresse IPv6Address et l'ID de sous-réseau D sont fournis; 4: l'ID de sous-réseau D et l'adresse DL16Address sont fournis. Voir Tableau 16
	3	Index_EUI64	Data type: EUI64Address	Valeur: Adresse EUI64Address de l'appareil pour lequel la consultation d'adresse est nécessaire
	4	Index_128_Bit_Address	Data type: IPv6Address	Valeur: Adresse IPv6Address de l'appareil pour lequel la consultation d'adresse est nécessaire
	5	Index_DL_Subnet_ID	Data type: Unsigned16	Valeur: ID de sous-réseau D de l'appareil pour lequel la consultation d'adresse est nécessaire
	6	Index_DL_address_16_Bit	Data type: DL16Address	Valeur: Adresse DL16Address de l'appareil pour lequel la consultation d'adresse est nécessaire

	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Value_Type	Data type: Unsigned8	Type d'informations fournies Valeurs nommées: 0: une seule rangée si la valeur de l'ID de sous-réseau D est fournie comme argument d'entrée; 1: toutes les rangées si la valeur de l'ID de sous-réseau D n'est pas fournie comme argument d'entrée (c'est-à-dire que toutes les rangées pour l'adresse EUI64Address ou IPv6Address donnée sont retournées). Voir Tableau 17
	2	Value_Size	Data type: Unsigned8	Nombre de rangées retournées
	3	Data_Value_1	Data type: Address_Translation_Row	Adresse EUI64Address, adresse IPv6Address, ID de sous-réseau D, adresse DL16Address de l'appareil
	2+*n*	Data_Value_*n*	Data type: Address_Translation_Row	Adresse EUI64Address, adresse IPv6Address, ID de sous-réseau D, adresse DL16Address de l'appareil

Certains des arguments d'entrée ne sont pas applicables si l'argument Index_Info a certaines valeurs et ne doivent donc pas être inclus dans la demande. L'utilisation des arguments d'entrée pour la méthode Read_Address_Row est décrite dans le Tableau 16.

Tableau 16 – Utilisation des arguments d'entrée pour la méthode Read_Address_Row

Argument d'entrée	Non applicable à la valeur Index_Info
Attribute_ID	-
Index_Info	-
Index_EUI64	1, 3, 4
Index_128_Bit_Address	0, 2, 4
Index_DL_Subnet_ID	0, 1
Index_DL_Address_16_Bit	0, 1, 2, 3

Certains des arguments de sortie ne sont pas applicables si l'argument Value_Type a certaines valeurs et ne doivent donc pas être inclus dans la réponse. L'utilisation des arguments de sortie pour la méthode Read_Address_Row est décrite dans le Tableau 17.

Tableau 17 – Utilisation des arguments de sortie pour la méthode Read_Address_Row

Argument de sortie	Non applicable à la valeur Value_Type
Value_Type	-
Value_Size	0
Data_Value_1	-
Data_Value_n	0

Les interfaces de côté haut sur le DSO pour supprimer des adresses ou pour modifier des adresses ne sont pas spécifiées dans la présente norme.

6.3.5.5 Gestion des adresses DL16Address de multidiffusion

Les adresses DL16Address de la forme 0x 100x xxxx xxxx xxxx doivent être réservées pour la multidiffusion, en respectant la convention établie par l'IETF RFC 4944.

La gestion d'adresses DL16Address de multidiffusion n'est pas spécifiée dans la présente norme. Des attributs complémentaires pour l'objet service d'annuaire peuvent être spécifiés par les fournisseurs qui prennent en charge la gestion d'adresses DL16Address de multidiffusion.

6.3.6 Mise à niveau du firmware

Le gestionnaire de système fournit aux appareils la prise en charge pour les mises à niveau par liaison radio des firmwares. Le gestionnaire de système prend en charge les mises à jour de firmwares des suites de protocoles de communication.

Le gestionnaire de système doit fournir une interface pour accepter les mises à niveau de firmwares qui ont besoin d'être envoyées à tout appareil dans le réseau. Le gestionnaire de système doit utiliser l'UDO dans le DMAP de l'appareil pour envoyer cette mise à jour à l'appareil. Des mises à jour de firmwares des suites de protocoles de communication doivent être accomplies uniquement au moyen de l'UDO de gestionnaire de système. Cet UDO est décrit en 12.15.2.4.

Comme le gestionnaire de système maintient des informations relatives à tous les appareils dans le réseau, l'application de mise à jour d'hôte peut obtenir du gestionnaire de système des informations relatives aux appareils qui sont dans le réseau. L'application de mise à jour d'hôte peut utiliser ces informations pour déterminer quels appareils ont besoin de telles mises à niveau de firmware. La passerelle peut également être utilisée pour envoyer des mises à niveau de firmware à l'appareil. Si ces mises à niveau sont des mises à niveau de suites de protocoles de communication, elles doivent être envoyées au moyen de l'UDO de gestionnaire de système. Cela est décrit en U.3.2.

Le processus de mise à niveau de firmware doit assurer que les opérations de réseau sont maintenues à travers des mises à jour. Le processus peut inclure un mécanisme de basculement qui spécifie l'heure de basculement (après livraison de la mise à jour), le point auquel les appareils doivent commencer à utiliser le nouveau firmware. L'heure de basculement doit utiliser le sens partagé de temps qui a été configuré par le gestionnaire de système. Si le gestionnaire de système envoie la mise à niveau de firmware à l'appareil, il peut envoyer l'heure de basculement avec le téléchargement, ou il peut envoyer l'heure de basculement après que le téléchargement s'est achevé.

Comme les mises à niveau de firmware peuvent être spécifiques à un fournisseur, les mises à jour sont opaques pour le gestionnaire de système fournissant le service de mise à jour. Le gestionnaire de système accepte des mises à jour par l'intermédiaire des protocoles non spécifiés (un outil d'interface utilisateur avec un lecteur de DVD, par exemple) et fournit la mise à jour à des appareils choisis à des instants spécifiés en fonction de l'utilisateur ou autre entrée. Les détails relatifs aux questions de savoir comment l'application de mise à jour d'hôte communique avec le gestionnaire de système (telles que: quels appareils convient-il de mettre à jour?, quels sont leurs ID de fournisseur?, quand convient-il de mettre à jour les appareils?, et dans quel ordre convient-il de les mettre à jour?), ne sont pas spécifiés par la présente norme, mais de telles fonctions sont censées être prises en charge par le gestionnaire de système. Le gestionnaire de système peut programmer des mises à jour des appareils de façon à éviter ou réduire au maximum le temps d'interruption du réseau. Ce programme peut dépendre de la topologie du réseau.

La multidiffusion des mises à niveau de firmware n'est pas spécifiée par la présente norme.

L'UDO dans le gestionnaire de système doit être utilisé si le firmware du gestionnaire de système lui-même a besoin d'être mis à niveau. Les attributs, les méthodes et les

diagrammes d'état de l'UDO dans le gestionnaire de système sont selon la définition fournie en 12.15.2.4. L'identificateur d'objet pour l'UDO dans le SMAP doit être 7.

6.3.7 Surveillance des performances du système

6.3.7.1 Généralités

La surveillance des performances du système est effectuée par le gestionnaire de système afin de recueillir les informations qui peuvent être utilisées dans la prise des actions nécessaires pour optimiser les performances du système et pour réagir aux changements apportés à l'environnement radio et au statut de l'appareil. De telles actions sont effectuées par l'intermédiaire de la configuration de communication du système qui est décrite en 6.3.11.

La surveillance des performances du système est accomplie par l'intermédiaire du sondage des attributs d'appareil ou par la configuration des appareils pour générer des alertes qui fournissent des informations événementielles.

La surveillance des performances du système utilisant la publication périodique de rapports de santé issus des appareils est prise en charge par l'intermédiaire de l'utilisation du HRCO dans le DMAP de chaque appareil. Le HRCO, décrit en 6.2.7.7, peut être configuré par le gestionnaire de système pour rapporter périodiquement les valeurs d'un ou plusieurs attributs dans les objets de gestion de l'appareil. Avant que le gestionnaire de système ne configure le HRCO d'un quelconque appareil particulier pour éditer des rapports de santé, il a besoin de créer un objet de dispersion unique dans le SMAP pour agir comme étant l'abonné aux données qui seront éditées par le HRCO de cet appareil particulier. Des informations relatives à cet objet de dispersion unique doivent être acheminées vers le HRCO de cet appareil particulier en configurant l'attribut CommunicationEndPoint dans le HRCO. L'objet de dispersion est décrit en 12.15.2.6.

Des informations relatives aux capacités d'un nouvel appareil sont fournies au gestionnaire de système au cours de son processus de rattachement. Cela est débattu en 6.3.9.

Des appareils peuvent être configurés par le gestionnaire de système pour générer des alertes pour fournir des informations événementielles, par exemple, lorsqu'une liaison cesse de fonctionner ou lorsque la batterie d'un appareil de terrain a moins de 25 % de capacité restante. Cela est décrit en 6.3.7.2.

Alors que l'appareil mettant en œuvre le gestionnaire de système peut avoir une interface qui permet au personnel d'exploitation et de maintenance d'installation d'observer et commander les performances du réseau et des appareils, cette interface n'est ni obligatoire ni spécifiée par la présente norme.

L'UDO dans le DMAP d'un appareil peut être utilisé pour un téléchargement descendant, de l'appareil vers le gestionnaire de système, de grands blocs de données de performances d'appareil. De telles données peuvent être spécifiques à un fournisseur, spécifiques à un modèle ou spécifiques à une instance d'appareil. L'UDO dans le gestionnaire de système peut être utilisé pour un téléchargement montant de telles données en vue d'analyses complémentaires. Cette collecte de données et cette analyse des données ne sont pas spécifiées par la présente norme.

6.3.7.2 Alertes de la gestion de système

Le gestionnaire de système contient un objet récepteur d'alerte (ARO) qui reçoit des alertes de diagnostics de communication et des alertes de sécurité. De telles alertes sont décrites en 6.2.7.2. Ces alertes peuvent être utilisées par le gestionnaire de système pour surveiller les performances du système et entreprendre l'action adaptée, le cas échéant. L'identificateur d'objet pour l'ARO dans le SMAP doit être 8.

Après qu'un appareil a rejoint le réseau, il doit positionner les attributs Alert_Master_Comm_Diagnostics et Alert_Master_Security de l'ARMO afin qu'ils pointent vers le gestionnaire de système.

Les attributs de l'ARO dans le gestionnaire de système sont conformes à la définition donnée en 12.15.2.3. La valeur par défaut pour l'attribut ARO.Categories doit être 0110 0000.

Le diagramme d'états décrivant le traitement des rapports d'alertes par l'ARO est donné en 12.15.2.3.

6.3.7.3 System monitoring object (objet de surveillance de système)

Les attributs du SMO sont donnés dans le Tableau 18.

Tableau 18 – Attributs de SMO dans le gestionnaire de système

Nom du type d'objet normalisé: System monitoring object (SMO, objet de surveillance de système)				
Identificateur du type d'objet normalisé: 104				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Réservé pour les éditions futures de la présente norme	1..63	-	-	-

6.3.7.4 Configuration de la surveillance de système

La surveillance de performances de système peut avoir sa propre configuration permettant d'augmenter la surveillance lorsque cela est nécessaire. Par exemple, la liste d'alertes actives peut être réajustée en fonction de l'état courant du réseau. Pour le diagnostic du réseau, si un mode de défaillance est suspecté, le fait d'activer des alertes spécifiques peut fournir la preuve confirmant la défaillance en question. Une telle configuration du gestionnaire de système n'est pas spécifiée par la présente norme.

6.3.8 Service de configuration d'appareil

Avant qu'un appareil ne rejoigne le réseau, il exige les authentifiants de sécurité et les informations spécifiques au réseau qui sont appropriés. Ceux-ci sont fournis à l'appareil pendant le processus de configuration. Le processus de configuration, le rôle du gestionnaire de système dans ce processus et la définition de l'objet service de configuration d'appareil (DPO) sont décrits à l'Article 13.

6.3.9 Services de gestion d'appareil

6.3.9.1 Généralités

Un appareil conforme à la présente norme peut passer par plusieurs phases dans sa durée de vie opérationnelle. Ces phases sont décrites en 5.2.8. La gestion d'un appareil à travers certaines de ces phases est accomplie par le gestionnaire de système. Spécifiquement, le gestionnaire de système joue un rôle dans les processus de rattachement et de départ ainsi que dans la configuration de communication d'un appareil.

6.3.9.2 Processus de rattachement

6.3.9.2.1 Généralités

Un nouvel appareil doit obtenir de l'appareil de configuration les informations nécessaires relatives à la configuration. Cela est décrit à l'Article 13. L'attribut Join_Command dans le DMO d'un appareil doit être utilisé pour ordonner à l'appareil de rejoindre le réseau. Seul

l'appareil de configuration peut mettre à 1 l'attribut Join_Command, ce qui déclenche explicitement le processus de rattachement de l'appareil, étant donné que l'appareil n'a aucune connectivité à d'autres entités dans le réseau. L'attribut Join_Command ne doit être mis à 1 par l'appareil de configuration qu'à la suite d'une configuration réussie de l'appareil. Des routeurs d'annonce doivent relayer comme proxy les demandes de rattachement à la fréquence indiquée par l'attribut Proxy_Join_Request_Rate (attribut 36) du DMO. Cette fréquence assure que le réseau est protégé des attaques de déni de service tentées par l'intermédiaire des routeurs proxy. Pour une description de Proxy_Join_Request_Rate, voir le Tableau 10.

Le gestionnaire de système commande le traitement de nouveaux appareils rejoignant le réseau. Les appareils non rattachés qui mettent en œuvre une DLE selon la présente norme se mettent à l'écoute pour détecter des messages d'annonce issus de routeurs locaux dont les fonctions d'annonce sont configurées par le gestionnaire de système. Un tel routeur d'annonce doit apporter une assistance pendant le processus de rattachement d'un nouvel appareil en agissant comme un proxy pour le gestionnaire de système. Ce routeur d'annonce transmet la demande de rattachement issue du nouvel appareil vers le gestionnaire de système et transmet la réponse de rattachement issue du gestionnaire de système vers le nouvel appareil. Une demande de rattachement issue du nouvel appareil doit être traitée par le gestionnaire de système. Le gestionnaire de système doit générer une réponse de rattachement après avoir communiqué avec le gestionnaire de sécurité. Des routeurs d'annonce doivent relayer comme proxy les demandes de rattachement à la fréquence indiquée par l'attribut Proxy_Join_Request_Rate (attribut 36) du DMO. Cette fréquence protège le réseau contre des attaques de déni de service tentées par des routeurs proxy. Pour une description de cet attribut, voir le Tableau 10.

La demande de rattachement issue d'un nouvel appareil doit inclure des informations autres que de sécurité telles que l'adresse EUI64Address et les capacités de l'appareil ainsi que des informations de sécurité de l'appareil. La réponse de rattachement issue du gestionnaire de système doit inclure des informations autres que de sécurité telles que l'adresse IPv6Address assignée, l'adresse DL16Address assignée et des informations de contrat de l'appareil ainsi que des informations de sécurité telles que la clé T. Les informations de sécurité dans la demande de rattachement et dans la réponse de rattachement sont décrites en 7.4. Les contrats sont décrits en 6.3.11.2.

Plus de détails relatifs au processus de rattachement sont décrits en 7.4.

6.3.9.2.2 Méthodes de l'objet de gestion d'appareil pour routeur d'annonce

Le nouvel appareil doit utiliser la méthode Proxy_System_Manager_Join et la méthode Proxy_System_Manager_Contract définies pour le DMO du routeur d'annonce pour envoyer ses informations autres que de sécurité qui font partie intégrante de la demande de rattachement et pour obtenir ses informations autres que de sécurité qui font partie intégrante de la réponse de rattachement. Les informations autres que de sécurité qui font partie intégrante de la demande de rattachement sont réparties dans la demande de rattachement au réseau et la demande de contrat. Les informations autres que de sécurité qui font partie intégrante de la réponse de rattachement sont réparties dans la réponse de rattachement au réseau et la réponse de contrat. Les contrats sont décrits en 6.3.11.2.

La méthode Proxy_System_Manager_Join est définie dans le Tableau 19. La méthode Proxy_System_Manager_Contract est définie dans le Tableau 20.

Le nouvel appareil doit utiliser les méthodes définies en 7.4 pour le DMO du routeur d'annonce pour envoyer ses informations de sécurité qui font partie intégrante de la demande de rattachement et pour obtenir ses informations de sécurité qui font partie intégrante de la réponse de rattachement. L'utilisation de toutes ces méthodes par le nouvel appareil est décrite en 7.4.

L'accès au DMAP de l'appareil est limité au SMAP présent dans le gestionnaire de système. Le rattachement doit être autorisé seulement pour accéder aux méthodes

Proxy_System_Manager_Join et Proxy_System_Manager_Contract du DMO au cours du processus de rattachement.

</table>

6.3.9.2.3 Capacités de nouvel appareil

Les informations relatives aux capacités d'un nouvel appareil en ce qui concerne le rôle de l'appareil doivent être fournies au gestionnaire de système au cours du processus de rattachement de l'appareil. Ces informations sont décrites dans le Tableau 19.

6.3.9.3 Configuration d'appareil

Un appareil est configuré après avoir rejoint un réseau. La configuration d'appareil inclut d'obtenir des ressources de communication pour prendre en charge les besoins de communication de l'appareil et de configurer la pile de protocoles de l'appareil pour utiliser ces ressources pour la communication. Pendant cette configuration, le gestionnaire de système peut tenir compte des capacités d'un appareil. Un appareil peut être reconfiguré lorsque le réseau change ou lorsque les applications sur l'appareil ont besoin de changer leurs services.

La configuration d'appareil est habituellement accomplie pendant l'établissement de contrats. Cela est décrit en 6.3.11.2. Les attributs et les méthodes définis pour les objets de gestion du DMAP doivent être utilisés par le gestionnaire de système pour configurer l'appareil.

Le gestionnaire de système ne configure pas les UAP sur l'appareil. Cela est fait par des applications d'hôte sur des réseaux d'installation ou par des outils de maintenance tenus à la main.

6.3.9.4 Processus de départ

6.3.9.4.1 Généralités

Le gestionnaire de système commande le processus consistant pour un appareil précédemment rattaché à quitter le réseau. Ce processus de départ peut être initié par l'appareil lorsqu'il a l'intention de quitter le réseau ou il peut être initié par le gestionnaire de système.

Le processus de départ inclut deux scénarios: le redémarrage de l'appareil et la réinitialisation de l'appareil aux valeurs d'usine par défaut.

Le redémarrage d'appareil se produit lorsque l'appareil lui-même ou le gestionnaire de système amène l'appareil à redémarrer. Quelques exemples qui conduisent à ce scénario sont le remplacement de batterie ou le réamorçage pour appliquer une nouvelle image de firmware. Un appareil est réinitialisé à ses valeurs de réglage d'usine par défaut si l'appareil retourne à son état d'usine par défaut. Quelques exemples qui conduisent à ce scénario sont le fait que l'appareil est remis dans le stock général en vue d'un futur déploiement ou que l'appareil est déplacé vers un réseau différent.

6.3.9.4.2 Redémarrage d'appareil

Un processus de redémarrage d'appareil peut être initié par l'appareil lui-même ou par le gestionnaire de système. Il y a deux types de redémarrages: warmRestart et restartAsProvisioned. Dans tous les deux cas, les appareils déclencheront immédiatement le processus de rattachement à la suite de l'événement de redémarrage. Une écriture explicite de l'attribut Join_Command DMO à 1 n'est pas nécessaire à la suite d'un événement warmRestart ou restartAsProvisioned.

L'attribut Join_Command dans le DMO d'un appareil doit être utilisé pour ordonner à l'appareil d'accomplir soit un warmRestart, soit un restartAsProvisioned.

Un appareil qui reçoit la commande de warmRestart doit se réamorcer lui-même. Si l'attribut Non_Volatile_Memory_Capability dans le DMO est 1, l'appareil doit retenir les valeurs de tous les attributs constants et statiques dans tous les objets d'application présents dans le DMAP ainsi que dans les UAP de l'appareil. Tous les autres attributs sont réinitialisés à leurs valeurs par défaut. Si l'attribut Non_Volatile_Memory_Capability dans le DMO est 0, l'appareil doit retenir toutes les informations qui lui ont été fournies au cours de l'étape de configuration avant qu'il n'ait rejoint le réseau pour la première fois ainsi que toutes les informations constantes et statiques présentes dans les UAP. Tous les autres attributs sont réinitialisés à leurs valeurs par défaut et l'appareil retourne à son état configuré.

Un appareil qui reçoit la commande restartAsProvisioned doit réinitialiser tous les attributs constants et statiques dans tous les objets d'application présents dans le DMAP indépendamment de la valeur de réglage de l'attribut Non_Volatile_Memory_Capability présente dans le DMO, à l'exception du DPO. Un appareil qui reçoit la commande restartAsProvisioned doit se réamorcer lui-même tout en retenant toutes les informations qui lui avaient été fournies au cours de l'étape de configuration avant qu'il n'ait rejoint le réseau pour la première fois. Ces informations sont décrites à l'Article 13. Ces informations sont habituellement nécessaires à l'appareil pour rejoindre le réseau sans devoir passer une nouvelle fois par l'étape de configuration. L'appareil doit également retenir toutes les informations constantes et statiques présentes dans les UAP.

Le Tableau 21 recueille et présente les effets des différentes commandes de rattachement sur divers ensembles d'attributs.

Tableau 21 – Effet des différentes commandes de rattachement sur des ensembles d'attributs

Type de commande de rattachement	Attributs de DMAP (à l'exception du DPO)	Attributs d'UAP	Attributs de DPO
WarmRestart (Join_Command =2) when Non_Volatile_Memory_Capability = 1	KEEP	KEEP	KEEP
WarmRestart (Join_Command =2) when Non_Volatile_Memory_Capability = 0	CLEAR	KEEP	KEEP
RestartAsProvisioned (Join_Command = 3)	CLEAR	KEEP	KEEP
Réinitialisation aux valeurs d'usine par défaut (Join_Command = 4)	CLEAR	CLEAR	CLEAR

Un téléchargement descendant de firmware peut conduire à un redémarrage d'appareil. Les informations nécessaires à l'appareil pour utiliser le nouveau firmware et rejoindre le réseau peuvent être stockées dans l'appareil. L'appareil passe habituellement par un cycle de restartAsProvisioned dans ces cas.

6.3.9.4.3 Appareil réinitialisé aux valeurs d'usine par défaut

Un processus de réinitialisation d'appareil peut être initié par l'appareil lui-même ou par le gestionnaire de système.

L'attribut Join_Command dans le DMO d'un appareil doit être utilisé pour ordonner à l'appareil d'accomplir une réinitialisation. Une commande de réinitialisation force l'appareil à se réinitialiser aux valeurs d'usine par défaut, et tous les attributs sont réinitialisés à leurs valeurs par défaut. L'appareil est censé retourner à l'état d'usine par défaut qui est décrit dans l'Article 13.

6.3.9.4.4 Remplacement d'appareil

Si un ancien appareil (à savoir un appareil rattaché) est remplacé par un nouvel appareil (à savoir un appareil non rattaché), le gestionnaire de système est censé fournir l'ancienne adresse IPv6Address à cet appareil de remplacement. L'application d'hôte ou l'utilisateur est censé(e) informer le gestionnaire de système au sujet de ce remplacement à travers le chemin de communication 5 à la Figure 23. Le gestionnaire de système peut choisir de configurer d'autres attributs dans le DMAP de l'appareil de remplacement pour correspondre à ceux contenus dans l'ancien appareil. La configuration des UAP dans l'appareil de remplacement est censée être effectuée par des applications d'hôtes sur des réseaux d'installation ou par des outils de maintenance tenus à la main.

6.3.9.5 Device management service object (objet de service de gestion d'appareil)

L'objet de service de gestion d'appareil (DMSO) dans le gestionnaire de système doit traiter les informations autres que de sécurité dans la demande de rattachement issue du nouvel appareil qui sont transmises par le routeur d'annonce et doit générer des informations autres que de sécurité dans la réponse de rattachement.

Les attributs du DMSO sont donnés dans le Tableau 22.

Tableau 22 – Attributs du DMSO dans le gestionnaire de système

Nom du type d'objet normalisé: Device management service object (DMSO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 103				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Réservé pour les éditions futures de la présente norme	1..63	-	-	-

Un nouvel appareil communique avec un routeur d'annonce qui agit comme un proxy pour le gestionnaire de système et transmet tous les messages de rattachement entre le nouvel appareil et le gestionnaire de système. Le processus de rattachement est décrit en 7.4. Les méthodes utilisées pour envoyer des messages de demande de rattachement et de réponse de rattachement entre le nouvel appareil et le routeur d'annonce sont données en 6.3.9.2.2. Le routeur d'annonce doit utiliser la méthode System_Manager_Join et la méthode System_Manager_Contract définies dans le DMSO pour envoyer la demande de rattachement au réseau et la demande de contrat et pour recevoir la réponse de rattachement au réseau et la réponse de contrat qui sont associées au processus de rattachement de ce nouvel appareil.

L'objet source des méthodes System_Manager_Join et System_Manager_Contract est le DMO routeur proxy d'annonce qui communique avec le gestionnaire de système pour le compte du nouvel appareil.

La méthode System_Manager_Join est définie dans le Tableau 23. La méthode System_Manager_Contract est définie dans le Tableau 24.

Tableau 23 – Méthode System_Manager_Join

Nom du type d'objet normalisé: Device management service object (DMSO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 103				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
System_Manager_Join	1	Méthode permettant d'envoyer au gestionnaire de système la demande de rattachement au réseau d'un nouvel appareil et d'obtenir la réponse de rattachement au réseau		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	EUI64	Type: EUI64Address	Attribut DMO EUI64; voir Tableau 10
	2	DL_Subnet_ID	Type: Unsigned16	Sous-réseau D que le nouvel appareil essaie de rejoindre; il s'agit également du sous-réseau D du routeur d'annonce. Valeurs nommées: 0: l'appareil ne fait partie d'aucun sous-réseau D

	7	Comm_SW_Minor_Version	Type: Unsigned8	Attribut DMO Comm_ SW_Minor_Version; voir Tableau 10
	8	Size_of_Software_ Revision_Information	Type: Unsigned8	Longueur en octets de Software_Revision_ Information
	9	Software_Revision_Information	Type: VisibleString SIZE(0..16)	Attribut DMO Software_Revision_ Information; voir Tableau 10
	10	DeviceCapability	Type: OctetString	Attribut DLMO DeviceCapability; voir Tableau 141

	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Assigned_Network_ Address_128_Bit	Type: IPv6Address	Cette valeur est écrite dans l'attribut DMO Network_Address_ 128_Bit; voir Tableau 10
	2	Assigned_DL_Address_16_Bit	Type: DL16Address	Cette valeur est écrite dans l'attribut DMO DL_Address_16_Bit; voir Tableau 10
	3	Assigned_Device_Role	Type: BitArray16	Cette valeur est écrite dans l'attribut DMO Assigned_Device_Role; voir Tableau 10
	4	System_Manager_ Network_Address_128_Bit	Type: IPv6Address	Cette valeur est écrite dans l'attribut DMO System_Manager_ 128_Bit_Address; voir Tableau 10
	5	System_Manager_ DL_Address_16_Bit	Type: DL16Address	Cette valeur est écrite dans l'attribut DMO System_Manager_ DL_Address_16_Bit; voir Tableau 10
	6	System_Manager_EUI64	Type: EUI64Address	Cette valeur est écrite dans l'attribut DMO System_Manager_EUI64Address; voir Tableau 10

Nom du type d'objet normalisé: Device management service object (DMSO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 103				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
	7	MIC	Type: OctetString4	Cette valeur est utilisée pour protéger les arguments 1 à 6. Cette valeur MIC est générée par le gestionnaire de sécurité. Voir 7.4.4.3.2
	8	Assigned_Max_TSDU_Size	Type: Unsigned16	Indique la TSDU maximale prise en charge en octets qui peut être convertie par la source en taille d'APDU maximale en prenant en compte les tailles de la TL, de la sécurité, des en-têtes d'AL et du TMIC.

Tableau 24 – Méthode System_Manager_Contract

Nom du type d'objet normalisé: Device management service object (DMSO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 103				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
System_Manager_Contract	2	Méthode permettant d'envoyer au gestionnaire de système la demande de contrat d'un nouvel appareil et d'obtenir la réponse de contrat. Les contrats sont décrits en 6.3.11.2.		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	EUI64	Type: EUI64Address	Adresse EUI64Address du nouvel appareil tentant de rejoindre le réseau
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Contract_Response	Type: New_Device_Contract_Response (voir Tableau 31)	Réponse de contrat pour prendre en charge une future communication du nouvel appareil vers le gestionnaire de système; les contrats sont décrits en 6.3.11.2
	2	MIC	Type: OctetString4	Cette valeur est utilisée pour protéger les arguments 1 à 6 avec la clé de rattachement. Cette valeur MIC est générée dans le gestionnaire de sécurité. Voir 7.4.4.3.2

Lorsque le DMSO génère des réponses de System_Manager_Join et de System_Manager_Contract, il envoie d'abord ces réponses au PSMO qui les envoie à son

tour au gestionnaire de sécurité. Le gestionnaire de sécurité doit protéger ces réponses avec un champ MIC en utilisant la clé de rattachement et les retourner au PSMO qui, à son tour, les remet en retour au DMSO. Le DMSO doit alors envoyer les réponses en retour au routeur d'annonce. Cette interaction avec le PSMO est décrite en 7.4.

6.3.10 Services de temps système

6.3.10.1 Généralités

Le temps dans la présente norme est basé sur le temps atomique international (TAI) comme référence temporelle. Le temps dans la présente norme est communiqué sous la forme de secondes écoulées depuis le 1er janvier 1958 (c'est-à-dire 1958/01/01 00:00).

Le système prend en charge la synchronisation afin que, au niveau de l'appareil, les applications puissent utiliser le temps pour coordonner des activités ou horodater des informations, améliorant l'utilisation de l'énergie et la fiabilité. Le temps système doit être disponible auprès d'au moins un appareil (une source de temps système) sur le réseau.

Une source de temps TAI n'est pas exigée pour l'exploitation d'un réseau conforme à la présente norme. Les sources alternatives de temps sont converties en unités TAI. La base de temps utilisée par le réseau doit être, à ±1 s près, le temps TAI réel. La passerelle doit convertir le temps TAI nominal du réseau en référence de temps système local s'il est disponible.

Le gestionnaire de système doit configurer au moins une source de temps système dans chaque sous-réseau D du réseau. Le gestionnaire de système lui-même peut être la source de temps système. Cela est décrit en 6.3.10.3. Le gestionnaire de système doit également configurer la topologie de distribution pour la diffusion du temps dans le sous-réseau D et pour la synchronisation des horloges d'appareil. Le gestionnaire de système configure chaque appareil dans le sous-réseau D avec l'/les horloge(s) parente(s) que l'appareil doit utiliser pour synchroniser son horloge. La DL dans chaque appareil est responsable de mesurer le temps et de garder les horloges synchronisées. Cela est décrit en 9.1.9.

Les routeurs dorsaux sont censés utiliser des techniques propriétaires ou normalisées pour maintenir la synchronisation. Ces techniques ne sont pas spécifiées par la présente norme.

Les appareils ayant besoin de convertir le temps TAI au format hh:mm:ss (tel que sur un écran utilisateur) peuvent rendre compte d'un réajustement de secondes intercalaires accumulées en temps universel coordonné (TUC).[6] Le gestionnaire de système doit fournir ce réajustement du TUC à ces appareils. Si l'appareil a besoin de ces informations de réajustement de TUC issues du gestionnaire de système, il convient qu'il les rafraîchisse peu souvent, mais périodiquement, comme au début de chaque mois ou à une quelconque autre limite arbitraire d'horloge.

Tous les appareils dans un réseau conforme à la présente norme partagent la référence de temps TAI avec des degrés variables d'exactitude. Pour prendre en charge une séquence d'événements ou autres opérations de temporisation des processus d'application, il convient que tous les appareils de routage au sein d'un réseau conforme à la présente norme soient exacts à ±10 ms près. L'exigence en matière de précision de l'horloge pour chaque appareil de routage est décrite en 9.1.9.2.2.

Le gestionnaire de système est responsable de coordonner le temps à travers différents sous-réseaux D en sélectionnant les sources appropriées de temps système dans chaque sous-réseau D. Cette coordination n'est pas spécifiée par la présente norme.

---

6 Une liste de tels réajustements est mise à jour à l'adresse ftp://maia.usno.navy.mil/ser7/tai-utc.dat.

Pour prendre en charge une séquence d'événements ou autres opérations de temporisation des processus d'application, il convient que les routeurs dorsaux soient également exacts à ±10 ms près. Ni la conversion des unités de temps utilisées par les routeurs dorsaux ni le réajustement pour s'aligner avec le temps TAI utilisé par les appareils conformes à la présente norme ne sont spécifiés par la présente norme.

Si le gestionnaire de système fait partie intégrante du sous-réseau D, alors la DL dans le gestionnaire de système est responsable de mesurer le temps et de garder l'horloge d'appareil synchronisée. Si le gestionnaire de système est connecté à la dorsale, il est censé maintenir la synchronisation d'horloge avec le reste du réseau et maintenir les informations relatives au temps en unités TAI. Dans ce cas, les techniques pour le faire ne sont pas spécifiées par la présente norme.

Les couches de protocoles qui requièrent le temps TAI courant de l'appareil peuvent l'obtenir auprès du DMO dans le DMAP.

6.3.10.2 Capacités d'exactitude d'horloge d'appareil

Le gestionnaire de système a besoin de connaître l'exactitude d'horloge de chaque appareil. Par exemple, il a besoin savoir si un appareil est capable de maintenir l'exactitude de ±1 ms pendant 30 s sans mise à jour d'horloge. Une telle information relative à un appareil doit être fournie au gestionnaire de système par le DLMO. Cela est décrit en Tableau 147.

6.3.10.3 Sélection de la source de temps système

L'appareil mettant en œuvre le rôle de gestionnaire de système peut également mettre en œuvre le rôle de source de temps système dans un réseau, ou il peut déléguer le rôle de source de temps système à n'importe quel(s) appareil(s) dans le réseau capable(s) de jouer ce rôle comme indiqué par l'attribut Device_Role_Capability dans le DMO de l'appareil. Le gestionnaire de système doit utiliser l'attribut Assigned_Device_Role dans le DMO de l'appareil pour le configurer comme source de temps système. Le gestionnaire de système peut sélectionner la source de temps système en fonction des capacités d'exactitude d'horloge de l'appareil.

La source de temps système est la source ultime du sens de temps dans un sous-réseau D. La source de système au sein d'un sous-réseau D doit être exacte à ±1 s près du temps TAI réel et doit augmenter de façon monotone à un taux qui poursuit le temps TAI avec une erreur maximale de 1×10^{-6}, c'est-à-dire que le taux d'accroissement du temps doit être exact, même si la source de temps elle-même est relativement inexacte.

Si plusieurs sources de temps système existent au sein d'un sous-réseau D, il convient qu'elles se poursuivent l'une l'autre à 0,1 ms près. Si la synchronisation de 0,1 ms parmi les sources de temps système du sous-réseau D ne peut pas être obtenue, le gestionnaire de système doit dicter l'instant où un appareil commute d'une source de temps système à l'autre. L'attribut dlmo.ClockStale décrit en 9.1.9.2.3 et en 9.4.2.14 doit être utilisé pour informer l'appareil de l'instant auquel commuter vers une autre source de temps système. Des chemins de propagation de temps sont décrits en 6.3.10.4. Si les appareils doivent commuter de sources de temps système, les chemins de propagation de temps peuvent être réarrangés par le gestionnaire de système selon ce qui est approprié.

Le gestionnaire de système doit s'assurer que chaque sous-réseau D a au moins une source de temps système. Quelques exemples de sources de temps système incluent:

- Dans une application extérieure, le gestionnaire de système peut désigner quelques appareils avec des capacités de système de positionnement global (GPS) comme sources de temps système. Le temps peut être propagé à travers les sous-réseaux D à partir de ces sources.
- Dans un grand réseau avec une dorsale Ethernet, la dorsale elle-même peut fournir un service de temps qui est synchronisé à 0,1 ms près à une référence de temps partagé

pour les appareils qui sont sur la dorsale. Le gestionnaire de système peut désigner les routeurs dorsaux comme sources de temps système, et le temps peut être propagé de ces routeurs dorsaux vers des appareils dans les sous-réseaux D.

- Le gestionnaire de système peut périodiquement synchroniser à une source de temps distante par l'intermédiaire d'une connexion, sans fil ou câblée, de longue distance. Cette source de temps fournit une exactitude de ±1 s. Le gestionnaire de système peut alors agir comme la source de temps système dans le réseau.

Si les plusieurs sources de temps système existent dans un sous-réseau D, le gestionnaire de système peut assigner une des sources de temps système comme étant la source par défaut et les autres comme étant des secours. Les techniques pour une telle assignation ne sont pas spécifiées par la présente norme.

Des corrections d'horloge au sein d'une source de temps système sont habituellement appliquées à un taux qui peut s'assurer que la correction n'excède pas 0,5 ms dans une période donnée de 30 s. Les corrections discontinues d'horloge sont prises en charge, avec l'ordre donné aux appareils sur un sous-réseau D de réajuster leurs horloges à un instant spécifique. Cela est décrit en 9.1.9.3.6.

6.3.10.4 Topologie de distribution du temps

En plus des sources de temps système, le gestionnaire de système configure également des destinataires d'horloges et des répétiteurs d'horloges dans un sous-réseau D.

Tous les appareils dans un sous-réseau D, à l'exception des sources de temps système, sont configurés comme destinataires d'horloge, c'est-à-dire qu'ils reçoivent les mises à jour périodiques d'horloge issues d'une ou plusieurs sources d'horloge dans leurs voisinages immédiats. Une source d'horloge peut être une source de temps système ou un répétiteur d'horloge.

Les répétiteurs d'horloge sont des destinataires d'horloge qui agissent également comme sources d'horloge pour certains voisins. Les répétiteurs d'horloge propagent le temps à travers un sous-réseau D. L'exigence en matière de précision de l'horloge pour un répétiteur d'horloge est décrite en 9.1.9.2.2.

Les relations source/destinataire d'horloge et, donc, les topologies de distribution du temps, sont définies par le gestionnaire de système. Les chemins de propagation du temps dans ces topologies correspondent habituellement à des graphes de cheminement, mais cela n'est exigé. Les chemins circulaires de propagation de temps ne sont pas autorisés. La propagation d'horloge peut être arrangée afin que les répétiteurs d'horloge fournissent des mises à jour à leurs destinataires peu après qu'ils ont reçu eux-mêmes leurs mises à jour.

Le gestionnaire de système utilise le DLMO d'un appareil pour configurer sa/ses source(s) d'horloge. Le temps d'un destinataire d'horloge peut être mis à jour au cours de chaque interaction avec une source d'horloge désignée. La sélection des sources d'horloge et la temporisation des mises à jour d'horloge sont arrangées par le gestionnaire de système. Ces mises à jour d'horloge sont décrites en 9.1.9.2.

6.3.10.5 Surveillance de l'exactitude de la synchronisation du temps

La gestion de système peut prendre en charge des mécanismes pour recueillir des informations relatives à l'exactitude du sens de temps distribué, ainsi que pour produire une alerte lorsque le sens du temps entre une paire d'appareils varie suffisamment au point de causer des problèmes au sein du système. Les alertes décrites en 9.6 peuvent être utilisées dans ce but par le gestionnaire de système.

Les attributs spécifiés par un fournisseur dans le DMO d'un appareil peuvent être utilisés pour recueillir de telles informations. Les alertes spécifiées par un fournisseur issues du DMO

peuvent être utilisées pour diagnostiquer des problèmes relatifs à la synchronisation d'horloge et à la maintenance d'horloge.

6.3.10.6 System time service object (objet de service de temps système)

Le gestionnaire de système contient l'objet de service de temps système (STSO), qui doit fournir l'ajustement de secondes intercalaires accumulées TUC aux appareils dans le réseau. D'autres attributs spécifiés par un fournisseur peuvent être ajoutés au STSO.

Les attributs du STSO dans le gestionnaire de système sont donnés dans le Tableau 25.

NOTE Pour plus d'informations sur cet ajustement de secondes intercalaires, voir https://en.wikipedia.org/wiki/Leap_second.

Tableau 25 – Attributs du STSO dans le gestionnaire de système

Nom du type d'objet normalisé: System time service object (STSO, objet de service de temps système)				
Identificateur du type d'objet normalisé: 100				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Current_UTC_Adjustment	1	Valeur courante de l'ajustement de secondes intercalaires accumulées du TUC	Type: Integer16 Classification: Dynamic Accessibilité: Read only Valeur par défaut: 35	Les appareils qui ont besoin de convertir le temps TAI au format hh:mm:ss ont besoin de ce réajustement issu du gestionnaire de système; unités en secondes; noter que l'ajustement peut être négatif; noter que le TUC et le TAI sont basés sur des dates de début différentes, mais cette différence n'est pas couverte par cet attribut; le 2012.06.30 23:59:60, la valeur est passée de 34 s à 35 s. Le mécanisme utilisé par le gestionnaire de système pour obtenir cet ajustement n'est pas spécifié.
Next_UTC_Adjustment_Time	2	Temps TAI lorsque la valeur du réajustement TUC changera par rapport à l'actuel	Type: TAITimeRounded Classification: Dynamic Accessibilité: Read only Valeur par défaut: Voir description	Si le gestionnaire de système connaît le prochain temps auquel cette valeur de réajustement TUC changera, le SM est censé indiquer ce temps en unités TAI. Si le gestionnaire de système ne connaît pas ce temps, il est censé indiquer le temps TAI courant et, en conséquence, la valeur de l'attribut Next_UTC_Adjustment doit être la même que la valeur de Current_UTC_Adjustment.
Next_UTC_Adjustment	3	Prochaine valeur de l'ajustement de secondes intercalaires accumulées du TUC	Type: Integer16 Classification: Dynamic Accessibilité: Read only Valeur par défaut: 35	Ajustement TUC qui entrera en vigueur au temps spécifié par l'attribut Next_UTC_Adjustment_Time
Réservé pour les éditions futures de la présente norme	4..63	-	-	-
NOTE Les temps TUC, TAI et GPS sont basés sur des dates de début différentes, mais cette différence n'est pas couverte par cet attribut. Le 2009/01/01, la valeur Current_UTC_Adjustment est passée de 33 s à 34 s. Le temps GPS est toujours en retard de 19 s par rapport au temps TAI. Les informations de temps GPS incluent le décalage nécessaire pour effectuer la conversion au format ou partir du format TUC.				

6.3.11 Configuration de communication de système

6.3.11.1 Généralités

Le gestionnaire de système fournit la commande de la configuration de communication de système en temps d'exécution. Il prend en charge la configuration du réseau, y compris les attributs de la suite de protocoles de la DL à l'AL.

La configuration de communication de système inclut l'assignation d'intervalles de temps, de modèles et de graphes aux appareils dans le réseau. Il convient que le gestionnaire de système prenne en compte les capacités de l'appareil dans le réseau tout en configurant de telles assignations. Le cas échéant, il convient que le système soit reconfiguré pour récupérer après des scénarios de défaillance.

6.3.11.2 Services de contrat

6.3.11.2.1 Définition de contrat

La configuration de communication de système est réalisée au moyen des services de contrat fournis par le gestionnaire de système.

Un contrat se réfère à un accord entre le gestionnaire de système et un appareil dans le réseau qui doit impliquer l'allocation de ressources du réseau par le gestionnaire de système pour prendre en charge un besoin particulier de communication de cet appareil. Cet appareil est la source des messages de communication et l'appareil avec lequel il souhaite communiquer est la destination.

Un contrat doit établir et prendre en charge le chemin de communication entre les appareils dans le réseau qui sont conformes à la présente norme pour prendre en charge le besoin de communication d'un processus d'application. Un processus d'application qui requiert la communication avec un processus d'application dans un autre appareil doit demander un contrat. De telles demandes de contrat peuvent provenir d'un processus d'application dans l'un quelconque des appareils conformes à la présente norme, tels qu'un appareil de terrain, une passerelle, un routeur dorsal, ou un gestionnaire de système.

Tels que montrés à la Figure 27, les contrats doivent être établis par le gestionnaire de système. Ils doivent également être maintenus, modifiés et résiliés par le gestionnaire de système. Le gestionnaire de système doit interagir avec les appareils affectés dans le réseau pour accomplir chacune de ces opérations.

Figure 27 – Interaction UAP-gestionnaire de système au cours de l'établissement d'un contrat

6.3.11.2.2 Directionnalité de contrat

Les contrats doivent être unidirectionnels, c'est-à-dire qu'un contrat particulier est limité à la communication d'une source vers une destination. Pour la communication dans le sens opposé, un contrat séparé doit être établi.

Pour une communication bidirectionnelle entre deux appareils, chaque appareil doit obtenir du gestionnaire de système un contrat indépendant afin d'envoyer ses messages vers l'autre appareil. Les processus d'application homologues dans ces appareils sont censés être configurés de telle manière qu'ils établissent ces contrats avant de commencer la messagerie dans un sens ou dans l'autre. De telles configurations sont faites soit par le gestionnaire de système si les processus d'application sont les DMAP, soit par des applications d'hôte sur des réseaux d'installation, soit par des outils de maintenance tenus à la main si les processus d'application sont des UAP.

6.3.11.2.3 Définition d'un identificateur de contrat

Un ID de contrat (identificateur de contrat) est un identificateur assigné par le gestionnaire de système qui doit être fourni à la source après que les ressources réseau nécessaires ont été allouées pour assurer la prise en charge de la communication demandée.

L'ID de contrat est pertinent au niveau de la source, car il est utilisé par le gestionnaire de système pour informer chaque couche de protocoles dans la source de la façon de traiter les unités de données de service. Les couches ont besoin de cette information avant d'émettre des SDU vers la destination en passant par le réseau. Le processus d'application demandant un contrat doit récupérer l'ID de contrat assigné et doit l'utiliser pour envoyer des unités de données de protocole en descendant la suite de protocoles. Les configurations des suites de protocoles à chaque couche pour traiter de telles PDU de couche supérieure doivent être référencées à l'ID de contrat. Plus de détails sont fournis en 6.3.11.2.9.

Les ID de contrat sont uniques seulement en ce qui concerne la source, à savoir que le gestionnaire de système peut assigner la même valeur numérique d'ID de contrat à deux appareils indépendants pour prendre en charge leurs demandes indépendantes de contrat. La combinaison d'une adresse IPv6Address source et de son ID de contrat doit être unique à travers le réseau.

L'ID de contrat est également pertinent au niveau du routeur dorsal qui prend en charge la communication prévue pour une destination dans le sous-réseau D pris en charge par le routeur dorsal en question. La raison en est que la DL dans le routeur dorsal a besoin de déterminer comment envoyer la NPDU vers sa destination, en passant par le réseau D. La configuration de la DL dans le routeur dorsal pour traiter de telles NPDU doit être référencée à la combinaison de l'adresse IPv6Address source et de son ID de contrat. Plus de détails sont fournis en 6.3.11.2.9.2.

L'ID de contrat n'est pertinent au niveau d'aucun autre appareil intermédiaire sur le chemin entre la source et la destination.

Alors que les ID de contrat sont des valeurs à 2 octets, le gestionnaire de système doit limiter l'assignation des ID de contrat qui s'inscrivent dans la plage 1..255 aux contrats impliquant un ou plusieurs appareils de terrain, car de tels appareils ont habituellement de plus strictes contraintes de mémoire que les autres appareils, permettant de ce fait à de tels appareils de terrain de stocker des ID de contrat en utilisant un seul octet. L'ID de contrat 0 est réservé pour signifier "noContract" (absence de contrat).

6.3.11.2.4 Architecture prenant en charge la messagerie relative à un contrat

6.3.11.2.4.1 Généralités

Le DMO dans chaque appareil et le SCO dans le gestionnaire de système doivent travailler ensemble pour fournir à chaque appareil des services relatifs à un contrat tels que l'établissement de contrat, la maintenance et la modification de contrat, et la résiliation de contrat.

6.3.11.2.4.2 Traitement de services relatifs à un contrat au sein d'un appareil

Le DMO dans chaque appareil doit être responsable de demander, de maintenir, de modifier et de résilier chaque contrat assigné à l'appareil en question.

N'importe quel processus d'application qui requiert un contrat a besoin d'envoyer la demande au DMO qui à son tour doit envoyer la demande au gestionnaire de système. Après que le contrat a été établi, ce processus d'application ne doit pas essayer d'utiliser des ressources réseau excédant celles qui ont été allouées pour ce contrat. Après que le contrat a été établi, ce processus d'application peut ultérieurement demander une modification ou une résiliation de ce contrat, selon le cas.

L'attribut structuré Contract_Table du DMO peut être accessible directement ou indirectement par le SCO présent dans le gestionnaire de système.

Le gestionnaire de système accède indirectement à l'attribut de structure Contract_Table lorsqu'il envoie à l'appareil une quelconque réponse relative au contrat. L'appareil doit mettre à jour l'attribut structuré Contract_Table du DMO chaque fois qu'une réponse de contrat est reçue en provenance du gestionnaire de système. Une nouvelle entrée dans l'attribut structurée Contracts_Table du DMO doit être créée chaque fois qu'une réponse de contrat associée à la création réussie d'un nouveau contrat est reçue en provenance du gestionnaire de système.

Le gestionnaire de système peut directement lire ou écrire n'importe quel élément présent dans l'attribut structuré Contract_Table du DMO une fois que l'entrée de contrat existe dans l'appareil.

6.3.11.2.4.3 Traitement de services relatifs à un contrat dans le réseau

Le SCO dans le gestionnaire de système est responsable d'établir, de maintenir, de modifier et de résilier tous les contrats dans le réseau. Le SCO doit coordonner avec le DMO de chaque appareil l'accomplissement de ces opérations.

6.3.11.2.4.4 System communication configuration object (objet de configuration de communications système)

Les attributs du SCO sont donnés dans le Tableau 26. Les méthodes du SCO sont données dans le Tableau 27.

Figure 28 – Interaction, relative à un contrat, entre DMO et SCO

6.3.11.2.4.5 Messages relatifs à un contrat

Tous les messages relatifs à un contrat échangés entre le SCO dans le gestionnaire de système et le DMO de l'appareil doivent être des messages C/S de niveau application (à savoir écritures et lectures sur des attributs d'objets normalisés et exécutions sur des méthodes d'objets normalisées). Cela est illustré à la Figure 28.

Les messages relatifs à un contrat incluent des demandes de contrat et des réponses de contrat; ceux-ci sont décrits en 6.3.11.2.5.4.

6.3.11.2.5 Etablissement de contrat

6.3.11.2.5.1 Généralités

Des contrats doivent être établis par le gestionnaire de système lorsqu'il reçoit une demande de contrat. Un processus d'application, qui a besoin de communiquer avec un processus homologue à travers le réseau, émet une demande de contrat à destination du DMAP au sein de l'appareil. Le DMO dans cet appareil demandeur doit envoyer cette demande de contrat au SCO dans le gestionnaire de système. Chaque demande de contrat doit inclure des arguments qui sont utilisés par le SCO pour déterminer l'allocation de ressources réseau nécessaires pour prendre en charge cette demande. Ces arguments sont débattus en 6.3.11.2.5.4.

Si un appareil reçoit une demande de service, mais n'a pas déjà un contrat nécessaire afin d'envoyer la réponse de service, il convient qu'il demande un contrat. L'appareil ne doit pas envoyer la réponse de service tant que la réponse de contrat n'a pas été reçue en provenance du SCO du gestionnaire de système et toutes les ressources nécessaires pour prendre en charge le contrat n'ont pas été configurées avec succès.

Les algorithmes utilisés par le SCO pour déterminer l'allocation nécessaire des ressources réseau ne sont pas spécifiés dans la norme, car ils sont tous internes au gestionnaire de système. Les fournisseurs sont censés mettre en œuvre des algorithmes dans le gestionnaire de système qui peuvent déterminer l'allocation nécessaire de ressources réseau pour les demandes de contrat envoyées par les appareils gérés par le gestionnaire de système en question.

En se basant sur cette détermination, le SCO doit allouer les ressources réseau en communiquant avec les appareils nécessaires dans le réseau et en fournissant à chacun de ceux-ci les configurations nécessaires de suites de protocoles. Cela doit inclure la configuration de la destination et de la source. Des détails sont fournis en 6.3.11.2.6. Des contrats doivent être établis pour la communication tant programmée que non programmée entre les applications.

Comme partie intégrante de la configuration de la source, le SCO doit également fournir l'ID de contrat. Lorsque la source reçoit cette configuration, elle doit utiliser ces informations de contrat pour commencer à émettre les TSDU qui avaient besoin de cette prise en charge des communications. Après que le contrat a été établi, la source ne doit pas essayer d'utiliser des ressources réseau excédant celles qui ont été allouées pour ce contrat.

6.3.11.2.5.2 Relation entre contrats et sessions

Des sessions doivent être établies entre l'accès T dans la source et l'accès T correspondant dans la destination. Toute la communication entre ces accès doit être sécurisée en utilisant une clé T qui est émise par le gestionnaire de sécurité. L'établissement de sessions est décrit en 7.5. Les contrats doivent soutenir la communication entre les processus d'application homologues qui résident sur ces accès T dans la pile de protocoles.

Plusieurs contrats peuvent être établis entre ces processus d'application homologues pour prendre en charge les différents besoins de communication. Chaque processus d'application

dans un appareil étant associé à un accès T, tous ces contrats de ces processus d'application homologues doivent utiliser les mêmes accès T dans la source et dans la destination et, donc, la même clé T doit être utilisée pour sécuriser toute la communication qui se produit en utilisant ces multiples contrats.

La clé T entre les accès T correspondants dans la source et dans la destination a besoin d'être établie avant qu'un contrat ne puisse être utilisé pour envoyer des messages par ces accès T. Donc, avant que le DMO n'envoie la demande de contrat au SCO, il est censé vérifier avec le DSMO dans le DMAP pour voir si une clé T existe entre les accès T correspondants dans la source et la destination. Si une telle clé T n'existe pas, le DSMO est censé envoyer une demande de clé T au gestionnaire de sécurité et obtenir une nouvelle clé T. Cette demande de clé T est décrite en 7.6.3. Si une clé T existe déjà entre les accès T correspondants, le DMO peut immédiatement envoyer la demande de contrat au SCO.

Si, pour une raison quelconque, le gestionnaire de sécurité ou l'appareil lui-même met fin à une clé T existante d'un accès T particulier dans l'appareil, tout contrat qui utilise cet accès T particulier échouera, car le message ne sera pas envoyé en descendant la pile de protocoles dans l'appareil. Dans ce cas, la TL est censée renvoyer une indication d'échec au processus d'application qui a généré le message. Ce processus d'application à son tour est censé envoyer une demande de contrat au DMO qui vérifie avec le DSMO l'existence d'une clé T. Le DSMO peut envoyer une nouvelle demande de clé T au gestionnaire de sécurité, s'il y a lieu.

6.3.11.2.5.3 Appareils qui peuvent demander des contrats

Seule une source de trafic doit présenter une demande de contrat au gestionnaire de système. Les autres appareils dans le réseau ne sont pas autorisés à présenter une demande de contrat pour le compte de la source.

6.3.11.2.5.4 Arguments de demande et de réponse de contrat

Les arguments de demande de contrat sont des éléments d'information qui sont fournis par l'application demandeuse de contrat. Ils sont basés sur le besoin de communication auquel le processus d'application demandeur est intéressé.

Il convient de concevoir les applications de telle sorte qu'elles demandent seulement la plus petite quantité de prise en charge de communication nécessaire pour satisfaire à leurs besoins de communication. Par exemple, il convient qu'une application qui a besoin d'éditer des messages périodiques toutes les minutes ne demande pas une période de 10 s.

Les arguments de réponse de contrat doivent inclure l'ID de contrat et autres informations. Ces informations sont destinées à fournir la configuration de suite de protocoles de base nécessaire au niveau de la source.

Les arguments inclus dans les messages de demande et de réponse de contrat sont décrits dans le Tableau 27.

Tableau 27 – Méthode du SCO pour l'établissement, la modification ou le renouvellement de contrat *(1 de 9)*

Nom du type d'objet normalisé: System communication configuration (SCO, objet de configuration de communications système)				
Identificateur du type d'objet normalisé: 102				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
Contract_ Establishment _ Modification_ Renewal	1	Méthode permettant d'établir un nouveau contrat, de modifier ou de renouveler un contrat existant en envoyant une demande au gestionnaire de système		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Contract_Request_ID	Unsigned8	Valeur numérique, assignée de manière unique par l'appareil envoyant la demande au gestionnaire de système, pour identifier la demande faite. Prend la valeur par défaut zéro et se réinitialise à zéro. S'incrémente avec chaque utilisation. Cet ID doit être répété si exactement la même demande est renvoyée de nouveau en raison de l'absence de réponse. Repasse par zéro
	2	Request_Type	Unsigned8	Type de demande de contrat envoyée au gestionnaire de système. Valeurs nommées: 0: nouveau contrat; 1: modification de contrat; 2: renouvellement de contrat. Certains des arguments d'entrée ci-dessous ne sont pas applicables sur la base de cette valeur d'argument; voir le Tableau 28 pour les détails
	3	Contract_ID	Unsigned16	ID de contrat existant qui a besoin d'être modifié ou renouvelé
	4	Communication_ Service_Type	Unsigned8	Type de service de communication pour lequel le contrat est demandé. Valeurs nommées: 0: périodique/programmé; 1: non périodique/non programmé. Certains des arguments d'entrée ci-dessous ne sont pas applicables sur la base de cette valeur d'argument; voir le Tableau 28 pour les détails
	5	Source_SAP	Unsigned16	TDSAP dans la source qui utilisera ce contrat, une fois qu'il est assigné, pour envoyer des messages d'application en descendant la pile de protocoles
	6	Destination_Address	IPv6Address	Adresse de l'appareil vers laquelle la source souhaite envoyer des messages d'application; noter que ces informations peuvent être fournies à la source au cours de la configuration ou au cours de la configuration du processus d'application
	7	Destination_SAP	Unsigned16	TDSAP dans la destination qui sera utilisée pour envoyer ces messages vers l'AL; noter que ces informations peuvent être fournies à la source au cours de la configuration ou au cours de la configuration du processus d'application

Identificateur du type d'objet normalisé: 102				
	Arguments d'entrée			
	Numéro de l'argument	Nom de l'argument	Type de l'argument (type et taille des données)	Description de l'argument
	8	Contract_Negotiability	BitString8	Détermine si le gestionnaire de système peut changer le contrat demandé pour satisfaire aux ressources de réseau disponibles et si le gestionnaire de système peut révoquer ce contrat pour rendre des ressources disponibles pour des contrats de plus haute priorité. Indices nommés: 0: non révocable; 1: non négociable; 2..7: réservés. La négociabilité de contrat est décrite en 6.3.11.2.7.2
	9	Contract_Expiration_Time	Unsigned32	Détermine la durée pendant laquelle il convient que le gestionnaire de système conserve le contrat avant qu'il ne soit résilié; unités en secondes
	10	Contract_Priority	Unsigned8	Demande une priorité de base pour tous les messages envoyés en utilisant le contrat. Valeurs nommées: 0: meilleur effort mis en file d'attente; 1: temps réel séquentiel; 2: tampon temps réel; 3: commande réseau. La priorité de contrat est décrite en 6.3.11.2.7.3
	11	Payload_Size	Unsigned16	Indique la taille maximale en octets (représentée comme taille d'APDU) de charge utile que la source est susceptible de vouloir transmettre. Plage de valeurs: 3..1 252

Tableau 27 *(3 de 9)*

Identificateur du type d'objet normalisé: 102				
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	12	Reliability_And_Publish DoNotAutoRetransmit	Unsigned8	PublishDoNotAutoRetransmit: Le bit 0 indique si la retransmission d'anciennes données d'édition n'est pas prise en charge du fait que la valeur en tampon précédente est toujours écrasée en écriture par les nouvelles données d'édition. Le bit 0 n'est applicable qu'aux communications périodiques et est égal à 0 pour les communications non périodiques (voir 12.12.2 pour une description). [a] Fiabilité: Les bits 1..7 indiquent la fiabilité demandée pour livrer à la destination les APDU émises. Bit 0: Unsigned1: Valeurs nommées: 0: retransmission auto; 1: aucune retransmission auto. Bits 1..7: Unsigned7: Valeurs nommées: 0: faible; 1: moyenne; 2: élevée
	13	Requested_Period	Integer16	Utilisé pour la communication périodique pour identifier la période d'édition souhaitée dans la demande de contrat. Plage valide: Une valeur de $N > 0$ spécifie une période de N s tandis qu'une valeur de $N < 0$ spécifie une période de -1/N s. $N = 0$ désactive la communication
	14	Requested_Phase	Unsigned8	Utilisé pour la communication périodique pour identifier la phase souhaitée (dans les limites de la période d'édition) des publications dans la demande de contrat. Plage valide: 0..99; toute autre valeur indique que l'appareil se préoccupe seulement de la période et ne se préoccupe pas de la phase. Voir 6.3.11.2.7.4

Tableau 27 *(4 de 9)*

	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	15	Requested_Deadline	Unsigned16	Utilisé pour la communication périodique pour identifier le retard maximal de transport de bout en bout souhaité. Unité:10 ms
	16	Committed_Burst	Integer16	Utilisé pour la communication non périodique pour identifier le taux à long terme qui a besoin d'être pris en charge pour les messages client/serveur ou source/puits. Plage valide: Une valeur de $N > 0$ spécifie une fréquence d'APDU par seconde moyenne tandis qu'une valeur de $N < 0$ spécifie une fréquence de -1/N APDU par seconde. $N = 0$ n'est pas valide
	17	Excess_Burst	Integer16	Utilisé pour la communication non périodique pour identifier le taux à court terme qui a besoin d'être pris en charge pour les messages client/serveur ou source/puits. Plage valide: voir argument d'entrée 16
	18	Max_Send_Window_ Size	Unsigned8	Utilisé pour la communication non périodique pour identifier le nombre maximal de demandes client pouvant être simultanément en attente d'une réponse
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Contract_Request_ID	Unsigned8	L'argument d'entrée Contract_Request_ID qui a été reçu dans la demande de contrat correspondante est utilisé comme cet argument de sortie

Tableau 27 *(5 de 9)*

Nom du type d'objet normalisé: System communication configuration (SCO, objet de configuration de communications système)				
Identificateur du type d'objet normalisé: 102				
	Arguments de sortie			
	Numéro de l'argument	Nom de l'argument	Type de l'argument (type et taille des données)	Description de l'argument
	2	Response_Code	Unsigned8	Indique si le gestionnaire de système a réussi à prendre en charge la demande de contrat; indique si la source peut utiliser le contrat immédiatement ou si elle doit attendre; indique également si la communication demandée est prise en charge telle quelle ou si le gestionnaire de système a négocié la demande à la baisse. Valeurs nommées: 0: succès avec effet immédiat; 1: succès avec effet différé; 2: succès avec effet immédiat, mais négocié à la baisse; 3: succès avec effet différé, mais négocié à la baisse; 4: échec sans autre conseil; 5: échec avec conseil de répétition de tentative; 6: échec avec conseil de répétition de tentative et de négociation. Selon la valeur de cet argument, certains des arguments de sortie ci-dessous ne sont pas applicables. Voir le Tableau 29 pour les détails et le 6.3.11.2.12 pour les scénarios d'échec
	3	Contract_ID	Unsigned16	Valeur numérique assignée de façon unique par le gestionnaire de système au contrat étant établi et envoyé à la source. Les ID de contrat sont uniques par appareil. Selon les ressources demandées, plusieurs ID de demande de contrat issus d'un appareil peuvent faire l'objet d'un mapping à un seul ID de contrat. Dans l'appareil, l'ID de contrat est passé dans le champ commande de DSAP de chaque couche et est utilisé pour consulter les actions contractées qui doivent être prises sur la PDU associée pendant qu'elle descend dans la suite de protocoles à chaque couche (valeur 0 réservée signifiant l'absence de contrat)
	4	Communication_Service_Type	Unsigned8	Type de service de communication pris en charger par ce contrat. Unsigned8: voir argument d'entrée 4. Certains des arguments de sortie ci-dessous ne sont pas applicables sur la base de cette valeur d'argument; voir le Tableau 29 pour les détails

Tableau 27 *(6 de 9)*

Nom du type d'objet normalisé: System communication configuration (SCO, objet de configuration de communications système)				
Identificateur du type d'objet normalisé: 102				
	Arguments de sortie			
	Numéro de l'argument	Nom de l'argument	Type de l'argument (type et taille des données)	Description de l'argument
	5	Contract_Activation_Time	TAINetworkTime	Heure de début pour que la source commence à utiliser le contrat assigné
	6	Assigned_Contract_Expiration_Time	Unsigned32	Détermine la durée pendant laquelle le gestionnaire de système doit conserver le contrat avant qu'il ne soit résilié. Unité: s
	7	Assigned_Contract_Priority	Unsigned8	Etablit une priorité de base pour tous les messages envoyés en utilisant le contrat. Voir argument d'entrée 10. La priorité de contrat est décrite en 6.3.11.2.7.3.
	8	Assigned_Max_TSDU_Size	Unsigned16	Indique la TSDU maximale prise en charge en octets qui peut être convertie par la source en taille d'APDU maximale en prenant en compte les tailles de la TL, de la sécurité, des en-têtes d'AL et du TMIC. Plage valide: 70..1 280. Le gestionnaire de système doit prendre en compte l'attribut constant Max_NSDU_Size rapporté par les NLMO de la source et de la destination (voir Tableau 206) lors de la détermination de la valeur de cet argument. La fragmentation est réalisé à la NL si la NPDU excède la taille maximale d'une DSDU. La fragmentation et le réassemblage sont décrits en 10.2.5
	9	Assigned_Reliability_And_PublishDoNotAutoRetransmit	Unsigned8	Voir argument d'entrée 12
	10	Assigned_Period	Integer16	voir argument d'entrée 13
	11	Assigned_Phase	Unsigned8 Plage valide: 0..99	Utilisé pour la communication périodique pour identifier la phase assignée (dans les limites de la période d'édition) des publications dans le contrat

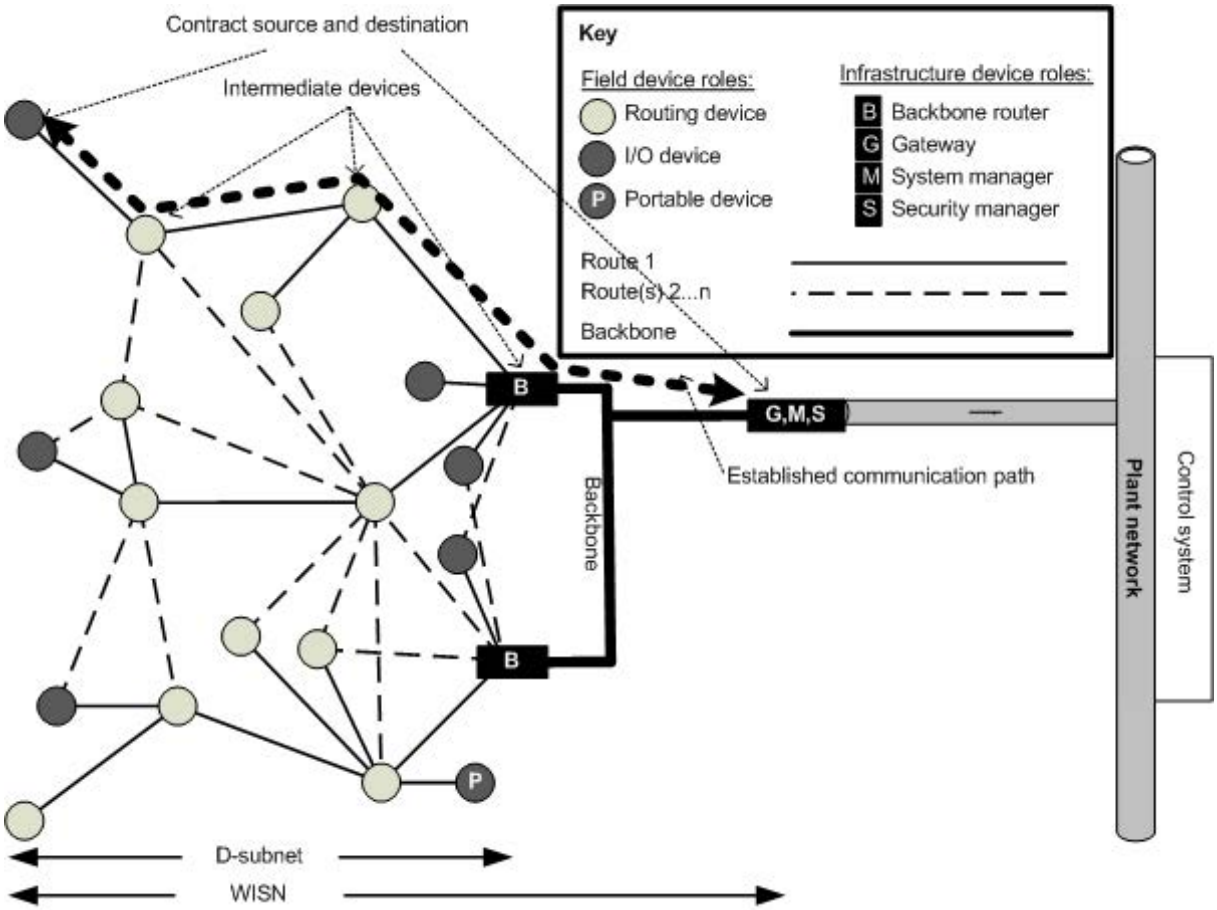
6.3.11.2.6 Configuration de suites de protocoles

6.3.11.2.6.1 Généralités

En tant que partie intégrante de l'établissement de contrat, le SCO doit configurer les appareils nécessaires dans le réseau en fournissant à chacun de ceux-ci les configurations de suites de protocoles nécessaires. Cela doit inclure la configuration de la destination et de la source, telle que montrée à la Figure 29.



Légende

Figure 29 – Source, destination et appareils intermédiaires du contrat

Les appareils intermédiaires dans le réseau qui prennent en charge le chemin de communication établi entre la source et la destination doivent être configurés par le SCO. De tels appareils intermédiaires le long du chemin peuvent inclure aussi bien des routeurs de terrain que des routeurs dorsaux.

6.3.11.2.6.2 Configuration des routeurs de terrain intermédiaires

La configuration des routeurs de terrain intermédiaires doit être limitée à la DLE dans chaque routeur de terrain, car le message de la source vers la destination ne traverse que par la DLE de chaque routeur de terrain le long du chemin.

Les attributs et les méthodes définis pour le DLMO des routeurs de terrain doivent être utilisés par le gestionnaire de système pour configurer les routeurs de terrain intermédiaires.

6.3.11.2.6.3 Configuration des routeurs dorsaux intermédiaires

La configuration des routeurs dorsaux intermédiaires doit être limitée à la NL et, dans certains cas, à la DLE dans chaque routeur dorsal, car le message de la source vers la destination traverse par la DLE dans le cas des routeurs dorsaux qui appartiennent aux sous-réseaux D de source et de destination correspondants et par la NLE de chaque routeur dorsal le long du chemin.

Les attributs et les méthodes définis pour le DLMO et le NLMO des routeurs dorsaux doivent être utilisés par le gestionnaire de système pour configurer les routeurs dorsaux intermédiaires.

6.3.11.2.6.4 Configuration de la destination

La configuration de la destination doit inclure la configuration de toutes les couches de protocoles. Les attributs et les méthodes définis pour le DLMO, le NLMO et le TLMO doivent être utilisés par le gestionnaire de système pour configurer la destination.

6.3.11.2.6.5 Configuration de la source

Les arguments de sortie décrits dans le Tableau 27 sont utilisés à diverses couches de la source pour déterminer le traitement des PDU appartenant à ce contrat.

Les attributs et les méthodes définis pour le DLMO, le NLMO et le TLMO doivent être utilisés par le gestionnaire de système pour configurer la source.

Une réponse de contrat doit être envoyée à la source soit après que toutes les ressources réseau nécessaires ont été configurées, soit après que le gestionnaire de système a déterminé le temps qu'il faudrait pour configurer toutes les ressources réseau. Selon la situation, le gestionnaire de système doit indiquer si le contrat assigné peut être utilisé avec effet immédiat ou avec effet différé. Le diagramme de séquence de message à la Figure 30 illustre le cas de l'effet immédiat.

Après que le contrat a été établi, la source ne doit pas essayer d'utiliser des ressources réseau excédant celles qui ont été allouées pour ce contrat.

6.3.11.2.6.6 Informations de contrat dans l'objet de gestion d'appareil

Le DMO dans la source doit maintenir une liste de tous les contrats assignés, et ce, en utilisant l'attribut de Contracts_Table. Cet attribut doit être basé sur la structure de données Contract_Data. Lorsqu'un nouveau contrat est établi, une nouvelle rangée doit être ajoutée à cet attribut Contracts_Table avec les informations de contrat appropriées. Lorsqu'un contrat existant est modifié ou résilié, la rangée correspondante doit être modifiée ou supprimée dans cet attribut Contracts_Table.

Le SCO peut également modifier les paramètres des attributs Contract_Table en y accédant directement sans échanger les structures Contract_Data entières.

Les éléments de la structure de données Contract_Data sont définis dans le Tableau 30.

Tableau 30 – Structure de données Contract_Data *(1 de 3)*

Nom du type de données normalisé: Contract_Data		
Code du type de données normalisé: 401

Assigned_Excess_Burst	16	Type: Integer16 Classification: Static Accessibilité: Read/write Plage valide: Une valeur de N > 0 spécifie une fréquence d'APDU par seconde moyenne tandis qu'une valeur de N < 0 spécifie une fréquence de -1/N APDU par seconde. N = 0 n'est pas valide. Cet élément est le même que l'argument de sortie Assigned_Excess_Burst en Tableau 27
Assigned_Max_Send_Window_Size	17	Type: Unsigned8 Classification: Static Accessibilité: Read/write Cet élément est le même que l'argument de sortie Assigned_Max_Send_Window_Size en Tableau 27
[a] Le codage de cet attribut est l'inverse de l'attribut associé 7 du Tableau 265.		

6.3.11.2.6.7 Configuration de nouvel appareil

Le processus pour un nouvel appareil à rattacher est décrit en 7.4. En tant que partie intégrante du processus de rattachement pour un nouvel appareil, un contrat entre le nouvel appareil et le gestionnaire de système doit être établi.

Le nouvel appareil doit utiliser la méthode Proxy_System_Manager_Contract définie pour le DMO du routeur d'annonce pour envoyer cette demande de contrat, qui est alors transmise au gestionnaire de système, et pour obtenir la réponse de contrat issue du gestionnaire de système par l'intermédiaire du routeur d'annonce. La méthode Proxy_System_Manager_Contract est définie dans le Tableau 20. Le routeur d'annonce doit utiliser la méthode System_Manager_Contract définie dans le DMSO pour transmettre cette demande de contrat et pour recevoir la réponse de contrat associée au processus de rattachement de ce nouvel appareil. La méthode System_Manager_Contract est définie dans le Tableau 24. Le DMSO travaille avec le SCO pour générer cette réponse de contrat. Lorsque le nouvel appareil obtient cette réponse de contrat, une nouvelle rangée doit être ajoutée à l'attribut Contracts_Table dans le DMO du nouvel appareil avec les informations pertinentes de contrat.

Les arguments de sortie dans ces deux méthodes doivent être basés sur la structure de données New_Device_Contract_Response. Les éléments de la structure de données New_Device_Contract_Response sont définis dans le Tableau 31.

Tableau 31 – Structure de données New_Device_Contract_Response *(1 de 2)*

NL_Outgoing_Interface	9	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeurs nommées: 0: DL; 1: dorsale Cet attribut se rapporte à l'élément correspondant en Tableau 208 et est utilisé pour la configuration de la NL du nouvel appareil afin d'utiliser le contrat affecté au nouvel appareil

Le nouvel appareil doit utiliser les informations de DL fournies dans la DPDU d'annonce pour prendre en charge ce contrat. Après que l'appareil a rejoint le réseau, le gestionnaire de système doit accéder aux attributs de DLMO pertinents dans l'appareil pour modifier ces informations de DL selon le cas. Plus d'informations relatives à ces informations de DL et aux attributs de DLMO sont fournies en 9.1.14.

Si le nouvel appareil n'est pas autorisé par le gestionnaire de sécurité à rejoindre le réseau, il convient que le gestionnaire de sécurité informe le gestionnaire de système pour libérer ce contrat et les ressources réseau associées. Lorsqu'il en a ainsi reçu notification, le gestionnaire de système doit libérer le contrat et les ressources réseau associées d'un tel appareil qui n'est pas autorisé à rejoindre le réseau.

6.3.11.2.7 Qualité de service

6.3.11.2.7.1 Généralités

Le contrat assigné par le gestionnaire de système à un processus d'application demandeur indique également la qualité du service (QoS) pour le service de communication fourni. L'établissement de contrat doit être utilisé pour atteindre cet accord de QoS entre le processus d'application demandeur et le gestionnaire de système.

Un processus d'application qui veut communiquer avec son homologue peut indiquer la QoS désirée pour cette communication dans sa demande de contrat. Les arguments d'entrée décrits dans le Tableau 27 peuvent être utilisés dans ce but.

Les arguments d'entrée Contract_Priority et Payload_Size peuvent être utilisés dans des demandes de contrat concernant les services de communication tant périodiques que non

périodiques. Les arguments d'entrée Requested_Period, Requested_Phase et Requested_Deadline sont pertinents pour les communications périodiques. Les arguments d'entrée Committed_Burst, Excess_Burst et Max_Send_Window_Size sont pertinents pour les communications non périodiques. L'argument d'entrée Reliability_And_PublishDoNotAutoRetransmit contient des informations relatives à la fiabilité souhaitée qui sont pertinentes pour les communications tant périodiques que non périodiques. Il indique également si le processus d'application souhaite réémettre d'anciennes données de communication périodique si de nouvelles données ne sont pas disponibles.

Dans la réponse de contrat, le gestionnaire de système doit indiquer le niveau de QoS fourni pour le service de communication assigné. Les arguments de sortie décrits dans le Tableau 27 correspondant aux arguments d'entrée susmentionnés doivent être utilisés dans ce but.

6.3.11.2.7.2 Négociabilité de contrat

Une source qui envoie une demande de contrat doit également indiquer si, oui ou non, le service et la QoS de communication demandés sont négociables, c'est-à-dire, si, oui ou non, le gestionnaire de système peut assigner un contrat qui fournit un service et une QoS de communication différents de ceux demandés s'il ne peut pas prendre en charge la demande en l'état et si, oui ou non, le gestionnaire de système peut révoquer le contrat s'il y a lieu. Les arguments d'entrée Contract_Negotiability doivent être utilisés dans ce but.

Le Tableau 27 contient les arguments qui sont nécessaires pour la négociation du contrat entre la source et le gestionnaire de système. Si le gestionnaire de système n'est pas capable de prendre en charge une demande de contrat, il peut choisir de fournir des conseils de négociation de contrat. De tels conseils doivent être fournis en utilisant les arguments de sortie dans le Tableau 27 qui commencent par le mot "supportable", par exemple, Supportable_Contract_Priority.

Si le gestionnaire de système n'est pas capable de prendre en charge la demande de contrat au moment où elle a été reçue, mais il prévoit d'être capable de prendre en charge une telle demande dans le futur, il peut indiquer cela en utilisant l'argument de sortie Retry_Backoff_Time.

6.3.11.2.7.3 Priorités de contrat et priorités de message

Deux niveaux de priorité doivent être pris en charge dans le système, la priorité de contrat et la priorité de message.

La priorité de contrat doit établir une priorité de base pour tous les messages envoyés en utilisant ce contrat. Quatre priorités de contrat doivent être prises en charge en utilisant 2 bits comme suit:

- 0b11, Network control (commande réseau). La commande réseau peut être utilisée pour la gestion critique du réseau par le gestionnaire de système.
- 0b10, Real time buffer (tampon temps réel). Le tampon temps réel peut être utilisé pour les communications périodiques dans lesquelles le tampon de messages est écrasé en écriture chaque fois qu'un message plus récent est généré.
- 0b01, Real time sequential (temps réel séquentiel). Le temps réel séquentiel peut être utilisé pour les applications telles que la voix ou la vidéo qui ont besoin d'une livraison séquentielle des messages.
- 0b00, Best effort queued (meilleur effort mis en file d'attente). Le meilleur effort mis en file d'attente peut être utilisé pour les communications client/serveur.

La priorité de message doit établir une priorité au sein d'un contrat. Deux priorités de message doivent être prises en charge en utilisant 1 bit, low = 0 et high = 1 Un autre 1 bit est réservé pour de futures versions de la présente norme et doit être mis à 0.

La priorité de contrat doit être spécifiée par l'application, au cours du temps d'établissement de contrat, dans sa demande de contrat. Elle peut être utilisée par le gestionnaire de système pour établir les chemins préférentiels pour les contrats de haute priorité et pour équilibrer la charge du réseau. Le gestionnaire de système doit acheminer la priorité assignée du contrat vers la source dans la réponse de contrat.

La priorité de message doit être fournie par l'application pour chaque message envoyé en descendant la suite de protocoles. Dans la source, la priorité de message doit descendre la suite de protocoles. La priorité de contrat doit être ajoutée au niveau de la NL. La priorité de contrat doit prévaloir sur la priorité de message.

La priorité combinée de contrat/message doit être utilisée pour résoudre la compétition pour des ressources limitées lorsque ces messages sont transmis à travers le réseau. La DL doit utiliser ces informations pour conduire des décisions de mise en file d'attente lorsqu'elle transmet des messages sur le sous-réseau D. Elles ne doivent être incluses que dans l'en-tête de la DL. Quand le message est envoyé sur une dorsale, la priorité doit être incluse dans les en-têtes de réseau. La NL doit utiliser une priorité pour conduire des décisions de mise en file d'attente sur une dorsale.

6.3.11.2.7.4 Arguments relatifs à la phase

L'argument d'entrée Requested_Phase doit être utilisé par le processus d'application sollicitant le contrat pour demander une phase qui est le décalage temporel par rapport au début d'une période. Le décalage temporel est exprimé sous la forme d'un pourcentage du temps au sein d'une période. Toutes les périodes doivent être calculées de sorte que leurs temps de début soient synchrones du début du temps TAI. Les applications peuvent utiliser l'argument Requested_Phase pour obtenir une exécution en boucle synchronisée et distribuée avec une latence minimale et une gigue bornée. La temporisation exacte de la phase telle qu'elle se rapporte à la DL est spécifiée par le nombre de liaisons, qui est décrit en 9.4.3.7.

6.3.11.2.8 Diagramme de séquence de message d'établissement de contrat

La Figure 30 montre un exemple d'un diagramme de séquence de message pour l'établissement d'un contrat. Cet exemple n'implique pas de temporisations et l'appareil de source accepte le contrat établi par le gestionnaire de système même si ce contrat fournit un service de communication différent de celui demandé.

Figure 30 – Exemple d'établissement de contrat

6.3.11.2.9 Utilisation d'identificateur de contrat

6.3.11.2.9.1 Généralités

L'ID de contrat doit être fourni par le gestionnaire de système à la source. Le processus d'application demandant un contrat doit récupérer l'ID de contrat assigné et doit l'utiliser pour envoyer des unités de données de protocole en descendant la suite de protocoles. Comme cela a été décrit précédemment, chaque couche de la source est configurée pour traiter de PDU de couche supérieure qui sont accompagnées de l'ID de contrat, qui est passé comme un paramètre de commande de DSAP.

La Figure 31 montre comment l'ID de contrat doit être utilisé lorsque l'unité de données descend la suite de protocoles de la source.

Use contract ID to determine max APDU size	Utiliser l'ID de contrat pour déterminer la taille d'APDU maximale
Include contract ID (and message priority) as DSAP control parameter along with PDU	Inclure l'ID de contrat (et la priorité de message) comme paramètre de commande de DSAP, avec la PDU
Use contract ID to determine destination EUI-64 and destination SAP/port, which then determine the session key	Utiliser l'ID de contrat pour déterminer l'EUI-64 de destination et le port/SAP de destination, qui déterminent alors la clé de session
Include contract ID (and message priority) as DSAP control parameter along with PDU	Inclure l'ID de contrat (et la priorité de message) comme paramètre de commande de DSAP, avec la PDU
Use contract ID to determine 128-bit destination address, destination alias, and whether contract ID should be included in network layer header	Utiliser l'ID de contrat pour déterminer l'adresse de destination de 128 bits, le pseudonyme de destination et si, oui ou non, il convient d'inclure l'ID de contrat dans l'en-tête de couche réseau

Anglais	Français
If layer below is DL, include contract ID (and contract priority + message priority) as DSAP control parameter, along with PDU	Si la couche en dessous est DL, inclure l'ID de contrat (et la priorité du contrat + la priorité de message) comme paramètre de commande de DASP, avec la PDU
If layer below is backbone, include traffic class/ priority field and hop limit field in network layer header	Si la couche en dessous est la dorsale, inclure le champ classe de trafic/priorité et le champ limite de sauts dans les en-têtes de couche réseau
Use contract ID to select appropriate DL info (e.g. graph, route, 16-bit DL address of next hop, timeslot template, etc.)	Utiliser l'ID de contrat pour sélectionner les info adéquates de DL (par exemple: graphe, chemin, adresse DL de 18 bits du prochain saut, le modèle d'intervalle de temps, etc.)
Include necessary info in DL header and send packet down to MAC/PHY for transmission	Inclure les info nécessaires dans l'en-tête de DL et descendre le paquet vers la MAC/PHY pour émission

Figure 31 – Utilisation de l'ID de contrat dans la source

6.3.11.2.9.2 Utilisation de l'identificateur de contrat dans les routeurs dorsaux intermédiaires

L'inclusion de l'ID de contrat dans l'en-tête de réseau de la NPDU par la source doit être configurée par le gestionnaire de système. Si le chemin de communication de la source vers la destination passe par la dorsale, alors le gestionnaire de système doit informer la source d'inclure l'ID de contrat dans son en-tête de réseau. Plus de détails sont fournis en 10.5.3.

6.3.11.2.9.3 Relation entre contrats et alertes

L'accès au DMAP est limité au SMAP qui réside dans le gestionnaire de système. En contradiction avec ce principe général, les maîtres d'alertes sont autorisés à accéder à l'objet ARMO présent dans le DMAP. L'accès de DMAP par les maîtres d'alertes doit être limité à l'ARMO, à moins que le maître d'alertes n'utilise la session DMAP-SMAP établie lorsque l'appareil avait rejoint le réseau. L'ARMO dans le DMAP doit émettre les alertes qui appartiennent aux différentes catégories alertes vers les maîtres d'alertes respectifs qui sont décrits dans le 6.2.7.2. Si ces maîtres d'alertes sont des appareils différents avec leurs propres adresses IPv6Address uniques, l'ARMO doit avoir un contrat séparé avec chacun d'eux pour communiquer les alertes. L'ARMO dans l'appareil demande ces contrats au gestionnaire de système par l'intermédiaire du DMO dans l'appareil.

6.3.11.2.10 Résiliation, désactivation et réactivation de contrat

6.3.11.2.10.1 Généralités

Les contrats peuvent être résiliés lorsque le besoin de communication qui avait établi le contrat a été satisfait. Les contrats peuvent également être résiliés lorsque la source ou la destination n'est plus disponible.

Lorsqu'il y a résiliation de contrat, le SCO doit informer le DMO de la source, si la source est encore disponible. Le DMO à son tour informe le processus d'application qui utilisait ce contrat.

Lorsqu'il y a résiliation de contrat, le SCO peut également libérer les ressources réseau qui étaient allouées pour prendre en charge le contrat. En outre, les informations relatives à la sécurité, y compris les clés T entre la source et la destination, peuvent également être supprimées par le gestionnaire de sécurité selon les interactions avec le gestionnaire de système.

Un contrat peut également être désactivé si le besoin de communication est censé être suspendu pendant une période. Le contrat peut être réactivé lorsque le besoin de communication reprend.

6.3.11.2.10.2 Résiliation de contrat lorsqu'un appareil quitte le réseau ou n'est plus disponible

Lorsque le gestionnaire de système détermine qu'un appareil ne fait plus partie du réseau, il doit résilier tous contrats associés à cet appareil et libérer les ressources réseau qui étaient allouées pour prendre en charge ces contrats. Le gestionnaire de système peut utiliser des informations issues d'autres appareils dans le voisinage de cet appareil pour décider que cet appareil ne fait plus partie du réseau. Le gestionnaire de système peut lire l'attribut de dlmo.Neighbor (décrit en 9.4.3.4) de ces appareils voisins pour prendre cette décision.

Lorsqu'un appareil qui a l'attribut de DMO Non_Volatile_Memory_Capability = 1 perd la connectivité réseau/cycles de puissance ou passe par un redémarrage à chaud pour une raison quelconque, il doit maintenir toutes les informations nécessaires relatives aux contrats telles que décrites en 6.3.9.4.2. Ainsi, cet appareil peut reprendre le fonctionnement normal dès qu'il aura rétabli la synchronisation du temps avec le réseau. L'appareil est censé rétablir la synchronisation du temps en se mettant à l'écoute pour détecter des annonces ou en sollicitant des annonces.

Si le gestionnaire de système avait résilié tous les contrats de cet appareil alors que l'appareil ne faisait pas partie du réseau, l'appareil est censé ne pas réussir à reprendre le fonctionnement normal et il est donc censé exécuter un cycle restartAsProvisioned. Cet appareil doit maintenir toutes les informations qui lui avaient été fournies pendant l'étape de configuration avant qu'il n'ait rejoint le réseau pour la première fois ainsi que toutes les informations constantes et statiques présentes dans les UAP.

Lorsqu'un appareil qui a l'attribut de DMO Non_Volatile_Memory_Capability = 0 perd la connectivité réseau, procède à une mise sous/hors tension ou subit un cycle restartAsProvisioned pour une raison quelconque, il est censé répéter le processus de rattachement en utilisant les informations qui lui avaient été fournies pendant l'étape de configuration avant de rejoindre le réseau pour la première fois. Cet appareil doit également retenir toutes les informations constantes et statiques présentes dans les UAP.

Le DMO d'un appareil qui se réinitialise à l'état d'usine par défaut ou subit un cycle restartAsProvisioned doit résilier tous ses contrats en utilisant la méthode définie dans le Tableau 27 avant de se réinitialiser ou de redémarrer.

6.3.11.2.10.3 Résiliation de contrat lorsque la clé T est résiliée

Le gestionnaire de système peut résilier un contrat d'un appareil particulier s'il est informé par le gestionnaire de sécurité qu'une clé T correspondante de l'appareil en question a été résiliée. Tout contrat de l'appareil qui emploie l'accès T correspondant à cette clé T particulière de T peut être résilié.

6.3.11.2.10.4 Appareils qui peuvent résilier, désactiver et réactiver des contrats

Seuls la source ou le gestionnaire de système doit avoir la capacité de résilier un contrat existant de la source.

Seule la source doit avoir la capacité de désactiver et de réactiver un contrat existant de la source.

6.3.11.2.10.5 Arguments de demande et de réponse de résiliation, de désactivation et de réactivation de contrat

Si la source décide de résilier un contrat, elle doit envoyer une demande de résiliation de contrat au SCO. Le SCO doit alors envoyer la réponse en retour à la source l'informant que le contrat a été résilié. La demande doit être une Execute.Request au SCO avec l'ID de contrat comme l'un des arguments d'entrée, et la réponse doit être une Execute.Response avec le statut comme l'argument de sortie. Cela est décrit au Tableau 32.

Si la source décide de désactiver/réactiver un contrat, elle doit envoyer une demande de désactivation/réactivation de contrat au SCO. Le SCO doit alors envoyer la réponse en retour à la source l'informant que le contrat a été désactivé/réactivé. La demande doit être une Execute.Request au SCO avec l'ID de contrat comme l'un des arguments d'entrée, et la réponse doit être une Execute.Response avec le statut comme l'argument de sortie. Cela est décrit dans le Tableau 32.

Tableau 32 – Méthode du SCO pour la résiliation, la désactivation et la réactivation de contrat

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: System communication configuration object (SCO, objet de configuration de communications système)</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 102</th></tr>

</table>

Si le gestionnaire de système décide de résilier un contrat, il doit envoyer une commande de résiliation de contrat avec l'ID de contrat au DMO de la source. Le DMO doit alors retourner une réponse avec le statut.

La méthode du DMO permettant de résilier un contrat existant est décrite dans le Tableau 33.

Tableau 33 – Méthode du DMO pour résilier un contrat

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)		
Identificateur du type d'objet normalisé: 127		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Contract_Terminated	1	Méthode permettant de résilier un contrat existant dans l'attribut Contracts_Table dans le Tableau 10. Cette méthode utilise le modèle de méthode Delete_Row défini dans le Tableau J.5 avec les arguments suivants: Attribute_ID: 26 (Contracts_Table) Index_1: 1 (Contract_ID)

6.3.11.2.10.6 Configuration de suites de protocoles

Lorsque le SCO résilie un contrat, en plus d'informer la source au sujet de la résiliation, il peut également libérer les ressources réseau qui avaient été allouées dans la source, la destination, et les appareils intermédiaires. Des procédures semblables à celles utilisées pour la configuration de suites de protocoles pendant l'établissement de contrat (voir 6.3.11.2.6) peuvent être utilisées par le SCO pour libérer ces ressources réseau.

Le SCO informe le gestionnaire de sécurité, par l'intermédiaire du PSMO, de la résiliation du contrat. Le gestionnaire de sécurité peut décider de supprimer la clé T qui a été assignée pour la communication entre la source et la destination. Dans ce cas, le gestionnaire de sécurité doit envoyer les messages d'effacement de clé T à la source et la destination par l'intermédiaire du PSMO.

6.3.11.2.10.7 Diagramme de séquence de message de résiliation de contrat

La Figure 32 montre le diagramme de séquence de message pour la résiliation d'un contrat initiée par le gestionnaire de système.

Figure 32 – Résiliation de contrat

6.3.11.2.11 Maintenance et modification de contrat

6.3.11.2.11.1 Généralités

Le SCO a besoin de maintenir les contrats établis en s'assurant que les ressources réseau allouées sont disponibles dans des conditions normales. Si les ressources réseau allouées deviennent indisponibles, le SCO peut choisir d'allouer des ressources réseau alternatives afin de continuer à maintenir le contrat établi.

Un contrat peut être modifié si le besoin de communication de l'application correspondante (prise en charge par ce contrat) change. Un contrat peut également être modifié si le gestionnaire de système décide de changer les ressources réseau allouées pour le contrat.

Les modifications de contrat s'inscrivent dans deux catégories:

- modifications conduisant à une réduction des ressources réseau allouées; et
- modifications conduisant à un changement ou à une augmentation des ressources réseau allouées.

Pour les modifications de contrat à l'initiative de l'application, ces deux catégories suivent des étapes légèrement différentes.

Les modifications de contrat qui conduisent à une réduction des ressources réseau allouées peuvent avoir un effet immédiat, à savoir que la source peut commencer à utiliser la configuration de suite de protocoles du contrat modifié dès qu'elle reçoit la réponse accompagnée de ces informations de configuration en provenance du SCO si cette réponse l'indique dans l'argument de sortie Response_Code.

Les modifications de contrat qui conduisent à une augmentation ou à un changement des ressources réseau allouées ne doivent pas avoir un effet immédiat, à savoir que la source ne doit pas commencer à utiliser la configuration de suite de protocoles du contrat modifié dès qu'elle reçoit la réponse accompagnée de ces informations de configuration en provenance du SCO. La raison en est que le SCO a encore besoin d'augmenter ou de changer l'allocation des ressources réseau. La réponse issue du SCO doit inclure un argument de sortie Activation_Time qui indique à la source l'instant auquel elle peut commencer à utiliser la nouvelle configuration de suite de protocoles. Cela conduit à un effet différé.

6.3.11.2.11.2 Appareils qui peuvent modifier des contrats

Seule la source ou seul le gestionnaire de système doit avoir la capacité de modifier un contrat existant de cette source.

6.3.11.2.11.3 Arguments de demande et de réponse de modification de contrat

Si la source décide de modifier un contrat, elle doit envoyer une demande de modification de contrat au SCO. Le SCO doit alors envoyer une réponse en retour à la source l'informant que le contrat a été modifié. La demande doit être une Execute.Request au SCO, et la réponse

doit être un message Execute.Response. Les arguments d'entrée et de sortie sont fournis dans le Tableau 27. Le SCO peut également communiquer avec les appareils pertinents pour allouer ou désallouer les ressources réseau nécessaires.

Si le gestionnaire de système décide de modifier un contrat, il doit envoyer une commande de modification de contrat au DMO de la source en utilisant la méthode Modify_Contract. Le DMO doit alors envoyer une réponse en retour avec le statut. Le SCO peut également communiquer avec les appareils pertinents pour allouer ou désallouer les ressources réseau nécessaires.

La méthode du DMO permettant de modifier un contrat existant est décrite dans le Tableau 34.

Tableau 34 – Méthode du DMO pour modifier un contrat

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)		
Identificateur du type d'objet normalisé: 127		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Contract_Modified	2	Méthode permettant de modifier un contrat existant dans l'attribut Contracts_Table dans le Tableau 10. Cette méthode utilise le modèle de méthode Write_Row défini dans le Tableau J.3 avec les arguments suivants: Attribute_ID: 26 (Contracts_Table) Index_1: 1 (Contract_ID)

6.3.11.2.11.4 Renouvellement de contrat

Le renouvellement de contrat est l'équivalent d'une simple modification de contrat, seul l'argument d'entrée Contract_Expiration_Time étant mis à jour et tous les autres arguments d'entrée restant les mêmes que ceux contenus dans la demande de contrat d'origine.

6.3.11.2.11.5 Configuration de suites de protocoles

Comme partie intégrante de la modification de contrat, le SCO doit configurer / reconfigurer les appareils nécessaires dans le réseau en fournissant à chacun de ceux-ci les configurations nécessaires de suites de protocoles. Cela doit inclure la reconfiguration de la destination et de la source. Des procédures semblables à celles utilisées pour la configuration de suites de protocoles pendant l'établissement de contrat (voir 6.3.11.2.6) peuvent être utilisées par le SCO dans ce but.

6.3.11.2.11.6 Diagramme de séquence de message de modification de contrat

La Figure 33 montre le diagramme de séquence de message pour modifier un contrat avec effet immédiat.

Figure 33 – Modification de contrat avec effet immédiat

6.3.11.2.11.7 Modification de contrat et mises à jour de clé T

Les mises à jour de clé T ne sont pas traitées comme étant des modifications de contrat. De telles mises à jour de clés doivent être envoyées du gestionnaire de sécurité, en passant par l'objet proxy de gestion de sécurité (PSMO) dans le gestionnaire de système, vers les appareils pertinents qui possèdent la session correspondante.

6.3.11.2.12 Scénarios d'échec de contrat

Le Tableau 27 contient des arguments de sortie pour les scénarios d'échec dans lesquels le gestionnaire de système n'est pas capable de prendre en charge la demande de contrat. De tels échecs peuvent se produire si le service de communication demandé ne peut pas être pris en charge du tout, s'il ne peut pas être pris en charge en raison d'une condition temporaire, ou s'il ne peut pas être pris en charge si la demande n'est pas envoyée de nouveau par la source avec des arguments négociés à la baisse. Dans ces cas, le gestionnaire de système peut choisir d'inclure des arguments de sortie dans la réponse qui fournissent quelques conseils à la source. Ceux-ci comprennent Retry_Backoff_Time et Negotiation_Guidance.

6.3.12 Gestion de redondance

Bien que la présente norme incorpore des caractéristiques qui permettent la prise en charge de la connexion sans fil tant simplex que totalement redondante des appareils de terrain vers un réseau dorsal d'installation, la gestion de cette redondance n'est pas spécifiée dans la présente norme.

Le gestionnaire de système est censé être capable de configurer la redondance de chemin dans le sous-réseau D par l'intermédiaire des routeurs de terrain. Les appareils de terrain, y compris les routeurs de terrain, peuvent être configurés pour communiquer avec les routeurs dorsaux redondants.

La redondance au niveau appareil qui requiert une synchronisation entre les appareils redondants pour maintenir les informations d'état est autorisée, mais n'est pas spécifiée dans la présente norme.

6.3.13 Protocoles de gestion de système

La communication relative à la gestion entre appareils conformes à la présente norme et le gestionnaire de système doit être accomplie par l'intermédiaire de la messagerie normalisée de sous-couche d'application, comme cela est décrit en 12.12.

6.3.14 Politiques de gestion et administration de politiques

Les politiques de gestion et l'administration de politiques ne sont pas spécifiées par la présente norme. Une politique par défaut peut être établie pour rendre toutes les informations relatives à un appareil disponibles pour le gestionnaire de système (avec la sécurité appropriée). Des informations de vue d'ensemble peuvent être rendues disponibles à l'extérieur du réseau (par exemple, le réseau fonctionne dans des limites nominales).

6.3.15 Interaction opérationnelle avec le personnel d'exploitation et de maintenance d'installation

Alors que l'appareil mettant en œuvre le gestionnaire de système peut avoir une interface qui permet au personnel d'exploitation et de maintenance d'installation d'observer et commander les performances du réseau et des appareils, cette interface n'est ni obligatoire ni spécifiée par la présente norme.

7 Sécurité

7.1 Généralités

L'Article 7 décrit la fonctionnalité des composants de sécurité, son interface avec la DLE et la TLE, et la protection des données en transit. Il décrit également le rôle de gestionnaire de sécurité.

Le point central de l'Article 7 est de fournir la sécurité d'émission et les aspects de sécurité connexes, y compris le processus de rattachement, l'établissement de session, les mises à jour de clés, et les politiques associées. La présente norme ne traite pas des autres types de sécurité, tels que la sécurité des données au repos ou la sécurité d'appareil physique.

Les messages spécifiques qui sont protégés sont des DPDU à saut unique (saut par saut), les TPDU de transport de bout en bout et les structures de données de gestion de sécurité lorsqu'elles sont transportées dans des APDU. Un flot de données en régime établi utilisant des DPDU et des TPDU qui peuvent être protégées est décrit dans les grandes lignes à la Figure 34. Les points d'extrémité de TLE d'une association de sécurité T sont définis par les appareils de points d'extrémité ainsi que l'application finale.

7.2 Services de sécurité

7.2.1 Vue d'ensemble

Les services de sécurité dans la présente norme sont sélectionnés par la politique. La politique est distribuée avec chaque support cryptographique, permettant une application de politique focalisée. Une seule clé étant utilisée à un instant donné à la DL, à l'exception d'une brève période de commutation de clé, le sous-réseau entier est soumis aux mêmes politiques à la DL. Le gestionnaire de sécurité commande les politiques pour tous les supports cryptographiques qu'il produit.

Les appareils avec les authentifiants appropriés participent aux communications sécurisées avec d'autres appareils par l'utilisation d'une clé symétrique secrète partagée qui est utilisée pour authentifier et, par configuration de sécurité, pour chiffrer leurs messages entre eux.

NOTE 1 Bien que l'authentification implique l'utilisation d'une primitive de chiffrement, elle ne conduit pas à la confidentialité du contenu des messages; un processus de chiffrement (passe) distinct est exigé pour la confidentialité du contenu des messages.

Les services de sécurité sont appliqués au fond de la pile de protocoles de communication, houblon-saut par saut à la DL, et au sommet de la pile de protocoles de communication, bout en bout à la TL. Les services de gestion de sécurité sont également utilisés par l'AL pour le processus de rattachement, la distribution de clé et la gestion de session. Lorsque des clés secrètes sont utilisées, la sécurité de DL protège contre les attaquants qui sont à l'extérieur du système et ne partagent pas de secrets du système, alors que la sécurité de TL protège contre les attaquants qui peuvent être sur le chemin de réseau entre la source et la destination.

Dans les deux cas, une clé de données symétrique (également appelée clé T), partagée parmi des communicants prévus, est utilisée pour ajouter un contrôle d'intégrité de message (MIC) codé et dur du point de vue cryptographique à la PDU et, quand cela est spécifié, pour fournir la confidentialité (par chiffrement) de la charge utile de la PDU. Les attaquants qui ne partagent pas la clé ne peuvent pas modifier le message sans une très forte probabilité de détection et ne peuvent déchiffrer aucune charge utile chiffrée.

L'opération de sécurité est basée sur un sens partagé du temps qui habituellement est aligné avec le temps TAI (voir 5.6). Les DLE et les TLE expéditrices s'authentifient à leurs homologues destinataires en utilisant le temps TAI nominal d'émission de DPDU et le temps approché de la création de TPDU.

Lorsque trois appareils ou plus partagent une clé secrète commune, l'authentification de la source n'est plus garantie au sein du groupe en raison de la clé symétrique partagée. Dans ce cas, l'authentification de la source au sein d'un groupe exige des mécanismes complexes; ainsi, l'authentification du nœud expéditeur spécifique (au sein du groupe de multidiffusion) n'est pas adressée.

Les composants de sécurité principaux des services fournis comprennent:

- l'autorisation de relations de communication sécurisées entre les entités;
- l'authenticité de message, assurant que les messages sont émis par un membre autorisé d'une relation de communications et qu'ils n'ont pas été modifiés alors qu'ils sont en transit entre l'émetteur et le destinataire par une entité à l'extérieur de la relation;
- l'assurance que la temporisation de la livraison et le réarrangement des messages n'excèdent pas les limites envisagées;
- la confidentialité des données qui cache le contenu (autre que la taille) parmi les charges utiles de message; et
- la protection contre les attaques par rejet malveillantes.

Diverses combinaisons de ces services sont fournies tant à une DLE qu'à une TLE. En outre, divers services cryptographiques sont disponibles pour être utilisés par le DSMO pour le processus de rattachement, l'établissement de session et la mise à jour de clé.

NOTE 2 La protection contre la compromission des frontières cryptographiques à l'intérieur du matériel des appareils conformes à la présente norme ne relève pas du domaine d'application de la présente norme. D'autres publications, y compris l'ISO/IEC 15408 et l'ISO/IEC 19790 (similaires à la série [US] NIST FIPS 140), traitent de ces questions. Les décisions de conformité sont laissées à ceux qui évaluent les appareils.

7.2.2 Clés

7.2.2.1 Généralités

Des clés symétriques sont utilisées pour le chiffrement et l'authentification des données (voir 7.3.2.5, 7.3.2.6, 7.3.3.8 et 7.3.3.9). Des clés asymétriques peuvent être utilisées pour le processus de rattachement, voir 7.4. Chaque clé est limitée dans le temps et peut être mise à jour. La Figure 35 montre les types de clés spécifiées par la présente norme et leurs durées de vie associées, y compris un certificat de sécurité à clés asymétriques (s'il en existe un).

Figure 35 – Clés et durées de vie associées

7.2.2.2 Clés symétriques

Toutes les clés symétriques WISN doivent être des valeurs à 128 bits. Les clés symétriques utilisées comprennent:

- Clé globale (global key): clé bien connue qui ne peut pas être utilisée pour garantir la moindre propriété de sécurité et qui n'expire jamais.
- K_open: clé globale utilisée comme clé de rattachement dans l'étape de configuration décrite en 13.3. La valeur réelle pour cette clé est 0x004F 0050 0045 004E 0000 0000 0000 0000, qui est la représentation de la chaîne Unicode de 16 octets terminée par un caractère nul "OPEN(null)(null)(null)(null)". L'identificateur CryptoKeyIdentifier pour cette clé est 1.
- K_global: clé globale utilisée comme clé de rattachement dans la phase de configuration et comme clé D dans la phase de rattachement. L'utilisation de cette clé dans la phase de configuration est décrite en 13.3. La valeur réelle pour cette clé est 0x0049 0053 0041 0020 0031 0030 0030 0000, qui est la représentation de la chaîne Unicode de 16 octets terminée par un caractère nul "ISA(space)100(null)". L'identificateur CryptoKeyIdentifier pour cette clé est 0.
- Clé de rattachement (K_join): clé reçue à la conclusion de l'étape de configuration, qui est utilisée pour rejoindre un réseau pour lequel l'appareil est configuré. La valeur par défaut de la clé K_join est la même que la valeur par défaut de la clé K_global.
- Clé principale (master key): clé dérivée à la conclusion d'un plan d'agrément de clé, qui est utilisée comme KEK pour la communication entre le gestionnaire de sécurité et l'appareil, ainsi que comme base pour dériver d'autres clés. Cette clé expire et a besoin d'être mise à jour périodiquement.
- Clé D: clé utilisée pour chiffrer/déchiffrer et/ou authentifier des DPDU. Cette clé expire et a besoin d'être mise à jour périodiquement.
- Clé T: clé utilisée pour chiffrer/déchiffrer et/ou authentifier des TPDU. Cette clé expire et a besoin d'être mise à jour périodiquement.

7.2.2.3 Clés asymétriques et certificats

La prise en charge de la cryptographie asymétrique est une option de la construction d'un appareil.

Toutes les clés asymétriques WISN doivent avoir une force cryptographique d'au moins 128 bits. Les clés asymétriques utilisées comprennent:

- CA_root: La clé publique de l'autorité de certification qui a signé le certificat de clés asymétriques de l'appareil. Cette clé est communément appelée clé racine; elle est

utilisée lors de la vérification de la vraie identité de l'appareil communiquant le certificat, ainsi que d'un certain nombre d'informations de codage connexes.

- Cert-A: Le certificat de clés asymétriques de l'appareil A, utilisé pour apporter la preuve de la vraie identité de l'appareil, ainsi que d'informations de codage connexes. Elle est utilisée pendant l'exécution d'un protocole authentifié d'établissement de clé à clés asymétriques.

La description du support cryptographique à clés asymétriques est fournie à l'Article H.3.

7.2.2.4 Durée de vie d'une clé

7.2.2.4.1 Généralités

Les clés symétriques sont limitées par une durée de vie et il convient qu'elles soient invalidées après que la durée de vie expire. Pour maintenir la sécurité des communications en cours, les clés de DL et de TL courantes sont mises à jour à intervalles réguliers pendant l'exploitation du système. Les clés de DL sont partagées parmi toutes les DLE communicantes d'un sous-réseau DL tandis que les clés de TL sont partagées uniquement entre une paire (ou potentiellement un ensemble plus grand) de TLE ayant précédemment établi une relation de communications TL. A l'opposé, les KEK sont partagées uniquement entre un appareil et le gestionnaire de système.

Dans la présente spécification, les durées de vie des clés (et les informations connexes) sont définies comme suit:

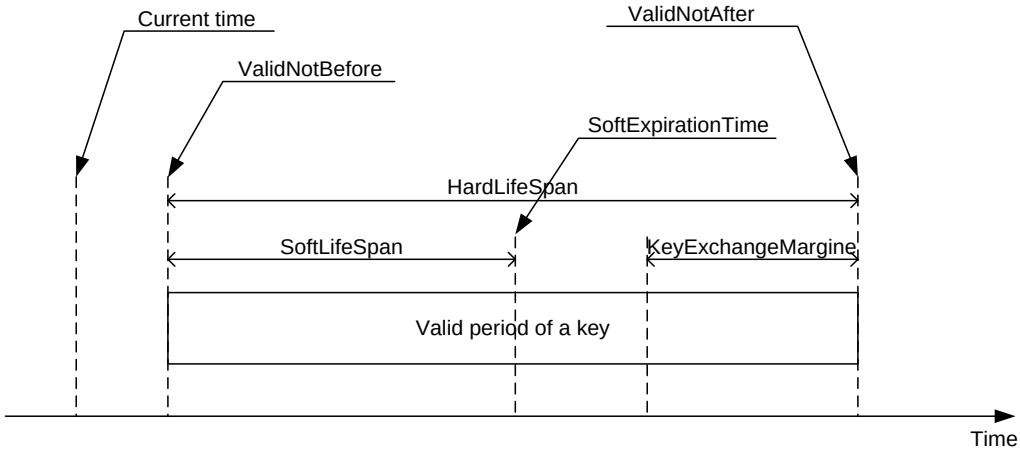
ValidNotBefore:	temps TAI absolu auquel une clé sera activée;
ValidNotAfter:	temps TAI après lequel une clé deviendra non valide;
SoftExpirationTime:	temps TAI auquel il convient qu'un appareil se prépare pour mettre à jour une clé;
HardLifeSpan:	durée relative de ValidNotBefore à ValidNotAfter;
KeyExchangeMargin:	temps minimal exigé pour achever un cycle de mise à jour de clé.

NOTE 1 Etant donné que les valeurs ci-dessus sont utilisées dans le présent document en tant que variables dans des formules, elles utilisent la typographie applicable aux variables.

La relation des définitions des durées de vie ci-dessus est illustrée à la Figure 36. Le mécanisme de mise à jour de clé utilisant ces définitions de temps est décrit en 7.6.

La valeur spéciale 0xFFFF FFFF est utilisée pour désigner des clés qui n'expirent jamais; elle est utilisée pour les clés globales spécifiées en 7.2.2.2. Ainsi, tout calcul du délai d'expiration d'une clé doit remplacer une valeur de résultat 0xFFFF FFFF par 0x0000 0000. De la même manière, toute logique qui détermine si une clé a expiré du fait que le délai d'expiration de la clé se situe dans un passé proche doit déterminer que l'expiration n'est pas arrivée lorsque cette valeur pour le délai d'expiration est 0xFFFF FFFF.

NOTE 2 Les clés de DL, de TL et les clés KEK (maître de l'appareil) sont plus sûres si elles expirent, car les clés qui n'expirent pas augmentent la vulnérabilité du système aux attaques et observations prolongées.



Légende

Anglais	Français
Current time	Instant courant
Valid period of a key	Période valide d'une clé
Time	Temps

Figure 36 – Durées de vie des clés

NOTE 3 Une clé utilisée après sa dure durée de vie peut rendre les communications vulnérables aux attaques par rejet.

Il convient que les certificats à clés asymétriques aient une durée de vie (ValidNotBefore et ValidNotAfter), conformément à la définition en 7.4.6.2.1.1.

La durée de vie KeyExchangeMargin peut être utilisée comme un déclencheur pour invoquer la méthode PSMO.Key_Update_Request() pour garder la session sécurisée continue. Il convient que la valeur de KeyExchangeMargin soit mise à "5 fois DSMO.pduMaxAge" secondes, soit:

- 2 × DSMO.pduMaxAge secondes pour une communication aller-retour par la méthode Security_New_Session();
- 2 × DSMO.pduMaxAge secondes pour une communication aller-retour par la méthode New_Key(); et
- d'autres DSMO.pduMaxAge secondes pour la durée de traitement.

7.2.2.4.2 Expiration de la durée de vie d'une clé

7.2.2.4.2.1 SoftExpirationTime

Lorsque SoftExpirationTime est passé, l'appareil possédant la clé se prépare pour obtenir une nouvelle clé issue du gestionnaire de sécurité. L'appareil peut appeler la méthode PSMO.Security_New_Session() sur le gestionnaire de système pour demander explicitement une clé, ou il peut attendre que sa méthode DSMO.New_Key() soit appelée par le gestionnaire de sécurité. Si l'appareil souhaite être sûr de la mise au jour d'une clé, il convient qu'il appelle explicitement la méthode PSMO.Security_New_Key() sur le gestionnaire de système.

Il n'est pas nécessaire que l'appareil commence le processus de mise à jour de clé immédiatement après l'expiration de SoftExpirationTime. La mise à jour de clé peut être accomplie à tout moment jusqu'à ValidNotAfter. Pour garder la session sécurisée courante avec un homologue, une demande de nouvelle clé peut être émise à tout moment entre SoftExpirationTime et ValidNotAfter. Il convient que l'appareil appelle la méthode PSMO.Security_New_Key() avant (HardExpirationTime – KeyExchangeMargin).

7.2.2.4.2.2 ValidNotAfter

La clé ne doit pas être utilisée dans la communication active après ValidNotAfter et il convient que cette clé soit abrogée par tous les appareils utilisant la clé. Cependant, la clé peut être archivée d'une façon sécurisée, selon la politique d'archivage de clés du système.

7.3 Sécurité de PDU

7.3.1 Généralités

7.3.1.1 Niveau de sécurité

Le niveau de sécurité spécifie la méthode devant être appliquée à certaines PDU. Le niveau de sécurité est constitué d'une combinaison de la taille du MIC (0 bit, 32 bits, 64 bits ou 128 bits) et la question de savoir si la charge utile de PDU associée doit être chiffrée ou non. Le Tableau 35 montre les niveaux de sécurité utilisés dans la présente spécification et leurs attributs de sécurité correspondants.

Tableau 35 – Niveaux de sécurité

Valeur de niveau de sécurité	Attributs de sécurité	Utilisation
0	Aucune	TPDU
1	MIC-32	DPDU Data, DPDU ACK/NAK, TPDU
2	MIC-64	DPDU Data, TPDU
3	MIC-128	TPDU
4	ENC-only	Jamais
5	ENC-MIC-32	TPDU, DPDU Data
6	ENC-MIC-64	TPDU, DPDU Data
7	ENC-MIC-128	TPDU

NOTE 1 Les contraintes de taille et les taux de perte des PhPDU dictent la restriction des DPDU ACK/NAK au mode MIC-32 et la restriction des DPDU Data aux modes MIC-32, ENC-MIC-32, MIC-64 et ENC-MIC-64.

NOTE 2 Les DPDU ACK/NAK ne comportent pas de champ de charge utile auquel le mode ENC pourrait s'appliquer.

NOTE 3 Le mode ENC-only est exclu, car on ne peut pas déterminer si le déchiffrement éventuel est correct.

7.3.1.2 Champ contrôle de sécurité

Le champ contrôle de sécurité fait partie de chaque en-tête de sécurité de DL et de TL. Sa valeur spécifie la présence de l'identificateur de clé et le niveau de sécurité devant être appliqué à la PDU. Les octets du champ SecurityControl doivent être conformes à l'IEEE 802.15.4:2011, 7.4.1.

Le Tableau 36 montre la structure du champ contrôle de sécurité.

Tableau 36 – Structure du champ contrôle de sécurité

Octet	Bits							
	7	6	5	4	3	2	1	0
1	Réservé			CryptoKeyIdentifierMode		Niveau de sécurité		

Le champ CryptoKeyIdentifierMode code la taille du champ CryptoKeyIdentifier qui suit immédiatement le champ SecurityControl dans la PDU. Si le mode d'identificateur de clé est mis à 0, le champ suivant CryptoKeyIdentifier est élidé.

Le champ niveau de sécurité doit être constitué de 3 bits tels que définis dans l'IEEE 802.15.4:2011, Tableau 58, et récapitulés dans le Tableau 35 de la présente norme. Le niveau de sécurité 0x04, correspondant au chiffrage seulement, ne doit jamais être utilisé pour une TPDU, ou la première DPDU d'une transaction D, de la présente norme. Le niveau de sécurité 0x00, correspondant à l'absence de protection, ne doit jamais être utilisé pour une DPDU dans la présente norme.

NOTE Le mode encryption-only (chiffrage seulement) ne fournit aucune protection contre un attaquant actif, car un tel attaquant est capable de complémenter arbitrairement des bits sélectionnés de n'importe quelle PDU en transit. Sans champ d'intégrité dur du point de vue cryptographique, il n'y a aucune méthode sécurisée pour que le destinataire détecte un tel changement et, donc, n'importe quel attaquant actif peut facilement fabriquer une PDU malveillante.

7.3.2 Sécurité de DPDU

7.3.2.1 Généralités

Le degré auquel un appareil est autorisé à participer à un sous-réseau D doit être déterminé par la politique du système appliquée aux authentifiants fournis par l'appareil. Les appareils sans authentifiants doivent être autorisés à une participation pleine, limitée ou nulle au-delà de tentatives de rattachement, telle que déterminée par la politique du système pour de tels appareils.

Toutes les DPDU incluent des champs de sécurité et un DMIC fort du point de vue cryptographique. Les détails des blocs modules de base cryptographiques sont montrés en Annexe H. En mode non sécurisé, la clé distribuée pourrait avoir voyagé sur une voie non sécurisée. Lorsqu'une clé D secrète correctement sécurisée est utilisée, les services de sécurité suivants sont toujours fournis:

a) authentification établie à la source de la DPDU;

b) intégrité de la DPDU; et

c) preuve que la DPDU était reçue à l'instant prévu, assurant le rejet des DPDU

   – dont la source n'était pas un appareil au sein du réseau qui partage une clé de données appropriée, ou

   – qui n'avaient pas été reçues dans la limite d'une fenêtre de temps acceptable par rapport à leur heure de formation ou d'émission, ou

   – qui avaient été reçues précédemment.

NOTE 1 L'autorisation est sous-entendue par le fait que l'appareil expéditeur a connaissance d'une clé de données symétrique partagée. Lorsque la clé n'est pas un secret partagé, l'autorisation s'étend à tous les appareils possibles par l'utilisation de la clé globale. Lorsque la clé est un secret partagé, une inférence est disponible que l'appareil expéditeur a obtenu la clé secrète partagée en provenance d'un gestionnaire de sécurité, et qu'il aurait obtenu la clé seulement si la base de données d'autorisations du gestionnaire de sécurité avait permis la relation de communication protégée qui en résulte. Une telle permission est habituellement basée sur le rôle de l'appareil. Voir Device_Role_Capability (identificateur de type d'objet normalisé 127, identificateur d'attribut 4, dans le Tableau 10) pour une définition des rôles et de leur carte de bits respective.

NOTE 2 La détection de la réception à un instant inadéquat rend inefficaces les attaques contre le flux de messages MAC qui sont basées sur le retard, le réarrangement ou le rejet de DPDU, car la durée d'émission de chaque DPDU est supérieure à la fenêtre de 1 ms dans la limite de laquelle un tel réarrangement aurait été indétectable.

NOTE 3 Ce service utilise l'heure d'émission de l'expéditeur, l'heure de réception du destinataire, et le fait que l'émission et la réception MAC sont fortement concomitantes pour assurer que toute DPDU reçue à un instant intempestif, y compris le rejet de DPDU ou le réarrangement de flux de DPD, sera détectée et la(les) DPDU anachronique(s) rejetée(s).

La quantité de redondance (à savoir la taille de DMIC) qui est utilisée pour fournir l'intégrité de DPDU est sélectionnée par la politique associée à la clé de données pertinente.

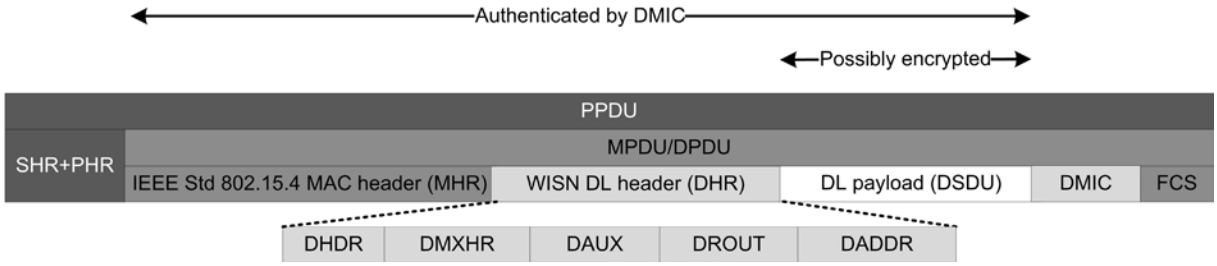
Le service de sécurité de DL complémentaire suivant est sélectionnable par la politique associée à la clé D pertinente:

d) Confidentialité de la charge utile des DPDU (à savoir le chiffrement).

Ce service de confidentialité ne doit pas être offert avec les clés K_open et K_global spécifiées en 7.2.2.2, car l'utilisation de ces clés avec leurs valeurs constantes bien connues rend la confidentialité impossible.

7.3.2.2 Structure de DPDU

La structure d'une DPDU est décrite en 9.3.1, et présentée dans les grandes lignes à la Figure 88 et à la Figure 37 dans la présente norme, avec la DSDU éventuellement chiffrée et les MHR, DHR et DSDU protégés par le DMIC.



Légende

Anglais	Français
Authenticated by DMIC	Authentifié par DMIC
Possibly encrypted	Possiblement chiffré
IEEE Std892.15.4 MAC header (MHR)	En-tête (MHR) de MAC selon l'IEEE std892.15.4
WISN DL header (DHR)	En-tête WISN DL (DHR)
DL payload (DSDU)	Charge utile de DL (DSDU)

Figure 37 – Structure de DPDU

La DPDU complète, du début du MHR jusqu'à la fin de la DSDU, doit être protégée par le DMIC. Les informations pertinentes pour le DSC sont l'en-tête d'extension MAC de la DL (DMXHR) tel que présenté dans le Tableau 112, le numéro de séquence de la DPDU de 8 bits tel que présenté dans le Tableau 110 et le numéro de voie de la PhPDU (dans la plage 0..15).

7.3.2.3 En-têtes de DPDU

7.3.2.3.1 En-tête MAC IEEE 802.15.4

La sécurité de la DPDU est fournie par la pile de protocoles définie dans la présente norme, au-dessus de la sous-couche MAC IEEE 802.15.4. L'en-tête MAC est défini en 9.3.3.2.

7.3.2.3.2 En-tête d'extension MAC de la DL

Le DMXHR présenté dans le Tableau 112 doit contenir 2 champs utilisés par la couche de sécurité. Le premier champ doit contenir le champ contrôle de sécurité tel que présenté dans les grandes lignes en 7.3.1.2. Le second champ doit contenir le CryptoKeyIdentifier tel que spécifié dans l'IEEE 802.15.4:2011, 7.4.3. Dans le DMXHR, le CryptoKeyIdentifier ne doit jamais être élidé avec le CryptoKeyIdentifierMode = 0.

La valeur par défaut du niveau de sécurité pour la DL doit être mise à 1 (MIC-32), correspondant à l'authentification uniquement avec une taille de DMIC de 32 bits.

Pour les étapes de traitement des DPDU, les contraintes suivantes doivent être respectées:

- Les tailles de DMIC de 0 bit et de 128 bits sont interdites, ce qui interdit donc les niveaux de sécurité de DPDU de 0 (none), 3 (MIC-128), 4 (ENC-only) et 7 (ENC-MIC-128).

NOTE 1 Le niveau MIC-64 garantit une protection adéquate pour les DPDU Data, étant donné leur petite taille maximale. Cette contrainte de taille rend la protection MIC-128 problématique tandis que le taux d'erreurs des PhPDU sous-jacentes dicte l'utilisation de MIC pour une meilleure intégrité des DPDU. Un MIC assure également une protection statistique contre du brouillage commis par une personne malveillante qui ne connaît pas la clé de chiffrement symétrique pertinente.

NOTE 2 Le niveau ENC-only n'est pas utile, car on ne peut pas déterminer à la réception si la DPDU est reçue intacte.

- Les DPDU ACK/NAK ne doivent utiliser que des DMIC de 32 bits, quel que soit le niveau de sécurité des DPDU Data d'une transaction D.

NOTE 3 Le niveau MIC-32 garantit une protection adéquate pour les DPDU Data, étant donné leur taille minimale et les contraintes réglementaires en ce qui concerne la durée des messages SCS auxquels ils s'appliquent. Les DPDU ACK/NAK ne transportent aucune charge utile à laquelle les fonctionnalités ENC (chiffrement) de la DL pourraient être appliquées.

7.3.2.4 Interface entre la DLE et le DSC

7.3.2.4.1 Généralités

Le Figure 38 résume la relation entre la DLE et le DSC pour les transactions de DPDU. Cet écoulement couvre le cas normal où une DPDU est émise et acquittée et aucune erreur ne se produit. Pour plus de détail, voir la documentation pour les DSAP correspondants en 7.3.2.4.2, 7.3.2.4.3, 7.3.2.4.4, 7.3.2.4.5, 7.3.2.4.6, 7.3.2.4.7, 7.3.2.4.8 et 7.3.2.4.9.

Toutes les interfaces entre la DLE et le DSC sont des interfaces internes au sein de la DLE, et sont donc inobservables. Par conséquent, elles ne sont pas soumises à une normalisation.

Figure 38 – DLE et traitement de DLS pour un initiateur de transaction D

Le DLE assemble les DPDU devant être protégées. Par convention de documentation, les champs de sécurité dans l'en-tête de la DPDU sont peuplés par le DSC.

Certaines informations de sécurité de DPDU sont fournies par la DLE au DSC:

- le temps TAI programmé de l'intervalle de temps, utilisé dans le nonce pour détecter les DPDU différées et reproduites;

NOTE 1 Le temps TAI programmé transmis au DSC est le temps de début TAI programmé de l'intervalle de temps auquel la transaction D est assignée. Le DSC tronque ce temps à 2^{-10} s (approximativement 1 ms).

NOTE 2 Il existe un scénario selon la présente norme où un seul appareil pourrait initier plusieurs émissions qui ont toutes le même temps de début d'intervalle de temps programmé. Dans ce cas, un appareil (habituellement un routeur dorsal) fonctionne simultanément sur plusieurs voies, en utilisant des modèles d'intervalle de temps synchronisé de telle manière qu'il puisse utiliser soit une seule antenne partagée, soit plusieurs antennes étroitement espacées, programmées de sorte que les émissions sur une ou plusieurs voies ne perturbent pas la réception sur d'autres voies. Alors qu'un tel fonctionnement n'est pas explicitement décrit par la norme, il est également intentionnellement non interdit. La prise en charge d'un tel fonctionnement donne naissance aux deux composants de nonce suivants qui sont inclus dans la construction du nonce de la DPDU.

- le numéro de voie de chaque DPDU, utilisé dans le nonce pour détecter les DPDU construites pour être utilisées dans une voie donnée qui sont rejouées dans le même intervalle de temps dans une autre voie;

NOTE 3 Le numéro de voie utilise la convention de numérotation de voies selon la présente norme, les numéros 0..15 correspondant respectivement aux voies 11..26 de l'IEEE 802.15.4.

- le numéro de séquence d'un seul octet trouvé dans l'en-tête MAC, utilisé dans le nonce pour différencier entre les DPDU Data d'une transaction D et les éventuelles DPDU ACK/NAK qui pourraient être générées dans des intervalles de temps avec le même temps de début TAI programmé;

NOTE 4 Les bits de poids faible de l'octet du numéro de séquence de MHR codent la position d'origine zéro de la DPDU dans la transaction D: 0 pour la DPDU Data, 1 pour la première DPDU ACK/NAK, 2 pour la deuxième DPDU ACK/NAK, etc.

- le DSC a besoin de l'adresse EUI64Address de l'appareil de destination afin de traiter sa DPDU ACK/NAK;

NOTE 5 Lorsqu'elle est connue de la DLE, cette adresse D est récupérée directement de la table dlmo.Neighbor.

- lorsque l'adresse EUI64Address d'une destination en monodiffusion n'est pas connue de la DLE, l'indicateur EUI64Address-requested (adresse EUI64Address demandée) dans l'octet de contrôle de trame de DHDR (Tableau 111) doit être mis à 1), ce qui incite la destination à retourner son adresse EUI64Address dans la DPDU ACK/NAK.

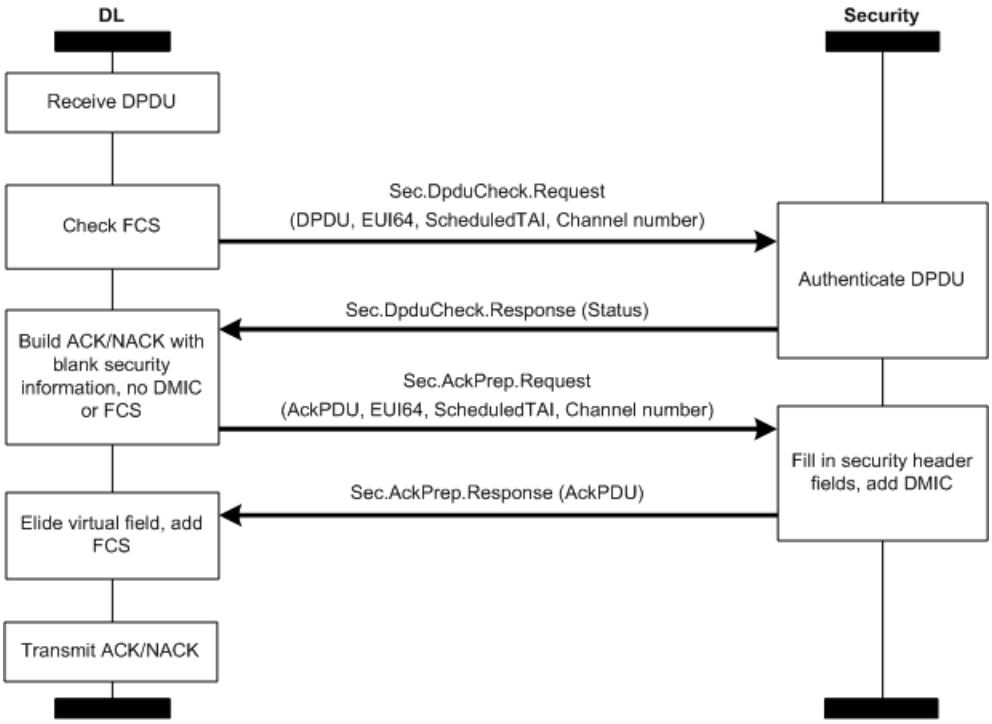
NOTE 6 Le DSC utilise la taille de DSDU pour chiffrer seulement la DSDU et pas l'en-tête de la DPDU, alors que le DMIC protège la DPDU entière. Ce détail n'est pas montré à la Figure 38 ou Figure 39.

La DLE maintient une copie du DMIC sortant à des fins d'utilisation ultérieure pour relier sans ambiguïté les DPDU ACK/NAK de réponse aux DPDU Data de la transaction D. La DLE aboute alors une FCS IEEE 802.15.4 à la DPDU et l'émet sans retard indu.

Lorsque la DLE reçoit une DPDU ACK/NAK, elle demande au DSC d'authentifier la DPDU. Certaines informations de sécurité de DPDU sont fournies par la DLE au DSC:

- Chaque DPDU ACK/NAK doit faire écho au DMIC de la DPDU initiale de la transaction D comme un champ virtuel (voir Tableau 117) dans le calcul de son MIC D. La DPDU ACK/NAK complète, incluant ce champ virtuel, est reconstruite par la DLE avant qu'elle ne soit vérifiée par le DSC.
- L'adresse EUI64Address de l'émetteur de la DPDU ACK/NAK est soit obtenue par consultation, soit fournie au sein de la DPDU ACK/NAK elle-même.
- Le temps TAI programmé du début de l'intervalle de temps de la transaction D, qui est habituellement le même que le temps de début d'intervalle de temps TAI utilisé par l'initiateur de transaction D. Cependant, lorsque le saut de voie lent est utilisé, la DPDU ACK/NAK peut inclure un décalage d'intervalle de temps (voir 9.3.4), auquel cas le nonce formé pour vérifier la DPDU ACK/NAK doit utiliser le temps de début TAI programmé de l'intervalle de temps référencé par le décalage d'intervalle de temps; à savoir, l'intervalle de temps programmé de la DLE donnant acquittement.
- Le numéro de voie pour envoyer la DPDU ACK/NAK est fourni au DSC.
- Le numéro de séquence de MHR est fourni au DSC de la même manière qu'il est fourni pour les DPDU Data de la transaction D.

La Figure 39 illustre la relation entre une DLE et son DSC pour les transactions D dans lesquelles la DLE est un destinataire ou un répondeur des DPDU Data de la transaction D.



Légende

Anglais	Français
Receive DPDU	Recevoir DPDU
Check FCS	Vérifier FCS
Build ACK/NACK with blank security information, no DMIC or FCS	Bâtir ACK/NACK avec des informations de sécurité vides, pas de DMIC ni de FCS

Anglais	Français
Elide virtual field, add FCS	Elider le champ virtuel, ajouter FCS
Transmit ACK/NACK	Emettre ACK/NAK
Security	Sécurité
Authenticate DPDU	Authentifier la DPDU
Fill in security header fields, add DMIC	Remplir les champs d'en-tête de sécurité, ajouter DMIC

Figure 39 – DPDU reçues – DLE et DSC

Lorsqu'elle reçoit une DPDU, la DLE envoie une demande à la DSE d'authentifier la DPDU et, s'il y a lieu, de déchiffrer la charge utile de la DPDU. Le temps TAI programmé et le numéro de voie sont inclus avec cette demande. L'adresse EUI64Address de la source de la DPDU a besoin d'être connue a priori par la DLE, à l'exception du cas d'une demande de rattachement où elle est transportée dans l'en-tête de la DPDU comme adresse source. Le DSC répond normalement avec une authentification positive.

La DLE construit la DPDU ACK/NAK. La DPDU ACK/NAK doit utiliser le même temps TAI programmé que les DPDU Data reçues de la transaction D, excepté lorsque la correction de décalage de lent saut de voie est fournie dans la DPDU ACK/NAK comme débattu ci-dessus. La DPDU ACK/NAK doit également faire écho au DMIC de la DPDU initialement reçue de la transaction D comme un champ virtuel, conformément au Tableau 117. Le DSC sécurise alors la DPDU ACK/NAK, incluant le DMIC de la DPDU comme un champ virtuel. La DLE élide le champ virtuel, aboute une FCS IEEE 802.15.4 et émet la DPDU ACK/NAK.

Lorsque le sens local du temps d'une DLE est corrigé par une DPDU ACK, faisant que son temps est réinitialisé à un intervalle de temps antérieur, il doit y avoir une pause forcée du service, égale à l'ampleur de la correction d'intervalle de temps plus au moins un intervalle de temps.

7.3.2.4.2 Sec.DpduPrep.Request

7.3.2.4.2.1 Généralités

Sec.DpduPrep.Request ordonne au DSC de protéger une unité de données de protocole de DL selon le cas.

7.3.2.4.2.2 Sémantique de la primitive de service

La sémantique de Sec.DpduPrep.Request est comme suit:

```
Sec.DpduPrep.Request    (
    DPDU,
    EUI64,
    ScheduledTAI,
    ChannelNumber,
    AckHandle)
```

Le Tableau 37 spécifie les éléments pour la Sec.DpduPrep.Request.

Tableau 37 – Eléments de la Sec.DpduPrep.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
DPDU (la DPDU devant être émise)	1	Type: OctetString
EUI64 (adresse EUI64Address de l'appareil expéditeur)	2	Type: EUI64Address
ScheduledTAI (32 bits du temps de début de l'intervalle de temps tronqué à une résolution de 2^{-10} s)	3	Type: Unsigned32
ChannelNumber (le numéro de voie utilisée dans la DPDU émise)	4	Type: Unsigned8 Plage valide: 0..15
AckHandle (abstraction qui connecte chaque invocation de Sec.DpduPrep.Request avec le rappel subséquent par Sec.DpduPrep.Response)	5	Type: Extrait

Le DSC fournit à la DLE le contrôle de sécurité (octet 1) approprié et le CryptoKeyIdentifier (octet 2) obtenu à partir du KeyDescriptor pour la clé D courante, pour être utilisés dans le sous-en-tête du DMXHR de la DPDU, dont le format est décrit en 9.3.3.4. Voir 7.3.2.5 sur la sélection de la clé D correcte.

Le DSC peuple le champ DMIC comme spécifié par la politique de la clé D sélectionnée.

7.3.2.4.2.3 Utilisation appropriée

La DLE invoque la primitive Sec.DpduPrep.Request pour ajouter de la protection de sécurité à une DPDU avant qu'elle ne soit émise.

7.3.2.4.2.4 Effet à la réception

A la réception de la primitive Sec.DpduPrep.Request, le DSC commence les étapes appropriées de traitement des DPDU pour protéger la DPDU conformément à ce que dicte la politique.

7.3.2.4.3 Sec.DpduPrep.Response

7.3.2.4.3.1 Généralités

Sec.DpduPrep.Response rend compte du résultat d'une Sec.DpduPrep.Request.

7.3.2.4.3.2 Sémantique

La sémantique de Sec.DpduPrep.Response est comme suit:

```
Sec.DpduPrep.Response    (
    DPDU,
    Status,
    AckHandle)
```

Le Tableau 38 spécifie les éléments pour Sec.DpduPrep.Response.

Tableau 38 – Eléments de Sec.DpduPrep.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
DPDU	1	Type: OctetString
Status (le résultat d'une primitive Sec.DpduPrep.Request)	2	Type: Unsigned Valeurs nommées: 0: réussite; > 0: échec
AckHandle (abstraction qui connecte chaque invocation de Sec.DpduPrep.Request avec le rappel subséquent par Sec.DpduPrep.Response)	3	Type: Extrait

7.3.2.4.3.3 Moment de sa génération

Le DSC génère la Sec.DpduPrep.Response en réponse à une Sec.DpduPrep.Request. La Sec.DpduPrep.Response retourne une valeur de statut qui indique soit SUCCESS et la DPDU peu sécurisée, soit le code d'erreur approprié.

7.3.2.4.3.4 Utilisation appropriée

A la réception de Sec.DpduPrep.Response, la DL reçoit notification du résultat de la demande de protéger une DPDU sortante.

7.3.2.4.4 Sec.DAckCheck.Request

7.3.2.4.4.1 Généralités

Sec.DAckCheck.Request ordonne au DSC de protéger une DPDU ACK/NAK entrante.

7.3.2.4.4.2 Sémantique de la primitive de service

La sémantique de Sec.DAckCheck.Request est comme suit:

```
Sec.DAckCheck.Request     (
    AckPDU,
    EUI64,
    ScheduledTAI,
    ChannelNumber,
    AckHandle)
```

Le Tableau 39 spécifie les éléments pour la Sec.DAckCheck.Request.

Tableau 39 – Eléments de Sec.DAckCheck.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
AckPDU (l'AckPDU devant être vérifiée)	1	Type: OctetString
EUI64 (adresse EUI64Address de l'appareil donnant acquittement)	2	Type: EUI64Address
ScheduledTAI (32 bits du temps de début de l'intervalle de temps tronqué à une résolution de 2^{-10} s)	3	Type: Unsigned32
ChannelNumber (le numéro de voie utilisé pour recevoir la DPDU ACK/NAK entrante)	4	Type: Unsigned Plage valide: 0..15
AckHandle (abstraction qui connecte chaque invocation de Sec.DAckCheck.Request avec le rappel subséquent par Sec.DAckCheck.Response)	5	Type: Extrait

Le DSC vérifie que le DHR de la PDU ACK/NAK DPDU a utilisé le mode DMIC (voir Tableau 118) spécifié par la politique de clé D courante. La clé D utilisée pour authentifier la DPDU ACK/NAK est la même que celle utilisée pour les DPDU Data de la transaction D.

Le DSC vérifie le champ DMIC comme dicté par les étapes de traitement des DPDU et les politiques courantes.

7.3.2.4.4.3 Utilisation appropriée

La DLE invoque la primitive Sec.DAckCheck.Request pour vérifier une DPDU ACK/NAK après sa réception.

7.3.2.4.4.4 Effet à la réception

A la réception de la primitive Sec.DAckCheck.Request, le DSC exécute les étapes appropriées du traitement des DPDU tel que spécifié en 7.3.2.6 pour vérifier la DPDU ACK/NAK reçue.

7.3.2.4.5 Sec.DAckCheck.Response

7.3.2.4.5.1 Généralités

Sec.DAckCheck.Response rend compte du résultat d'une Sec.DAckCheck.Request.

7.3.2.4.5.2 Sémantique

La sémantique de Sec.DAckCheck.Response est comme suit:

```
Sec.DInitialCheck.Response (
    AckPDU,
    Status,
    AckHandle)
```

Le Tableau 40 spécifie les éléments pour Sec.DAckCheck.Response.

Tableau 40 – Eléments de Sec.DAckCheck.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
AckPDU	1	Type: OctetString
Status (le résultat d'une primitive Sec.DAckPrep.Request)	2	Type: Unsigned Valeurs nommées: 0: réussite; > 0: échec
AckHandle (abstraction qui connecte chaque invocation de Sec.DAckCheck.Request avec le rappel subséquent par Sec.DAckCheck.Response)	3	Type: Extrait

7.3.2.4.5.3 Moment de sa génération

Le DSC génère la Sec.DAckCheck.Response en réponse à une Sec.DAckCheck.Request. La Sec.DAckCheck.Response retourne une valeur de statut qui indique soit SUCCESS, soit le code d'erreur approprié.

7.3.2.4.5.4 Utilisation appropriée

A la réception de Sec.DAckCheck.Response, la DL reçoit notification du résultat de la vérification et du déchiffrement éventuel d'une DPDU entrante.

7.3.2.4.6 Sec.DInitialCheck.Request

7.3.2.4.6.1 Généralités

Sec.DInitialCheck.Request ordonne au DSC de vérifier et éventuellement de déchiffrer une unité de données de protocole de DL entrante selon le cas.

7.3.2.4.6.2 Sémantique de la primitive de service

La sémantique de Sec.DInitialCheck.Request est comme suit:

```
Sec.DInitialCheck.Request   (
    DPDU,
    EUI64,
    ScheduledTAI,
    ChannelNumber,
    AckHandle)
```

Le Tableau 41 spécifie les éléments pour la Sec.DInitialCheck.Request.

Tableau 41 – Eléments de Sec.DInitialCheck.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
DPDU (la DPDU devant être vérifiée et éventuellement déchiffrée)	1	Type: OctetString
EUI64 (adresse EUI64Address de l'appareil expéditeur)	2	Type: EUI64Address
ScheduledTAI (32 bits du temps de début de l'intervalle de temps tronqué à une résolution de 2^{-10} s)	3	Type: Unsigned32
ChannelNumber (le numéro de voie utilisé pour recevoir la DPDU entrante)	4	Type: Unsigned Plage valide: 0..15
AckHandle (abstraction qui connecte chaque invocation de Sec.DInitialCheck.Request avec le rappel subséquent par Sec.DInitialCheck.Response)	5	Type: Extrait

Le DSC vérifie que le DMXHR de la DPDU a le contrôle de sécurité (octet 1) approprié en le comparant à la politique courante. Le CryptoKeyIdentifier (octet 2) est utilisé pour récupérer le support de clé correct. Voir 7.3.2.6.

Le DSC vérifie le champ DMIC comme dicté par les politiques courantes.

7.3.2.4.6.3 Utilisation appropriée

La DL invoque la primitive Sec.DInitialCheck.Request pour vérifier et éventuellement déchiffrer une DPDU avant qu'elle ne soit émise.

7.3.2.4.6.4 Effet à la réception

A la réception de la primitive Sec.DInitialCheck.Request, le DSC commence les étapes appropriées de traitement des PDU pour vérifier la DPDU entrante comme cela est dicté par les étapes de traitement des PDU entrantes en 7.3.2.6.

7.3.2.4.7 Sec.DInitialCheck.Response

7.3.2.4.7.1 Généralités

Sec.DInitialCheck.Response rend compte du résultat d'une Sec.DInitialCheck.Request.

7.3.2.4.7.2 Sémantique

La sémantique de Sec.DInitialCheck.Response est comme suit:

```
Sec.DInitialCheck.Response (
                    DPDU,
                    Status,
                    AckHandle)
```

Le Tableau 42 spécifie les éléments pour Sec.DInitialCheck.Response.

Tableau 42 – Eléments de Sec.DInitialCheck.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
DPDU	1	Type: OctetString
Status (le résultat d'une primitive Sec.DpduPrep.Request)	2	Type: Unsigned Valeurs nommées: 0: réussite; > 0: échec
AckHandle (abstraction qui connecte chaque invocation de Sec.DInitialCheck.Request avec le rappel subséquent par Sec.DInitialCheck.Response)	3	Type: Extrait

7.3.2.4.7.3 Moment de sa génération

Le DSC génère la Sec.DInitialCheck.Response en réponse à une Sec.DInitialCheck.Request. La Sec.DInitialCheck.Response retourne une valeur de statut qui indique soit SUCCESS, soit le code d'erreur approprié.

7.3.2.4.7.4 Utilisation appropriée

A la réception de Sec.DInitialCheck.Response, la DL reçoit notification du résultat de la vérification et du déchiffrement éventuel d'une DPDU entrante.

7.3.2.4.8 Sec.DAckPrep.Request

7.3.2.4.8.1 Généralités

Sec.DAckPrep.Request ordonne au DSC de protéger une DPDU ACK/NAK selon le cas.

7.3.2.4.8.2 Sémantique de la primitive de service

La sémantique de Sec.DAckPrep.Request est comme suit:

```
Sec.DAckPrep.Request      (
    AckPDU,
    EUI64,
    ScheduledTAI,
    ChannelNumber,
    AckHandle)
```

Le Tableau 43 spécifie les éléments pour la Sec.DAckPrep.Request.

Tableau 43 – Eléments de Sec.DAckPrep.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
AckPDU (inclut l'en-tête virtuel)	1	Type: OctetString
EUI64 (adresse EUI64Address de l'appareil donnant acquittement)	2	Type: EUI64Address
ScheduledTAI (32 bits du temps de début de l'intervalle de temps tronqué à une résolution de 2^{-10} s)	3	Type: Unsigned32
ChannelNumber (le numéro de voie utilisé pour émettre la DPDU ACK/NAK)	4	Type: Unsigned8 Plage valide: 0..15
AckHandle (abstraction qui connecte chaque invocation de Sec.DAckPrep.Request avec le rappel subséquent par Sec.DAckPrep.Response)	5	Type: Extrait

Le DSC peuple la DPDU ACK/NAK avec le contrôle de sécurité (octet 1) approprié tel que décrit dans le Tableau 118. Dans le cas où plusieurs clés D sont actuellement valides, la clé utilisée pour authentifier la DPDU ACK/NAK est la même qui est utilisée pour la DPDU correspondante pour cette DPDU ACK/NAK.

Le DSC peuple le champ DMIC comme dicté par les politiques courantes. Noter que le champ DMIC dans une PDU ACK/NAK est toujours de 32 bits.

7.3.2.4.8.3 Utilisation appropriée

La DL invoque la primitive Sec.DAckPrep.Request pour protéger une DPDU ACK/NAK avant qu'elle ne soit émise.

7.3.2.4.8.4 Effet à la réception

A la réception de la primitive Sec.DAckPrep.Request, le DSC commence les étapes appropriées de traitement des PDU pour protéger la DPDU ACK/NAK conformément à ce que dicte la politique. Noter que la DPDU ACK/NAK est seulement authentifiée et n'est jamais chiffrée.

7.3.2.4.9 Sec.DAckPrep.Response

7.3.2.4.9.1 Généralités

Sec.DAckPrep.Response rend compte du résultat d'une Sec.DAckPrep.Request.

7.3.2.4.9.2 Sémantique

La sémantique de Sec.DAckPrep.Response est comme suit:

```
Sec.DAckPrep.Response    (
    AckPDU,
    Status,
    AckHandle)
```

Le Tableau 44 spécifie les éléments pour Sec.DAckPrep.Response.

Tableau 44 – Eléments de Sec.DAckPrep.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
AckPDU	1	Type: OctetString
Status (le résultat d'une primitive Sec.DAckPrep.Request)	2	Type: Unsigned Valeurs nommées: 0: réussite; > 0: échec
AckHandle (abstraction qui connecte chaque invocation de Sec.DAckPrep.Request avec le rappel subséquent par Sec.DAckPrep.Response)	3	Type: Extrait

7.3.2.4.9.3 Moment de sa génération

Le DSC génère la Sec.DAckPrep.Response en réponse à une Sec.DAckPrep.Request. La Sec.DAckPrep.Response retourne une valeur de statut qui indique soit SUCCESS, soit le code d'erreur approprié.

7.3.2.4.9.4 Utilisation appropriée

A la réception de Sec.DAckPrep.Response, la DL reçoit notification du résultat de la demande de vérifier une AckPDU entrante.

7.3.2.4.10 Construction du nonce pour les DPDU

La présente norme utilise une construction de nonce de DPDU différente de celle de l'IEEE 802.15.4. Un nonce de 13 octets est exigé pour le moteur CCM*. Le nonce doit être construit comme une concaténation allant du premier (le plus à gauche) octet au dernier (le plus à droite) octet des champs de données conformément au Tableau 45, où:

- l'adresse EUI64Address doit être utilisée comme une matrice de 8 octets (dans la convention MSB) de la même manière que l'adresse source du nonce CCM* dans l'IEEE 802.15.4:2011, 7.3.2;
- le temps TAI doit être représenté par les 32 bits de poids faible du temps TAI en unités de 2^{-10} s suivant la description dans le Tableau 46;
- le dernier octet doit être construit comme suit:
  - Le bit 7 doit être zéro, réservant ainsi la valeur 0xFF pour la couche transport (voir Tableau 57).
  - Les bits 6..3 (4 bits) doivent indiquer la voie radio d'émission, dans la plage 0..15, correspondant aux numéros de voies 11..26 de l'IEEE 802.15.4, dans le même ordre.
  - Les bits 2..0 doivent être copiés à partir des 3 bits de poids faible correspondants du numéro de séquence du MHR.

Tableau 45 – Structure du nonce de DPDU WISN

<table>
<tr><th rowspan="2">Octet</th><th colspan="8">Bits</th></tr>
<tr><th>7</th><th>6</th><th>5</th><th>4</th><th>3</th><th>2</th><th>1</th><th>0</th></tr>
<tr><td>1</td><td colspan="8" rowspan="3">Adresse EUI64Address de l'initiateur de la DPDU</td></tr>
<tr><td>…</td></tr>
<tr><td>8</td></tr>
<tr><td>9</td><td colspan="8" rowspan="3">32 bits de poids faible du temps TAI du début d'intervalle de temps nominal (en unités de 2^{-10} s)</td></tr>
<tr><td>…</td></tr>
<tr><td>12</td></tr>
<tr><td>13</td><td>Réservé = 0</td><td colspan="3">Numéro de voie (0..15)</td><td colspan="4">3 bits de poids faible du numéro de séquence du MHR</td></tr>
</table>

Le temps TAI utilisé doit être une représentation fractionnaire à point fixe tronquée sur 32 bits du temps TAI à une granularité de 2^{-10} s et un intervalle de mesure de 2^{22} s. Avec cette représentation, il se passera plus de 48,5 jours avant que la même valeur du temps TAI ne se reproduise. Donc, la durée de vie maximale d'une clé D doit être de 48,5 jours avant qu'il ne soit nécessaire de déployer une nouvelle clé D. Le temps TAI pour cette opération doit être celui maintenu par la DLE.

NOTE 1 Il est important que la valeur de la représentation 32 bits du temps TAI ne se reproduise pas pendant la durée de vie d'une clé symétrique secrète pertinente afin d'éviter une collision potentielle de nonce avec la réutilisation qui entraînerait un keystream identique.

La représentation dans le nonce D de ce temps TAI de 32 bits tronqué, spécifié à 2^{-10} s, est décrite dans le Tableau 46.

Tableau 46 – Structure du temps TAI tronqué de 32 bits utilisé dans le nonce D-

Octet	Bits							
	7	6	5	4	3	2	1	0
1	Temps TAI tronqué (bits avec un poids de $2^{21}..2^{14}$ s)							
2	Temps TAI tronqué (bits avec un poids de $2^{13}..2^{6}$ s)							
3	Temps TAI tronqué (bits avec un poids de $2^{5}..2^{-2}$ s)							
4	Temps TAI tronqué (bits avec un poids de $2^{-3}..2^{-10}$ s)							

Les 3 bits de poids faible du numéro de séquence du MHR, ainsi que le numéro de voie, sont utilisés pour construire le dernier octet d'un nonce D. La DLE expéditrice doit assurer que les bits du numéro de séquence du MHR utilisés dans le nonce D sont uniques parmi tous ceux qu'il génère dans la limite du même intervalle de 2^{-10} s pour la même voie et la même clé D (voir 9.3.3.2 et 9.3.4). La valeur de 0xFF ne doit pas être utilisée pour le MHR. Sachant que ce nonce D a tout au plus huit valeurs distinctes pour une voie donnée et un intervalle de 2^{-10} s, une DLE ne doit pas émettre plus de huit DPDU par 2^{-10} s sur la même voie en utilisant la même clé D.

NOTE 2 L'inclusion du numéro de voie dans le nonce D fournit la prise en charge pour les appareils qui fonctionnent simultanément sur plusieurs voies.

NOTE 3 La construction du numéro de séquence du MHR est décrite en 9.3.3.2.

7.3.2.5 Traitement d'une DPDU devant être émise

Les entrées à la procédure de sécurité des DPDU sont:

- la DPDU devant être sécurisée;
- l'adresse EUI64Address de la DLE source;
- le temps de début TAI nominal de l'intervalle de temps utilisé pour la transaction D;
- l'octet du numéro de séquence du MHR; et
- le numéro de voie (0..15) devant être utilisé pour la transaction D.

Les sorties délivrées par cette procédure sont:

- le statut de la procédure; et
- si ce statut est succès, la DPDU sécurisée.

La procédure de sécurité pour les DPDU qui sont construites pour l'émission est constituée des étapes suivantes:

a) La procédure doit obtenir le KeyDescriptor issu du Tableau 93 satisfaisant aux critères de sélection suivants:

   1) Les entrées avec KeyUsage = '0x00' (autrement dit la clé D).Dans le cas initial, où une DLE en rattachement n'a aucun KeyDescriptor, l'appareil en rattachement crée un KeyDescriptor avec K_global. Le KeyDescriptor doit inclure au moins les paramètres suivants:

      CryptoKeyIdentifier = 0

      Security Level = 0x01 (MIC-32)

      KeyUsage = 0x00 (clé de groupe pour traitement de PDU)

      Key lifetime = never-expires (0xFFFF FFFF)

   2) De ces entrées, les entrées valides pour la période courante, satisfaisant à l'inégalité

      ValidNotBefore < temps courant < ValidNotAfter

      doivent être sélectionnées. Si aucune n'est disponible, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

3) De ces entrées, si au moins deux clés sont valides pour le temps courant et la procédure avait été appelée à partir d'une DAckPrep.Request ou DAckCheck.Request, la procédure doit sélectionner la clé utilisée pour authentifier les DPDU Data de la transaction D.

   Autrement, si au moins deux clés sont valides pour le temps courant, la procédure doit sélectionner la clé avec la plus grande valeur de ValidNotAfter.

4) De ces entrées, si au moins deux clés ont le même ValidNotAfter, la procédure doit sélectionner la clé avec le plus grand ValidNotBefore.

5) De ces entrées, si au moins deux clés ont le même SoftExpirationTime, la procédure doit sélectionner la clé avec le CryptoKeyIdentifier le plus élevé.

b) La procédure doit récupérer la politique dans le KeyDescriptor sélectionné.

c) La procédure doit déterminer si la DPDU devant être sécurisée satisfait à la contrainte relative à la taille maximale des DPDU, comme suit:

1) La procédure doit établir la taille M, en octets, du champ d'authentification de DMIC à partir du niveau de sécurité.

2) Le champ CryptoKeyIdentifierMode dans le DMXHR doit avoir la valeur 1. Si le DMXHR inclut le champ décalage d'intervalle de temps de saut lent de voie, la taille de DMXHR est de 3 octets; autrement, elle est de 2 octets.

3) La procédure doit déterminer l'expansion de données qui en résulte comme étant (DMXHR_size + M).

4) La procédure doit vérifier si la taille de la DPDU devant être sécurisée, y compris l'expansion des données, est inférieure ou égale à la taille de DPDU maximale. Si cette vérification échoue, la procédure doit retourner un statut de DPDU_TOO_LONG.

d) La procédure doit utiliser le temps TAI programmé du début de l'intervalle de temps, tel que décrit dans le Tableau 46. S'il y a un potentiel pour que l'appareil envoie plusieurs DPDU avec la même valeur de temps TAI, alors la procédure doit sélectionner une valeur devant être acheminée dans l'en-tête du MHR de la DPDU qui est différente de toutes les autres valeurs de ce type lancées par l'appareil à cette valeur particulière du temps TAI. Une procédure pour déterminer le numéro de séquence à partir duquel le MHR est dérivé est définie en 9.3.3.2.

e) La procédure doit insérer le DMXHR dans la DPDU tel que décrit dans les grandes lignes dans le Tableau 112, avec les champs mis comme suit:

1) Le sous-champ niveau de sécurité du champ contrôle de sécurité doit être mis au niveau de sécurité 001 par défaut.

2) Le sous-champ CryptoKeyIdentifierMode du champ contrôle de sécurité doit être mis au paramètre CryptoKeyIdentifierMode 01 par défaut.

f) La procédure doit mettre l'octet CryptoKeyIdentifier dans le DMXHR. Voir Tableau 112.

g) La procédure doit insérer le numéro de séquence du MHR dans le MHR de DPDU Data. Voir Tableau 110.

h) La procédure doit utiliser l'adresse EUI64Address de l'appareil émetteur, les 32 bits de poids faible du temps TAI en 2^{-10} s, les 3 bits de poids faible du numéro de séquence du MHR, et le numéro de voie pour construire le nonce selon le Tableau 45.

i) La procédure doit utiliser le nonce, le support de clé, l'en-tête, la charge utile et le mode CCM* de fonctionnement tels que décrits dans l'IEEE 802.15.4:2011, 7.3.4, pour sécuriser la DPDU:

1) Si le paramètre SecurityLevel spécifie l'utilisation du chiffrement (voir IEEE 802.15.4:2011, Tableau 58), l'opération de chiffrement doit être appliquée seulement au champ de la charge utile de la DPDU. Le champ de charge utile correspondant est passé au processus de transformation CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.4, comme étant la charge utile non sécurisée. La charge utile chiffrée résultante doit être substituée à la charge utile d'origine.

2) Les champs restants dans la DPDU, jusqu'au champ de charge utile non compris, doivent être passés au processus de transformation CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.4, comme étant le champ non-charge utile.

3) L'ordonnancement et la manière exacte d'accomplir les opérations relatives au chiffrement et à l'intégrité ainsi que le placement des données chiffrées ou du code d'intégrité ainsi obtenus au sein du champ de charge utile de la DPDU doivent être tels que définis dans l'IEEE 802.15.4:2011, 7.3.4.

j) La procédure doit retourner la DPDU sécurisée et un statut de SUCCESS.

7.3.2.6 Traitement des DPDU reçues

Les entrées à la procédure de sécurité pour les DPDU reçues sont la DPDU devant être dépourvue de sécurité, le numéro de voie sur lequel la DPDU a été reçue, et le temps TAI nominal du début de l'intervalle de temps dans lequel la DPDU a été reçue. Les sorties délivrées par cette procédure sont la DPDU non sécurisée, le niveau de sécurité, le CryptoKeyIdentifierMode, le CryptoKeyIdentifier et le statut de la procédure. Toutes les sorties de cette procédure sont supposées être non valides, jusqu'à ce que cela soit explicitement établi dans cette procédure. Il est supposé que les KeyDescriptors avec un seul et unique appareil ou un certain nombre d'appareils ont été établis par le DSMO.

La procédure de sécurité à la réception des DPDU est constituée des étapes suivantes:

a) La procédure doit mettre le niveau de sécurité et le CryptoKeyIdentifierMode aux valeurs des sous-champs correspondants du champ contrôle de sécurité du DMXHR de la DPDU entrante, et le CryptoKeyIdentifier aux valeurs des sous-champs correspondants du champ CryptoKeyIdentifier du DMXHR de la DPDU devant être dépourvue de sécurité.

b) La procédure doit obtenir le KeyDescriptor issu du Tableau 93 satisfaisant aux critères de sélection suivants:

1) Les entrées avec KeyUsage = '0x00' (autrement dit la clé D). Dans le cas initial, où un appareil en rattachement n'a aucun KeyDescriptor, l'appareil en rattachement crée un KeyDescriptor temporaire avec K_global. Le KeyDescriptor doit inclure au moins les paramètres suivants:

CryptoKeyIdentifier = 0

Security Level = 0x01 (MIC-32)

KeyUsage = 0x00 (clé de groupe pour traitement de PDU)

Key lifetime = never-expires (0xFFFF FFFF)

NOTE L'utilisation du KeyDescriptor pour K_global est décrite en 9.1.10.

2) De ces entrées, l'entrée avec le CryptoKeyIdentifier concordant au CryptoKeyIdentifier de la PDU entrante doit être sélectionnée.

3) Si cette procédure échoue, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

c) La procédure doit déterminer si le niveau de sécurité de la DPDU entrante se conforme à la politique de niveau de sécurité en comparant le SecurityLevel du KeyDescriptor concordant obtenu dans l'étape b) ci-dessus. S'il y a une discordance, la procédure doit retourner avec un statut IMPROPER_SECURITY_LEVEL.

d) Si la durée de vie dans le KeyDescriptor est finie (> 0x0000), la procédure doit vérifier que le numéro de séquence du MHR de 8 bits n'a pas été reçu précédemment pour la même valeur de l'adresse EUI64Address de la source, la même représentation fractionnaire à point fixe sur 32 bits du temps TAI et la même clé. Si cette vérification échoue, la procédure doit retourner avec un statut DUPLICATE_DPDU.

e) La procédure doit alors utiliser l'adresse EUI64Address de l'expéditeur, le temps TAI programmé, et les 3 bits de poids faible du numéro de séquence du MHR, et le numéro de voie pour générer le nonce conformément au Tableau 45. En plus, la procédure doit vérifier que le numéro de séquence du MHR de 8 bits n'est pas 0xFF. Si le numéro de

séquence du MHR de 8 bits est 0xFF, la procédure doit retourner avec un statut INVALID_SEQUENCE_NUMBER.

f) La procédure doit utiliser le nonce, la crypto clé issue du KeyDescriptor obtenu dans l'étape b), les en-têtes réels (les champs non-charge utile), la charge utile et le MIC de la DPDU entrante et le mode de fonctionnement CCM* tels que décrits dans les opérations (voir l'IEEE 802.15.4:2011, 7.3.5) pour authentifier et, si spécifié, déchiffrer la DPDU:

   1) Si le niveau de sécurité spécifie l'utilisation du chiffrement (voir l'IEEE 802.15.4:2011, Tableau 58), l'opération de déchiffrement doit être appliquée seulement au champ charge utile réel de la DPDU (voir l'IEEE 802.15.4:2011, 5.2.2.2.2). Le champ de charge utile correspondant doit être passé au processus de transformation inverse CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.5, comme étant la charge utile sécurisée.

   2) Les champs restants dans la DPDU doivent être passés au processus de transformation inverse CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.5, comme étant les champs non-charge utile (voir IEEE 802.15.4:2011, Tableau 57).

   3) L'ordonnancement et la manière exacte d'accomplir les opérations relatives au déchiffrement et à la vérification d'intégrité ainsi que le placement des données déchiffrées ainsi obtenues au sein du champ de charge utile de la DPDU doivent être tels que définis dans l'IEEE 802.15.4:2011, 7.3.5.

g) Si le processus de transformation inverse CCM* échoue, la procédure doit établir la DPDU non sécurisée comme étant la DPDU devant être dépourvue de sécurité et retourner un statut SECURITY_ERROR.

h) Si la durée de vie dans le KeyDescriptor expire, la procédure doit insérer la valeur nonce (inclut le numéro de séquence de MHR, le numéro de voie, l'adresse EUI64Address de la source et le temps TAI programmé) dans le champ NonceCache du KeyDescriptor correspondant, pour activer la protection contre le rejet.

i) La procédure doit retourner avec la DPDU non sécurisée, le niveau de sécurité, le CryptoKeyIdentifierMode, le CryptoKeyIdentifier et un statut SUCCESS.

7.3.2.7 Détection et rejet des unités de données de protocole dupliquées ou rejouées

Voir 7.3.2.6, d).

7.3.3 Fonctionnalité de sécurité de TL

7.3.3.1 Généralités

L'interaction du DSC et de la TL est décrite dans les grandes lignes. Les étapes de traitement de TL ont été écrites pour réutiliser les aspects communs entre la DL et la TL. Cependant, sachant que la DL et la TL existent à des couches d'abstraction du réseau différentes avec des exigences et des hypothèses différentes, il existe des différences considérables entre les étapes de traitement de la DL et de la TL.

Les services de sécurité à la TL sont sélectionnés par la politique associée à la clé pertinente de données de transport, obtenue comme partie intégrante d'une nouvelle demande de session ou d'une mise à jour de clé et basée sur la politique de transport maintenue par le gestionnaire de sécurité associée à tout ou partie des éléments suivants:

- l'appareil expéditeur;
- l'UAP demandeur; et/ou
- l'association de transport, telle que définie par ses points d'extrémité.

Le service de sécurité de transport suivant doit toujours être fourni avec une clé active:

- Communication autorisée avec authentification de TPDU, intégrité, et acheminement du temps nominal de création de TPDU, fournissant le rejet des TPDU périmées:
  – dont la source n'était pas un appareil au sein du réseau qui partage une clé de données appropriée; ou

– qui étaient gravement périmées, c'est-à-dire qui n'étaient pas reçues à un instant dans le délai maximal de DSMO.pduMaxAge secondes du temps nominal de création de la TPDU.

- Confidentialité de la charge utile de couche d'application au sein de la TPDU.

NOTE 1 Seize bits d'informations relatives au temps sont émis par chaque TPDU.

NOTE 2 Ces services utilisent le temps nominal d'émission de la source tel qu'authentifié au récepteur pour entraîner le rejet des TPDU qui sont excessivement retardées et pour fournir la détection des TPDU en doublons dans la limite de cette fenêtre de temps.

Le service de confidentialité ne doit pas être utilisé avec les clés qui ne sont pas des secrets partagés, car cela rendrait impossible la véritable confidentialité, et parce que cet aspect de la politique associée à de telles clés est constant.

Il convient que le MIC soit validé dans les limites de la période DSMO.pduMaxAge. Si la vérification échoue, la validation du MIC peut être répétée en décrémentant une fenêtre de temps pour récupérer le temps de création de la PDU.

7.3.3.2 Structure de TPDU

7.3.3.2.1 Généralités

La structure d'une TPDU est décrite en 11.5, et dans les grandes lignes à la Figure 109 et à la Figure 40 dans la présente norme, avec la TSDU éventuellement chiffrée et le contenu de l'en-tête UDP, de l'en-tête de sécurité et la TSDU protégés par le TMIC.

Légende

Anglais	Français
Authenticated by TMIC	Authentifié par TMIC
Possibly encrypted/decrypted	Possiblement chiffré/déchiffré
Uncompressed UDP header	En-tête UDP décompressé
Security header	En-tête de sécurité
Application Payload	Charge utile d'application

Figure 40 – Structure de TPDU et couverture protégée

La TPDU complète, du début de l'en-tête UDP jusqu'à la fin de l'Application Payload (charge utile d'application), doit être protégée par le TMIC. Chaque paramètre dans l'en-tête UDP est protégé en utilisant le pseudo-en-tête de composant de sécurité de transport (TSC) pour le calcul du TMIC. Le pseudo-en-tête de TSC est décrit en 7.3.3.2.2.

NOTE Le TSC est décrit en 11.2. Voir également la brève discussion des pseudo-en-têtes en 4.5.2.1.

7.3.3.2.2 Protection de TPDU

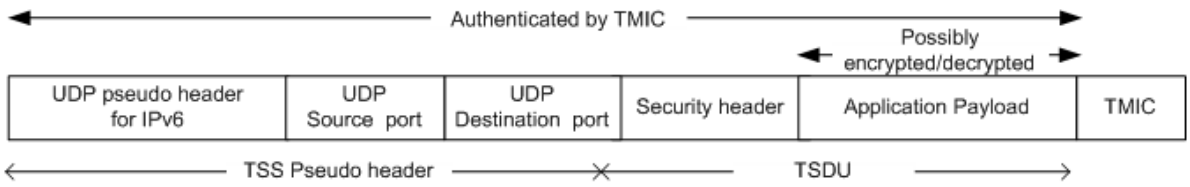
NOTE 1 L'utilisation d'IPV6 n'implique et ne fournit pas de connectivité Internet. Néanmoins, elle facilite l'utilisation d'outils de gestion IPvv6 communs au sein du réseau WISN.

Le TMIC est utilisé pour protéger l'information dans l'en-tête UDP, l'en-tête de sécurité de TL et la TSDU. Il protège également les adresses IPv6 source et de destination de la NL en utilisant une forme étendue du pseudo en-tête UDP pour IPv6. Le pseudo en-tête UDP pour IPv6 est décrit en 11.4.2 et dans le RFC IETF 2460:1998, 8.1. La taille de charge utile UDP et

la somme de contrôle (virtuelle) dans l'en-tête UDP ne sont pas utilisées pour le calcul du TMIC.

NOTE 2 La somme de contrôle et la taille de charge utile UDP n'apparaissent pas dans le pseudo-en-tête, car la somme de contrôle est élidée (absente de la TPDU) lorsque le TMIC est présent, et la taille de charge utile UDP est déterminée à partir de la longueur de la NSDU dans le pseudo-en-tête UDP pour IPv6.

Les paramètres pour le TMIC sont montrés à la Figure 41.



Légende

Anglais	Français
Authenticated by TMIC	Authentifié par TMIC
Possibly encrypted/decrypted	Possiblement chiffré/déchiffré
UDP pseudo-header for Ipv6	Pseudo-en-tête UDP pour IPv6
UDP source port	Port de source UDP
UDP destination port	Port de destination UDP
Security header	En-tête de sécurité
Application Payload	Charge utile d'application
TSS pseudo-header	Pseudo-en-tête TSS

Figure 41 – Paramètres de TMIC

Le TSC construit les paramètres de TMIC conformément à la Figure 41, avec la TPDU reçue, le temps TAI nominal auquel la TPDU a été créée, le KeyDescriptor et les informations de contrat fournies par la TL. Le TSC peut alors utiliser les paramètres pour l'opération de sécurité appropriée sur la TPDU.

L'en-tête IPv6 et les ports source et destination UDP sont passés de la TL au TSC. La combinaison de ces paramètres est un pseudo en-tête UDP étendu qui est appelé pseudo-en-tête de TSC dans la présente norme. La structure du pseudo-en-tête de TSC est montrée dans le Tableau 47. L'utilisation approprie est décrite en 7.3.3.5.4, en 7.3.3.5.5 et en 7.3.3.5.8.

Tableau 47 – Structure du pseudo-en-tête de TSC

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
Source IPv6Address	1	Type: IPv6Address Description: Adresse IPv6 décompressée de l'initiateur de la TPDU
Destination IPv6Address	2	Type: IPv6Address Description: Adresse IPv6 décompressée du destinataire prévu de la TPDU
NSDU size	3	Type: Unsigned16 Description: Longueur de NDSU en octets
Réservé	4	Type: Unsigned8 Description: Champ réservé. Actuellement rempli de 0
Next header	5	Type: Unsigned8 Plage valide: 17 (UDP) Description: Prochaine valeur d'en-tête dans l'en-tête IPv6. Il convient que cette valeur soit seulement de 17
UDP source port	6	Type: Unsigned16 Description: Numéro de port UDP source de l'initiateur de la TPDU
UDP destination port	7	Type: Unsigned16 Description: Numéro de port UDP de destination du destinataire prévu de la TPDU

7.3.3.3 Interface avec la TL pour une TPDU formée en vue de l'émission

L'interaction de TL avec la couche de sécurité pour une TPDU formée en vue de l'émission est récapitulée à la Figure 42. Lorsque le TSC reçoit l'adresse de source, le port de source, l'adresse de destination, le port de destination, et la taille de charge utile, il exécute une consultation de la table de KeyDescriptor pour voir si, oui ou non, la sécurité est activée pour cette session particulière.

Si le niveau de la sécurité de la session est égal à 0: none, une taille d'en-tête de 3 (octets) et une taille de TMIC de 0 octet doivent être retournées.

NOTE Lorsque le niveau de sécurité est zéro, la somme de contrôle UDP normalisée et trivialement falsifiée est utilisée pour détecter les erreurs qui se produisent pendant l'acheminement de la TPDU.

Autrement le TSC doit retourner les tailles appropriées du CryptoKeyIdentifier et du TMIC. Toutes les sessions à la TL sont en monodiffusion; par conséquent, la taille du CryptoKeyIdentifier doit être 0 ou 1 en fonction du nombre de clés valides disponibles à cet instant pour cette association de sécurité.

La TL appelle alors le TSC avec l'en-tête et la charge utile. Selon la politique de sécurité pour cette session particulière, la charge utile peut être chiffrée, et un TMIC peut être généré. L'en-tête et la charge utile résultants seront retournés à la TL pour émission.

TpduSecure.Response (header, payload, MIC)	TpduSecure.Response (en-tête, charge utile, MIC)

Figure 42 – Interaction de la TL et du TSC, TPDU sortante

7.3.3.4 Vue d'ensemble du traitement pour les TPDU reçues

L'interaction de la TL avec la couche de sécurité pour une TPDU reçue est récapitulée à la Figure 43. Lorsque le TSC reçoit l'adresse source, le port source, l'adresse de destination, et le port de destination, il accomplit une consultation dans la MIB pour voir si la sécurité est activée pour cette session particulière et retourne SEC_CHECK_REQUIRED ou SEC_CHECK_NOT_REQUIRED.

La TL doit alors appeler le TSC avec l'en-tête, la charge utile, et le MIC. Selon la politique de sécurité pour cette session particulière, la charge utile peut être déchiffrée, et un MIC peut être vérifié. Si le contrôle de sécurité échoue, un statut FAILURE sera retourné, avec la charge utile retournée intacte. Si l'opération réussit, la charge utile résultante et le codage récupéré de la durée de TPDU seront retournés à la TL.

Figure 43 – Interaction de la TL et du TSC, TPDU entrante

7.3.3.5 Interface de la TL au TSC

7.3.3.5.1 Généralités

La relation entre la TL et le TSC est décrite dans les grandes lignes en 7.3.3.2 pour l'interface de la TL pour une TPDU sortante et en 7.3.3.4 pour l'interface de la TL pour une TPDU entrante.

7.3.3.5.2 Sec.TpduOutCheck.Request

7.3.3.5.2.1 Généralités

Sec.TpduOutCheck.Request est une vérification de la TL au TSC pour obtenir la taille des champs de sécurité (éventuels) exigé dans la TPDU sortante.

7.3.3.5.2.2 Sémantique de la primitive de service

La sémantique de Sec.TpduOutCheck.Request est comme suit:

```
Sec.TpduOutCheck.Request (
    Source_Address,
    Source_Port,
```

Destination_Address,

Destination_Port,

Payload_Size)

Le Tableau 48 spécifie les éléments pour la Sec.TpduOutCheck.Request.

Tableau 48 – Eléments de Sec.TpduOutCheck.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
Source_Address	1	Type: IPv6Address Plage valide: toutes les valeurs avec réglage sur bit de poids fort
Source_Port	2	Type: Nombre entier
Destination_Address	3	Type: IPv6Address
Destination_Port	4	Type: Nombre entier
Payload_Size	5	Type: Nombre entier Plage valide: 0..Assigned_Max_TSDU_Size; voir 11.4.3.3

Le TSC doit utiliser Source_Address, Source_Port, Destination_Address, et Destination_Port pour récupérer la politique (éventuelle) appropriée pour l'association de sécurité.

7.3.3.5.2.3 Utilisation appropriée

La TL invoque la primitive Sec.TpduOutCheck.Request pour protéger une TPDU avant qu'elle ne soit émise.

7.3.3.5.2.4 Effet à la réception

A la réception de la primitive de Sec.TpduOutCheck.Request, le TSC détermine si la TPDU a besoin d'être protégée et renvoie les tailles correspondantes d'en-tête et de TMIC.

7.3.3.5.3 Sec.TpduOutCheck.Response

7.3.3.5.3.1 Généralités

Sec.TpduOutCheck.Response rend compte du résultat d'une Sec.TpduOutCheck.Request.

7.3.3.5.3.2 Sémantique

La sémantique de Sec.TpduOutCheck.Response est comme suit:

Sec. TpduOutCheck.Response (

Sec_Header_Size,

TMIC_Size)

Le Tableau 49 spécifie les éléments pour la Sec.TpduOutCheck.Response.

Tableau 49 – Eléments de Sec.TpduOutCheck.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
Sec_Header_Size (la taille d'en-tête supplémentaire exigée par le TSC, en octets complets)	1	Type: Nombre entier Plage valide: 0..Assigned_Max_TSDU_Size; voir Tableau 30
TMIC_Size (la taille du Transport Integrity Code, en octets complets)	2	Type: Nombre entier Valeurs valides: 0, 4, 8 ou 16

7.3.3.5.3.3 Moment de sa génération

Le TSC génère la Sec.TpduOutCheck.Response en réponse à une Sec.TpduOutCheck.Request. La Sec.TpduOutCheck.Response retourne les tailles complémentaires exigées pour prendre en charge la fonctionnalité de couche de sécurité. Une association de sécurité est une association de TL sécurisée basée sur:

- l'adresse source;
- le port source;
- l'adresse de destination;
- le port destination.

7.3.3.5.3.4 Utilisation appropriée

A la réception de Sec.TpduOutCheck.Response, la TL reçoit notification de la nécessité d'appliquer une opération de sécurité sur la TPDU, avec les octets complémentaires exigés pour prendre en charge cette opération.

7.3.3.5.4 Sec.TpduSecure.Request

7.3.3.5.4.1 Généralités

Sec.TpduSecure.Request ordonne au TSC d'exécuter les étapes appropriées pour sécuriser une TPDU sortante. Les informations relatives à l'association de sécurité sont contenues dans le pseudo-en-tête passé au TSC. Voir la Figure 108 en 11.4.2.

7.3.3.5.4.2 Sémantique de la primitive de service

La sémantique de Sec.TpduSecure.Request est comme suit:

```
Sec. TpduSecure.Request    (
    TSC_Pseudo_Header,
    TSC_Pseudo_Header_Size,
    TSDU,
    TSDU_Size)
```

Le Tableau 50 spécifie les éléments pour la Sec.TpduSecure.Request.

Tableau 50 – Eléments de Sec.TpduSecure.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
TSC_Pseudo_Header	1	Type: OctetStringN
TSC_Pseudo_Header_Size	2	Type: Nombre entier Plage valide: 0..127
TSDU	3	Type: OctetStringN
TSDU_Size	4	Type: Nombre entier Plage valide: 0..Assigned_Max_TSDU_Size; voir Tableau 30

Le TSC doit obtenir l'adresse source, le port source, l'adresse de destination, et le port de destination issus du pseudo-en-tête de TSC. Ces informations sont utilisées pour récupérer le support et les politiques de codage appropriées pour cette association de sécurité.

Le TSC inclut les informations relatives à la priorité dans l'en-tête de TPDU, protège la confidentialité des données de la TPDU et génère le champ TMIC comme dicté par les étapes de traitement des PDU et les politiques courantes.

Le TSC peuple l'en-tête de sécurité de TL tel que spécifié dans les étapes de traitement des TPDU et les politiques.

7.3.3.5.4.3 Utilisation appropriée

La TL appelle la primitive de Sec.TpduSecure.Request pour protéger une TPDU sortante après que la TL a reçu le nombre d'octets complémentaires exigés dans l'en-tête de transport et le TMIC.

7.3.3.5.4.4 Effet à la réception

A la réception de la primitive Sec.TpduSecure.Request, le TSC commence les étapes appropriées de traitement des PDU pour protéger la TPDU sortante comme cela est dicté par les étapes de traitement des TPDU sortantes en 7.3.3.8.

7.3.3.5.5 Sec.TpduSecure.Response

7.3.3.5.5.1 Généralités

Sec.TpduSecure.Response rend compte du résultat d'une Sec.TpduSecure.Request.

7.3.3.5.5.2 Sémantique

La sémantique de Sec.TpduSecure.Response est comme suit:

```
Sec. TpduSecure.Response (
    TSC_Pseudo_Header,
    TSC_Pseudo_Header_Size,
    TSDU,
    TSDU_Size,
    TMIC,
    TMIC_Size,
    Status)
```

Le Tableau 51 spécifie les éléments pour Sec.TpduSecure.Response.

Tableau 51 – Eléments Sec. TpduSecure.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
TSC_Pseudo_Header	1	Type: OctetStringN
TSC_Pseudo_Header_Size	2	Type: Unsigned7 Plage valide: 0..127
TSDU	3	Type: OctetStringN
TSDU_Size	4	Type: Unsigned Plage valide: 0..Assigned_Max_TSDU_Size; voir Tableau 30
TMIC	5	Type: OctetStringN
TMIC_Size	6	Type: Nombre entier Valeurs valides: 0, 4, 8, 16
Status	7	Type: Unsigned Valeurs nommées: 0: réussite; > 0: échec

7.3.3.5.5.3 Moment de sa génération

Le TSC génère la Sec.TpduSecure.Response en réponse à une Sec.TpduSecure.Request. La Sec.TpduSecure.Response retourne l'en-tête peuplé de transport de sécurité, une TSDU possiblement chiffrée et un TMIC avec les tailles appropriées. Enfin la Sec.TpduSecure.Response retourne une valeur de statut qui indique soit SUCCESS, soit le code d'erreur approprié.

7.3.3.5.5.4 Utilisation appropriée

A la réception de Sec.TpduSecure.Response, la TL reçoit notification du résultat de la protection d'une TPDU sortante.

7.3.3.5.6 Sec.TpduInCheck.Request

7.3.3.5.6.1 Généralités

Sec.TpduInCheck.Request ordonne au TDSC de vérifier et éventuellement de déchiffrer une unité de données de protocole de TL entrante selon le cas.

7.3.3.5.6.2 Sémantique de la primitive de service

La sémantique de Sec. TpduInCheck.Request est comme suit:

```
Sec.TpduInCheck.Request   (
    Source_Address,
    Source_Port,
    Destination_Address,
    Destination_Port,
    Payload_Size)
```

Le Tableau 52 spécifie les éléments pour la Sec.TpduInCheck.Request.

Tableau 52 – Eléments de Sec.TpduInCheck.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
Source_Address	1	Type: IPv6Address
Source_Port	2	Type: Unsigned16
Destination_Address	3	Type: IPv6Address
Destination_Port	4	Type: Unsigned16
Payload_Size	5	Type: Unsigned Plage valide: 0..Assigned_Max_TSDU_Size

Le TSC utilise Source_Address, Source_Port, Destination_Address, et Destination_Port pour récupérer la politique (éventuelle) appropriée pour l'association de sécurité.

7.3.3.5.6.3 Utilisation appropriée

La TL invoque la primitive Sec.TpduInCheck.Request pour vérifier si une vérification sécurisée et possiblement un déchiffrement d'une TPDU à l'avance sont exigés.

7.3.3.5.6.4 Effet à la réception

A la réception de la primitive de Sec.TpduInCheck.Request, le TSC détermine si la TPDU a besoin d'être vérifiée et, potentiellement, déchiffrée et retourne un statut de succès ou d'échec.

7.3.3.5.7 Sec. TpduInCheck.Response

7.3.3.5.7.1 Généralités

Sec.TpduInCheck.Response rend compte du résultat d'une Sec.TpduInCheck.Request.

7.3.3.5.7.2 Sémantique

La sémantique de Sec.TpduInCheck.Response est comme suit:

```
Sec.TpduInCheck.Response (
    Status)
```

Le Tableau 53 spécifie les éléments pour Sec.TpduInCheck.Response.

Tableau 53 – Eléments de Sec.TpduInCheck.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
Status (le résultat d'une primitive Sec.TpduInCheck.Request)	1	Type: Unsigned Valeurs nommées: 0: réussite; > 0: échec

7.3.3.5.7.3 Moment de sa génération

Le TSC génère la Sec.TpduInCheck.Response en réponse à une Sec.TpduInCheck.Request. La Sec.TpduInCheck.Response retourne une valeur de statut qui indique soit TRUE, soit FALSE, en fonction des politiques sur l'association de sécurité courante.

7.3.3.5.7.4 Utilisation appropriée

A la réception de Sec.TpduInCheck.Response, la TL reçoit notification de la nécessité d'appeler la Sec.TpduVerify.Request pour vérifier et possiblement déchiffrer la TPDU entrante.

7.3.3.5.8 Sec.TpduVerify.Request

7.3.3.5.8.1 Généralités

Sec.TpduVerify.Request ordonne au TSC de vérifier et, si configuré à cet effet, déchiffrer une TPDU entrante.

7.3.3.5.8.2 Sémantique de la primitive de service

La sémantique de Sec.TpduVerify.Request est comme suit:

```
Sec.TpduVerify.Request      (
    TSC_Pseudo_Header,
    TSC_Pseudo_Header_Size,
    TSDU,
    TSDU_Size,
    TMIC,
    TMIC_Size)
```

Le Tableau 54 spécifie les éléments pour la Sec.TpduVerify.Request.

Tableau 54 – Eléments de Sec.TpduVerify.Request

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
TSC_Pseudo_Header	1	Type: OctetString
TSC_Pseudo_Header_Size	2	Type: Unsigned Plage valide: 0..127
TSDU	3	Type: OctetString
TSDU_Size	4	Type: Unsigned Plage valide: 0..Assigned_Max_TSDU_Size; voir Tableau 30
TMIC	5	Type: OctetString
TMIC_Size	6	Type: Nombre entier Valeurs valides: 0, 4, 8 ou 16
Priority	7	Type: Unsigned4

Le TSC vérifie que le TL Security Header (en-tête de sécurité de TL) de la TPDU a le contrôle de sécurité (octet 1) approprié en le comparant à la politique courante. Le CryptoKeyIdentifier (octet 2), s'il est présent, est utilisé pour récupérer le support de clé correct. Voir 7.3.3.9.

Le TSC vérifie le champ TMIC comme dicté par les politiques courantes.

Le temps acheminé dans l'en-tête de sécurité de TL est utilisé dans la construction de nonce pour l'authentification et, si configuré, le déchiffrement de la TPDU reçue.

La priorité est fournie au TSC afin de permettre une mise en œuvre efficace de la protection contre le rejet.

7.3.3.5.8.3 Utilisation appropriée

La TL invoque la primitive Sec.TpduVerify.Request pour vérifier et éventuellement déchiffrer une TPDU avant qu'elle ne soit émise.

7.3.3.5.8.4 Effet à la réception

A la réception de la primitive Sec.TpduVerify.Request, le TSC commence les étapes appropriées de traitement des TPDU pour vérifier et, si configuré, déchiffrer la TPDU reçue comme dicté par les étapes de traitement pour les TPDU reçues en 7.3.3.9.

7.3.3.5.9 Sec.TpduVerify.Response

7.3.3.5.9.1 Généralités

Sec.TpduVerify.Response rend compte du résultat d'une Sec.TpduVerify.Request.

7.3.3.5.9.2 Sémantique

La sémantique de Sec.TpduVerify.Response est comme suit:

```
Sec.TpduVerify.Response    (
    TSDU,
    TSDU_Size,
    Time_Of_TPDU_Creation,
    Status)
```

Le Tableau 55 spécifie les éléments pour Sec.TpduVerify.Response.

Tableau 55 – Eléments de Sec.TpduVerify.Response

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
TSDU (après un déchiffrement exigé quelconque)	1	Type: OctetString
TSDU_Size	2	Type: Unsigned Plage valide: 0..Assigned_Max_TSDU_Size; voir 11.4.3.3
Time_Of_TPDU_Creation (représentation fractionnaire à point fixe sur 32 bits du temps TAI, modulo 2^{22} s, utilisée dans le nonce)	3	Type: Unsigned32
Status	4	Type: Unsigned Valeurs nommées: 0: réussite; > 0: échec

7.3.3.5.9.3 Moment de sa génération

Le TSC génère la Sec.TpduVerify.Response en réponse à une Sec.TpduVerify.Request. La Sec.TpduVerify.Response retourne une valeur de statut qui indique soit SUCCESS, soit le code d'erreur approprié.

7.3.3.5.9.4 Utilisation appropriée

A la réception de Sec.TpduVerify.Response, la TL reçoit notification du résultat de la vérification et du déchiffrement éventuel de la TPDU entrante.

7.3.3.6 Structure de l'en-tête de sécurité de TPDU

La structure de l'en-tête de sécurité de TPDU est telle que décrite dans le Tableau 56.

Tableau 56 – Structure de l'en-tête de sécurité de TL

Octet	Bits							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**
1	Security_Control							
2 (opt)	Crypto_Key_Identifier							
3	Nominal_Time							
4								

L'en-tête de sécurité de TL doit être ajouté à toutes les TPDU pour utiliser la compression d'en-tête dans la NL. Dans le cas où aucun KeyDescriptor ne correspond à une TPDU spécifique, cette TPDU doit être traitée comme si elle comportait un niveau de sécurité égal à NONE.

NOTE 1 Lorsque la TPDU n'a aucun TMIC, la somme de contrôle UDP est utilisée pour la détection d'erreurs.

Les champs comprennent:

- Security_Control: comme défini dans le 7.3.1.2.
- Crypto_Key_Identifier: spécifie le CryptoKeyIdentifier courant utilisé pour protéger cette TPDU.
- Nominal_Time: la partie de temps doit être égale à 16 bits du temps TAI, exprimé en 2^6 s en unités de 2^{-10} s, présentée dans l'ordre du bit de poids fort (MSB).

NOTE 2 Le fait de fixer la granularité du temps à 2^{-10} s donne à la TL la capacité d'émettre 1 023 TPDU par seconde. Avec la taille maximale de charge utile d'une TPDU, cela est adéquat pour le débit spécifié par 6LoWPAN. Une granularité variable pour le temps de TPDU, appropriée pour prendre en charge des processus d'automation de haut débit, est un domaine possible d'une normalisation future.

7.3.3.7 Construction du nonce pour les TPDU

La présente norme utilise une construction de nonce de TPDU différente (mais connexe) de celle de ses DPDU. Un nonce de 13 octets est exigé pour le moteur CCM*. Le nonce doit être construit comme une concaténation allant du premier (le plus à gauche) octet au dernier (le plus à droite) octet des champs de données conformément au Tableau 57, où:

- l'adresse EUI64Address doit être utilisée comme une matrice de 8 octets et le temps TAI tronqué;
- le temps TAI nominal de la création de la TPDU doit être réglé à une granularité de 2^{-10} s, et ne doit pas être plus précoce de plus de 1 s que le temps local réel du début de la création de la TPDU, et ne doit pas être plus tardif de plus de 1 s que le temps local réel de la fin de la création de la TPDU. Chaque TPDU sortante provenant d'une adresse EUI64Address source spécifique qui utilise une clé donnée doit être créée avec une valeur unique pour le temps TAI nominal de création de TPDU tronqué sur 32 bits. Ce codage restreint la fréquence maximale de la TL à 1 024 TPDU par seconde qui ne doit pas être dépassée. La structure du temps TAI nominal tronqué de 32 bits doit être telle que décrite dans le Tableau 58.

Tableau 57 – Structure du nonce de TPDU

Octet	Bits							
	7	6	5	4	3	2	1	0
1	EUI64Address							
...								
8								
9	Temps TAI nominal tronqué de création de TPDU							
...								
12								
13	0xFF							

La représentation nominale tronquée sur 32 bits du temps TAI utilisée dans le nonce T est décrite dans le Tableau 58.

Tableau 58 – Structure du temps TAI nominal tronqué de 32 bits utilisé dans le nonce T

Octet	Bits							
	7	6	5	4	3	2	1	0
1	Temps TAI nominal (bits avec un poids de $2^{21}..2^{14}$ s)							
2	Temps TAI nominal (bits avec un poids de $2^{13}..2^{6}$ s)							
3	Temps TAI nominal (bits avec un poids de $2^{5}..2^{-2}$ s)							
4	Temps TAI nominal (bits avec un poids de $2^{3}..2^{-10}$ s)							

Pour une granularité de 2^{-10} s, il y aura 48,5 jours avant que la représentation du temps de 32 bits ne se répète, fournissant de ce fait tout au plus 48,5 jours avant qu'une nouvelle clé n'ait besoin d'être déployée pour éviter une collision potentielle de nonce avec la réutilisation résultante de keystream.

NOTE Cette représentation est choisie parce que l'expéditeur et les récepteurs prévus sont présumés partager approximativement le même sens du temps et le même temps de début nominal pour n'importe quel intervalle de temps MAC.

7.3.3.8 Traitement pour les TPDU devant être émises

Les entrées à la procédure de sécurité pour les TPDU devant être émises sont:

- la TPDU devant être sécurisée;
- l'adresse EUI64Address de l'appareil source;
- le temps TAI nominal;
- les adresses IPv6Address source et de destination; et
- le port source et de destination.

Les sorties délivrées par cette procédure sont:

- le statut de la procédure; et
- si ce statut est SUCCESS, la TPDU sécurisée.

La procédure de sécurité pour les TPDU construites pour l'émission est constituée des étapes suivantes:

a) La procédure doit obtenir le KeyDescriptor issu du Tableau 93 satisfaisant aux critères de sélection suivants:

   1) Les entrées avec Type = 10 (TL). Si aucune n'est disponible, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

2) De ces entrées, les entrées avec le KeyLookupData concordant à SourceAddress||SourcePort||DestinationAddress||DestinationPort (voir Tableau 94) pour cette TPDU. Si aucun KeyDescriptor n'est disponible et les deux conditions suivantes sont toutes les deux vraies, la procédure doit traiter la TPDU comme étant une TPDU sans sécurité (niveau de sécurité= NONE). Autrement, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

3) Condition1: L'état de rattachement de l'appareil de réception est Provisioned ou Joining (voir Tableau 79).

4) Condition2: Les ports source et de destination sont tous deux pour le DMAP (à savoir 0xF0B0).

Ces conditions ont besoin d'être respectées pour émettre une TPDU de rattachement qui a un niveau de sécurité de NONE.

5) De ces entrées, les entrées valides pour la période courante, satisfaisant à l'inégalité "ValidNotBefore < temps courant < ValidNotAfter", doivent être sélectionnées. Si aucune n'est disponible, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

6) De ces entrées, si au moins deux clés sont valides pour le temps courant, la procédure doit sélectionner la clé avec la plus longue valeur de ValidNotAfter.

7) De ces entrées, si au moins deux clés ont le même ValidNotAfter, la procédure doit sélectionner la clé avec le plus petit ValidNotBefore.

8) De ces entrées, si au moins deux clés ont le même ValidNotBefore, la procédure doit sélectionner la clé avec le CryptoKeyIdentifier le plus élevé.

Si la procédure échoue, la procédure doit traiter la TPDU comme étant sans sécurité (niveau de sécurité = NONE).

b) La procédure doit récupérer la politique dans le KeyDescriptor sélectionné.

c) La procédure doit déterminer si la TPDU devant être sécurisée satisfait à la contrainte relative à la taille maximale des TPDU, comme suit:

1) La procédure doit établir la taille M, en octets, du champ d'authentification de TMIC à partir du niveau de sécurité.

2) La taille du champ Key Index dans l'en-tête de sécurité de TL doit être 1 octet, si plus de 1 clé est valide pour l'association de sécurité courante et 0 autrement.

3) La procédure doit déterminer l'expansion de données comme étant la taille de CryptoKeyIdentifier + M.

4) La procédure doit vérifier si la taille de la TPDU devant être sécurisée, y compris l'expansion de données, est inférieure ou égale à Assigned_Max_TSDU_Size (voir Tableau 30). Si cette vérification échoue, la procédure doit retourner un statut de TPDU_TOO_LONG.

d) La procédure doit construire l'octet de contrôle de sécurité de l'en-tête de sécurité de TL. Si le niveau de sécurité concorde avec plus d'un KeyDescriptor issu du Key Descriptor courant, le CryptoKeyIdentifier doit être utilisé avec le CryptoKeyIdentifierMode = 0x01; autrement, la procédure doit mettre le CryptoKeyIdentifierMode = 0x00.

e) La procédure doit mettre le CryptoKeyIdentifier = CryptoKeyIdentifier issu du courant Key Descriptor (s'il est présent) dans l'en-tête de sécurité de TL. Voir Tableau 56.

f) La procédure doit construire le temps TAI nominal au format TAITimeRounded décrit dans le Tableau 58.

g) La procédure doit régler les octets de Nominal_Time dans l'en-tête de sécurité de la TL sortante comme étant les derniers 16 bits de la valeur du temps TAI nominal au format TAITimeRounded. Voir octets 3 et 4 dans le Tableau 58.

h) Si aucun Key Descriptor n'a été trouvé, aller à l'étape j); autrement, la procédure doit utiliser l'adresse EUI64Address, le temps TAI nominal au format TAITimeRounded et la valeur 0xFF de 8 bits pour construire le nonce conformément au Tableau 57.

i) La procédure doit utiliser le nonce, le support de clé, l'en-tête de TPDU, la charge utile de TPDU et le mode CCM* de fonctionnement tels que décrits dans l'IEEE 802.15.4:2011, 7.3.4, pour sécuriser la TPDU:

   1) Si le paramètre SecurityLevel spécifie l'utilisation du chiffrement (voir IEEE 802.15.4:2011, Tableau 58), l'opération de chiffrement doit être appliquée seulement au champ de charge utile de la TPDU. Le champ de charge utile correspondant est passé au processus de transformation CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.4, comme étant la charge utile non sécurisée. La charge utile chiffrée résultante doit être substituée à la charge utile d'origine.

   2) Les champs restants dans la TPDU, jusqu'au champ de charge utile non compris, plus tous les éventuels champs virtuels exigés, doivent être passés au processus de transformation CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.4, comme étant le champ non-charge utile

   3) L'ordonnancement et la manière exacte d'accomplir les opérations relatives au chiffrement et à l'intégrité ainsi que le placement des données chiffrées ou du code d'intégrité ainsi obtenus au sein du champ de charge utile de la TPDU doivent être tels que définis dans l'IEEE 802.15.4:2011, 7.3.4.

j) La procédure doit retourner la TPDU sécurisée et un statut de SUCCESS.

7.3.3.9 Traitement pour les TPDU reçues

L'entrée à la procédure de sécurité pour les TPDU reçues est la TPDU devant être dépourvue de sécurité, qui contient les adresses IPv6Address source et destination et les ports source et de destination. Les sorties délivrées par cette procédure sont la TPDU non sécurisée, le niveau de sécurité, le CryptoKeyIdentifierMode, la source de clé, l'indice de clé et le statut de la procédure. Toutes les sorties de cette procédure sont supposées être non valides, jusqu'à ce que cela soit explicitement établi dans cette procédure. Chaque destinataire de TPDU maintient un cache des valeurs de nonce authentifiées des TPDU récemment reçues.

La procédure de sécurité à la réception des TPDU est constituée des étapes suivantes:

a) La procédure doit obtenir le niveau de sécurité et le CryptoKeyIdentifierMode issus des sous-champs correspondants du champ contrôle de sécurité et l'indice de clé issu des sous-champs correspondants du CryptoKeyIdentifier (s'il est présent) de l'en-tête de sécurité de la TPDU entrante.

b) La procédure doit reconstruire le temps TAI nominal d'initiateur de la formation de la TPDU qui est inféré (Voir Note 2).

c) La procédure doit comparer le temps dans l'étape b) et le temps TAI courant du destinataire. Si le temps dans l'étape b) est en avance de plus de 2 s par rapport au temps TAI courant du destinataire, ou en retard de plus de N secondes par rapport au temps TAI courant du destinataire (où N est un paramètre déterminé par une politique dont la valeur par défaut est 62 s), le processus de sécurité retourne FAILURE_TPDU_DID_NOT_AUTHENTICATE.

d) La procédure doit obtenir le KeyDescriptor issu du Tableau 93 satisfaisant aux critères de sélection suivants:

   1) Les entrées avec Type = 10 (TL).

   2) De ces entrées, les entrées avec le KeyLookupData concordant à SourceAddress||SourcePort||DestinationAddress||DestinationPort (voir Tableau 94) pour cette TPDU. Si aucun KeyDescriptor n'est disponible et les deux conditions suivantes sont toutes vraies, la procédure doit traiter la TPDU comme étant une TPDU sans sécurité (niveau de sécurité= NONE). Autrement, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

      i) Condition1: L'état de rattachement de l'appareil de réception est Provisioned ou Joining (voir Tableau 79).

      ii) Condition2: Les ports source et de destination sont tous deux pour les DMAP (à savoir 0xF0B0).

NOTE 1 Cette information est utilisée lors du traitement d'une TPDU de rattachement reçue qui a un niveau de sécurité de NONE.

3) De ces entrées, les entrées valides pour la période courante, satisfaisant à l'inégalité "ValidNotBefore < temps courant < ValidNotAfter", doivent être sélectionnées. Si aucune n'est disponible, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

4) De ces entrées, si au moins deux clés sont valides pour le temps courant, la procédure doit sélectionner la clé avec la plus longue valeur de ValidNotAfter.

5) De ces entrées, si au moins deux clés ont le même ValidNotAfter, la procédure doit sélectionner la clé avec le plus petit ValidNotBefore.

6) De ces entrées, si au moins deux clés ont le même ValidNotBefore, la procédure doit sélectionner la clé avec le CryptoKeyIdentifier le plus élevé.

7) Si la procédure échoue, la procédure doit retourner avec un statut UNAVAILABLE_KEY.

e) La procédure doit déterminer si le niveau de sécurité de la TPDU entrante se conforme à la politique de niveau de sécurité en comparant le SecurityLevel du Key Descriptor concordant obtenu dans l'étape b) ci-dessus. S'il y a une discordance, la procédure doit retourner avec un statut IMPROPER_SECURITY_LEVEL.

f) La procédure doit alors utiliser l'adresse EUI64Address de l'initiateur, le temps TAI nominal de formation de TPDU issu de l'étape b), les 16 bits de poids faible du temps TAI nominal (voir Tableau 58) reçus, pour générer le nonce conformément au Tableau 57.

g) La procédure doit utiliser le nonce, la clé issue du KeyDescriptor obtenu dans l'étape d), les en-têtes réels (les champs non-charge utile), la charge utile et le MIC de la TPDU entrante et le mode de fonctionnement CCM* tels que décrits dans les opérations (voir l'IEEE 802.15.4:2011, 7.3.5) pour authentifier et, si configuré pour l'association de transport, déchiffrer la TPDU:

1) Si le niveau de sécurité spécifie l'utilisation du chiffrement (voir l'IEEE 802.15.4:2011, Tableau 58), l'opération de déchiffrement doit être appliquée seulement au champ charge utile réel de la TPDU (voir l'IEEE 802.15.4:2011, 5.2.2.2.2). Le champ de charge utile correspondant doit être passé au processus de transformation inverse CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.5, comme étant la charge utile sécurisée.

2) Les champs restants dans la TPDU, plus tous les éventuels champs virtuels exigés, doivent être passés au processus de transformation inverse CCM* décrit dans l'IEEE 802.15.4:2011, 7.3.5, comme étant les champs non-charge utile (voir IEEE 802.15.4:2011, Tableau 57).

3) L'ordonnancement et la manière exacte d'accomplir les opérations relatives au déchiffrement et à la vérification d'intégrité ainsi que le placement des données déchiffrées ainsi obtenues au sein du champ de charge utile de la TPDU doivent être tels que définis dans l'IEEE 802.15.4:2011, 7.3.5.

h) Si le processus de transformation inverse CCM* échoue, alors la procédure peut décrémenter de 64 s le temps TAI nominal et répéter le processus ci-dessus pendant la période DSMO.pduMaxAge. Autrement, la procédure doit établir la TPDU devant être dépourvue de sécurité et retourner un statut de SECURITY_ERROR.

i) La procédure doit rechercher par consultation le nonce de la TPDU juste authentifiée dans le cache, avec les résultats possibles suivants:

1) Le temps du nonce est plus ancien que le temps le plus ancien dans le cache et le cache n'a pas de place pour une autre entrée plus ancienne, donc le processus de sécurité retourne FAILURE_OVERAGE_TPDU.

2) Le nonce est déjà dans le cache, donc le processus de sécurité retourne FAILURE_DUPLICATE_TPDU.

3) Toute charge utile chiffrée de la TPDU est déchiffrée, et le processus de sécurité retourne SUCCESS.

j) La procédure doit insérer la valeur de nonce dans le cache, au besoin en expulsant du cache l'entrée de cache ayant le temps TAI nominal inféré le plus ancien de formation de TPDU et retourner avec la TPDU dépourvue de sécurité, le niveau de sécurité, le

CryptoKeyIdentifierMode, la source de clé, l'indice de clé (si présent) et un statut de SUCCESS.

NOTE 2 Le temps TAI nominal de formation de TPDU de l'initiateur est initialement inféré à partir du temps TAI courant du destinataire et du temps TAI nominal fractionnaire de création de TPDU qui est spécifié dans la TPDU, en satisfaisant à la relation

((current-receiver-time + 2 s) ≥ originator's-nominal-time ≥ (current-receiver-time – DSMO.pduMaxAge)).

La durée de 2 s est prévue pour couvrir ±1 s plus les conditions aux limites.

Il est permis que le cache soit segmenté en des caches séparés pour chaque adresse EUI64Address d'envoi. Il est en plus permis que le cache soit segmenté par la QoS de couche réseau rapportée, afin qu'un cache ne contenant que quelques nonces de TPDU de faible priorité puisse aussi ne pas contenir des douzaines à des centaines de nonces pour devancer des TPDU de plus haute priorité. Il est également permis que la taille du cache soit adaptative, afin que les occurrences répétées du premier résultat de l'étape g) ci-dessus fasse croître le cache, avec la réduction appropriée de la taille du cache au cas où la capacité du cache en excès n'aurait pas été utilisée pendant une période prolongée.

7.3.3.10 Détection et rejet des TPDU dupliquées ou rejouées

Voir 7.3.3.9, i).

7.4 Processus de rattachement

7.4.1 Généralités

Le processus de rattachement décrit les étapes par lesquelles un nouvel appareil est admis dans un réseau conforme à une norme et obtient toutes les informations pertinentes pour être capable de communiquer avec d'autres appareils ainsi qu'avec le gestionnaire de système et le gestionnaire de sécurité.

NOTE Cette description suppose que l'appareil qui se rattache a une pile de protocoles DL conforme à l'une des éditions de la présente norme. Cependant, comme cette procédure est un protocole d'AL, elle est également utilisable pour les appareils qui ne comportent pas de pile de DL en omettant simplement les étapes relatives à la DL.

7.4.2 Conditions préalables

Le processus de rattachement suit l'étape de configuration, pendant laquelle les informations cryptographiques et les paramètres de configuration non cryptographiques peuvent être fournis au nouvel appareil. Un nouvel appareil doit obtenir de l'appareil de configuration ces informations nécessaires relatives à la configuration. Cela est décrit à l'Article 13. L'attribut Join_Command dans le DMO d'un appareil doit être utilisé pour ordonner à l'appareil de rejoindre le réseau.

Un appareil se rattachant doit rejoindre le réseau cible en utilisant l'une des approches de sécurité suivantes:

- clés symétriques;
- clés asymétriques;
- sans sécurité.

L'approche sans sécurité n'utilise pas une clé secrète pour le transfert de clés de rattachement. Au lieu de cela, elle utilise l'une des clés prédéfinies bien connues K_global ou K_open, telles que spécifiées en 7.2.2.2. Dans ce cas, le MIC fonctionne comme un CRC fort, qui n'offre aucune assurance de sécurité, mais a une probabilité très élevée de détection d'erreurs qui ne sont pas dues à une attaque délibérée. Dans ce cas, les sessions sécurisées de bout à bout (associations T) ne sont pas autorisées.

Un appareil mettant en œuvre l'approche de rattachement à clés symétriques doit avoir à la fois une clé de rattachement symétrique et l'adresse EUI64Address d'un gestionnaire de sécurité qui partage cette clé de rattachement.

Un appareil mettant en œuvre l'approche de rattachement à clés asymétriques doit avoir un certificat signé par une autorité de certification ayant la confiance du réseau-cible.

Un appareil mettant en œuvre l'approche de rattachement sans sécurité doit avoir la clé symétrique publiée, bien connue et non secrète commune à tous les réseaux conformes à une norme, K_global or K_open, telle que spécifiée en 7.2.2.2.

7.4.3 Etat final et propriétés souhaités de l'appareil

A la fin du processus de rattachement, le système doit avoir l'état suivant:

- le nouvel appareil et le gestionnaire de sécurité partagent en toute sécurité une clé principale symétrique de long terme;
- si une DLE de WISN est présente dans l'appareil, le nouvel appareil a le support cryptographique exigé pour que cette DLE échange des DPDU avec ses voisins directs;
- si une DLE WISN est présente dans l'appareil, le nouvel appareil a le support non cryptographique et les ressources exigés pour que cette DLE échange des DPDU avec au moins l'un de ses voisins directs; et
- le nouvel appareil doit avoir un contrat avec le gestionnaire de système.

NOTE 1 Une contrat avec le gestionnaire de système inclut une clé T partagée entre le gestionnaire de système et une TLE du nouvel appareil.

Lors de l'utilisation de l'approche à clés symétriques ou à clés asymétriques, le processus de rattachement fournit les assurances de sécurité suivantes:

- la protection contre les attaques de rejet sur les APDU de rattachement:
  - l'assurance cryptographique au nouvel appareil que le gestionnaire de sécurité est en vie;
  - l'assurance cryptographique au gestionnaire de sécurité que le nouvel appareil est en vie;
- authenticité:
  - assurance cryptographique que la demande de rattachement vient d'un appareil qui a le matériel de confiance valide;
  - assurance cryptographique que les APDU de rattachement n'ont pas été altérées;
- confidentialité:
  - protection cryptographique pour les clés dans la réponse de rattachement, telle qu'une oreille indiscrète ne puisse pas récupérer les clés transportées.

NOTE 2 Un défi ("challenge")/protocole de réponse est utilisé pour que le processus de rattachement sécurisé élimine toute nécessité de se fier, au moment du processus de rattachement, à une source de temps TAI de confiance mutuelle.

7.4.4 Etapes de processus de rattachement communes aux approches à clés symétriques et à clés asymétriques

7.4.4.1 Généralités

Lors de l'utilisation de l'approche sécurisée à clés symétriques ou à clés asymétriques, l'appareil passe par les étapes générales suivantes pour parachever le processus de rattachement.

Le gestionnaire de système commande le traitement d'un nouvel appareil rejoignant le réseau. Un appareil non rattaché qui met en œuvre une DLE conforme à la présente norme se met à l'écoute pour détecter des DPDU d'annonce issues de routeurs locaux, dont les fonctions d'annonce sont configurées par le gestionnaire de système.

Des annonces peuvent être trouvées en utilisant le balayage actif, le balayage passif, ou une combinaison des deux. Le balayage actif implique des DPDU de sollicitation envoyées par l'appareil se rattachant pour demander l'émission de DPDU d'annonce. Des informations détaillées pour le balayage actif/passif sont données en 9.1.13.

Un tel routeur d'annonce doit apporter une assistance pendant le processus de rattachement en agissant comme un proxy pour un gestionnaire de système, relatif au nouvel appareil. Comme proxy, ce routeur d'annonce transmet la demande de rattachement issue du nouvel appareil vers un gestionnaire de système et transmet la réponse de rattachement issue du gestionnaire de système en question vers le nouvel appareil. A la réception d'une demande de rattachement issue d'un nouvel appareil, un gestionnaire de système traite la demande, authentifie l'acceptabilité de la demande par une communication avec un gestionnaire de sécurité et génère en réponse une réaction de rattachement.

7.4.4.2 Construction des PDU du processus de rattachement

La demande de rattachement issue d'un nouvel appareil est constituée de PDU concaténées qui séparent les informations de sécurité, échangées entre l'appareil et un gestionnaire de sécurité, des informations autres que de sécurité, échangées entre l'appareil et un gestionnaire de système. La réponse de rattachement est constituée de semblables PDU concaténées qui séparent les informations de sécurité des informations autres que de sécurité.

Les informations autres que de sécurité échangées au cours du processus de rattachement sont décrites en 6.3.9.2. Cet échange utilise la méthode définie en 6.3.9.2.2 pour les DMO du routeur d'annonce et les méthodes définies en 6.3.9.5 pour le DMSO du gestionnaire de système.

Les informations de sécurité échangées au cours du processus de rattachement dépendent de l'approche de rattachement utilisée, telle que décrite en 7.4.5 pour l'approche à clés symétriques et en 7.4.6 pour l'approche à clés asymétriques.

Afin que le nouvel appareil construise ses PDU de processus de rattachement et les envoie au routeur d'annonce, il a besoin de connaître l'adresse EUI64Address du routeur d'annonce. Le processus suivi par le nouvel appareil pour obtenir cette adresse EUI64Address est décrit en 9.1.14. Les PDU de demande de processus de rattachement, du nouvel appareil vers le routeur d'annonce, et les PDU de réponse de processus de rattachement, du routeur d'annonce vers le nouvel appareil, doivent être construites comme suit, en utilisant cette adresse EUI64Address du routeur d'annonce et l'adresse EUI64Address du nouvel appareil:

- S'il y a une DLE de WISN présente dans l'appareil se rattachant, l'en-tête de DL pour ces PDU de processus de rattachement est construit tel que décrit en 9.3.
- L'en-tête de NL pour ces PDU de processus de rattachement est construit tel que décrit en 10.5.3.
- L'en-tête de TL pour ces PDU de processus de rattachement est construit tel que décrit en 11.5. Pour le calcul de la somme de contrôle UDP, le pseudo-en-tête UDP pour IPv6 utilise l'adresse EUI64Address du nouvel appareil et l'adresse EUI64Address du routeur d'annonce, représentées comme étant les adresses IPv6Address locales à une liaison des appareils respectifs, comme les adresses IPv6Address de la source et de la destination des PDU.
- Les DMAP de l'appareil se rattachant et du routeur d'annonce utilisent ces adresses IPv6Address locales à une liaison lors de l'acheminement des PDU relatives à la demande de rattachement vers leurs TLE.

- A la TL, la Sec.TpduOutCheck.Response doit retourner avec une valeur de 3 pour la taille d'en-tête de sécurité et de 0 pour la taille de TMIC, indiquant un en-tête de sécurité de TL avec le niveau de sécurité = 0 (NONE). En raison de l'absence (habituelle) de clés secrètes partagées, la protection de sécurité de TL n'est généralement pas disponible pour l'échange de TPDU des PDU de demande de rattachement issues nouvel appareil et des PDU de demande de réponse issues du routeur d'annonce.
- S'il y a une DLE présente, l'en-tête de sécurité de DPDU a un niveau de sécurité = 1 (MIC-32), utilisant donc un DMIC de 32 bits pour les DPDU de rattachement, qui doivent être construites telles que décrites en 7.3.2.5 en utilisant la clé D K_global (CryptoKeyIdentifier = 0). Parce que cette clé est bien connue, elle n'assure aucune protection contre les attaques délibérées. Par conséquent, ce DMIC de 32 bits n'est utilisé que pour détecter des erreurs involontaires dans les DPDU de demande et de réponse de rattachement. Le routeur D d'annonce doit utiliser son contrat existant avec le gestionnaire de système pour transmettre les PDU de processus de rattachement pour le compte de l'appareil qui fait la demande de rattachement.

NOTE Un nouvel appareil qui essaie de rejoindre le réseau n'a aucun contrat assigné par le gestionnaire de système. Par conséquent, la communication entre le nouvel appareil et le routeur d'annonce n'est basée sur aucun contrat.

Il convient que les messages de demande et de réponse de PSMO.Security_Sym_Confirm() soient protégés par des informations de clé D et de clé T qui sont distribuées dans le message de réponse de PSMO.Proxy_Security_Sym_Join().

7.4.4.3 Protection des messages de processus de rattachement

7.4.4.3.1 Généralités

Comme le nouvel appareil n'a pas la clé de sous-réseau D nécessaire et une clé T de niveau de TL avec le routeur d'annonce, tous les messages de processus de rattachement, autres que les messages de confirmation, entre le nouvel appareil et le routeur d'annonce doivent utiliser la K_global au niveau de la DL pour construire un DMIC de 32 bits. Au niveau de la TL, la somme de contrôle UDP doit être utilisée pour ces messages.

Les informations de sécurité dans la demande de rattachement, ainsi que toutes les informations revenant du gestionnaire de système et du gestionnaire de sécurité dans les messages de réponse de rattachement, sont protégées en utilisant la clé de rattachement. Cela est décrit en 7.4.5 pour l'approche à clés symétriques et en 7.4.6 pour l'approche à clés asymétriques.

7.4.4.3.2 Protection contre les attaques de rejet des PDU de rattachement

Pour protéger contre une attaque de rejet de PDU de rattachement, il convient que le gestionnaire de sécurité effectue une vérification pour détecter des doublons de défis avec un MIC valide issu du nouvel appareil. Si aucun doublon de défi n'est détecté, le gestionnaire de sécurité stocke la valeur de défi en vue d'une vérification ultérieure de doublons. En cas de détection d'un doublon, le gestionnaire de sécurité rejette la PDU avant de traiter la PDU de rattachement.

7.4.4.3.3 Protection d'un message sans sécurité dans le processus de rattachement

7.4.4.3.3.1 Généralités

Le paragraphe 7.4.4.3.3 décrit la configuration des valeurs de réglage de sécurité au cours du processus de rattachement. Les informations réseau non relatives à la sécurité sont configurées avec les méthodes DMSO.System_Manager_Join() et DMSO.System_Manager_Contract(). Les détails des méthodes sont spécifiés en 6.3.9.2. De tels messages non relatifs à la sécurité sont protégés avec des opérations cryptographiques à l'AL. Les messages non relatifs à la sécurité sont générés dans le gestionnaire de système et passés au gestionnaire de sécurité qui additionne alors le MIC en utilisant la clé de

rattachement. Les messages protégés sont émis vers l'appareil se rattachant, par l'intermédiaire du DMSO dans le gestionnaire de système. A l'appareil se rattachant, le MIC dans la réponse reçue est validé avec la même opération.

A l'appareil se rattachant, le MIC dans la réponse reçue est validé avec la même opération.

7.4.4.3.3.2 Génération de MIC pour la réponse de System_Manager_Join

La méthode DMSO.System_Manager_Join() est définie en 6.3.9.5. Le champ MIC est constitué des 4 octets de poids fort dans le MACTag généré par l'opération suivante:

MACTag = HMAC-MMOK_join[Output Argument number1 .. number6 in Tableau 23 || $\text{EUI64Address}_{\text{join\_device}}$ || $\text{Challenge}_{\text{join\_device}}$].

7.4.4.3.3.3 Génération de MIC pour la réponse System_Manager_Contract

La méthode DMSO.System_Manager_Contract est définie en 6.3.9.5. Le champ MIC est constitué des 4 octets de poids fort dans le MACTag généré par l'opération suivante:

MACTag = HMAC-MMOK_join[Output Argument number1 in Tableau 24 || $\text{EUI64Address}_{\text{join\_device}}$ || $\text{Challenge}_{\text{join\_device}}$]

7.4.4.3.3.4 Confirmation

Après la réception de DMO.Proxy_System_Manager_Join().Response et DMO.Proxy_System_Manager_Contract().Response, l'appareil se rattachant envoie un message pour informer que les informations réseau correctes ont été reçues par le gestionnaire de système.

Dans le processus de rattachement à clé symétrique, le processus de confirmation est intégré dans la méthode PSMO.Security_Confirm() spécifiée dans le Tableau 61.

Dans le processus de rattachement à clés asymétriques, le processus de confirmation est accompli avec la méthode PSMO.Network_Information_Confirmation() spécifiée dans le Tableau 74.

7.4.4.4 Temporisateurs de rattachement

Dans le processus de rattachement, deux temporisateurs sont définis. A l'expiration de l'un de ces temporisateurs, toute information (par exemple, état et paramètre reçu) placée en cache pour le processus de rattachement particulier doit être enlevée ou réinitialisée.

JT_1: Durée temporelle gérée dans l'appareil se rattachant, depuis le temps d'émission de la demande de rattachement de sécurité jusqu'au temps de validation correcte de la réponse de confirmation générée par le gestionnaire de sécurité. Si l'appareil se rattachant n'est pas un appareil dorsal, la valeur initiale pour JT_1 doit être mise à la valeur de DauxJoinTimeout qui est distribuée au sein de l'annonce de DL (voir Tableau 127). Autrement, la valeur réelle pour JT_1 doit être mise à 60 s pour l'appareil dorsal.

JT_2: Durée temporelle gérée dans le gestionnaire de sécurité, depuis le temps de réception de la demande de rattachement de sécurité jusqu'au temps de validation correcte du message de confirmation de sécurité générée par l'appareil se rattachant. La valeur réelle de JT_2 n'est pas spécifiée dans la présente norme.

NOTE JT_2 peut être inférieur à JT_1.

7.4.4.5 Processus de rattachement d'appareil dorsal

Un appareil dorsal rejoint un réseau cible en exécutant la méthode de rattachement dans le DMO du gestionnaire de système au lieu de celui du routeur d'annonce. Par conséquent, l'appareil dorsal n'a pas besoin de découvrir un routeur d'annonce; la

DPO.Target_System_Manager_Address doit être mise dans la phase de configuration. La vue d'ensemble du processus de rattachement de l'appareil dorsal est illustrée à la Figure 45 pour le processus de rattachement à clés symétriques et à la Figure 48 pour le processus de rattachement à clés asymétriques.

7.4.4.6 Contraintes de taille de TMIC pour la session entre le nœud de rattachement et le gestionnaire de système

A la fin du processus de rattachement, le gestionnaire de sécurité assigne un niveau de sécurité initial pour la session entre l'appareil se rattachant et le gestionnaire de système. Ce niveau de sécurité doit être de 0, 1, 2, 5 ou 6; il ne doit pas être égal à 3 (MIC-128) ni 7 (ENC-MIC-128), la valeur 4 (ENC-only) étant toujours invalide.

7.4.5 Processus de rattachement à clés symétriques

7.4.5.1 Généralités

La Figure 44 illustre la messagerie impliquée dans le processus de rattachement à clés symétriques par lequel un nouvel appareil doit rejoindre un réseau en fonctionnement dans lequel il n'a pas été récemment participant. Le flux montre le cas normal dans lequel il ne se produit pas d'erreur ou de temporisation. Les temporisations sont spécifiées au Tableau 92.

Sur l'appareil se rattachant, le processus de rattachement à clés symétriques doit être initié avec une DMO.Proxy_Security_Sym_Join().Request et finalisé avec une PSMO.Security_Confirm().Response valide. Sur le gestionnaire de sécurité, le processus de rattachement à clés symétriques doit être initié avec un message valide dérivé de PSMO.Security_Sym_Join().Request et finalisé avec un message valide dérivé avec PSMO.Security_Confirm().Request.

Figure 45 – Exemple: Vue d'ensemble du processus de rattachement à clés symétriques d'appareil dorsal

Comme montré à la Figure 44, un nouvel appareil doit utiliser les méthodes définies pour le DMO de routeur d'annonce pour envoyer et recevoir les messages de demande de rattachement et de réponse de rattachement. Les méthodes relatives aux informations autres que de sécurité sont décrites en 6.3.9.2. Les méthodes du DMO relatives aux informations de sécurité sont décrites en 7.4.5.2. Après émission de la DMO.Proxy_Security_Sym_Join().Request, le nouvel appareil doit démarrer le temporisateur de rattachement de comptage JT_1.

Le routeur d'annonce doit utiliser les méthodes définies pour le DMSO du gestionnaire de système pour envoyer et recevoir les messages de demande et de réponse relatifs à la non-sécurité. Ces méthodes de DMSO sont décrites en 6.3.9.5. Les méthodes définies pour l'objet proxy de gestion de sécurité (PSMO) du gestionnaire de système doivent être utilisées par le routeur d'annonce pour envoyer et recevoir les messages de demande et de réponse relatifs à la sécurité. Les méthodes du PSMO relatives aux informations de sécurité sont décrites en 7.4.5.2. Comme montré à la Figure 44, le PSMO reçoit la demande de rattachement relative à

la sécurité et la transmettra au gestionnaire de sécurité. Le gestionnaire de sécurité peut vérifier une liste blanche ou noire pour y détecter l'appareil et demander une vérification humaine avant de décider d'admettre ou rejeter l'appareil se rattachant. Si le résultat est positif, le gestionnaire de sécurité vérifie les informations cryptographiques de la demande de rattachement. Si les vérifications échouent, le gestionnaire de système reçoit l'instruction de révoquer les ressources allouées au nouvel appareil. Si l'essai réussit, le gestionnaire de sécurité agit comme suit:

NOTE 1 La méthodologie du filtrage de l'appareil se rattachant dans le gestionnaire de sécurité ne relève pas du domaine d'application de la présente norme.

a) démarre le temporisateur de rattachement JT_2;

b) génère une nouvelle clé principale pour le nouvel appareil;

c) crée une nouvelle session sécurisée pour le contrat entre le gestionnaire de système et le nouvel appareil;

d) récupère la clé D courante et le CryptoKeyIdentifier pour le sous-réseau du nouvel appareil;

e) génère un nouveau défi unique pour le nouvel appareil;

f) protège cryptographiquement les clés susmentionnées et forme un code de contrôle d'intégrité de message sur la réponse entière; et

g) envoie en retour au PSMO la réponse relative à la sécurité, y compris le code de contrôle d'intégrité de message.

Le PSMO envoie de nouveau cette réponse relative à la sécurité vers le routeur d'annonce qui, à son tour, la transmet au nouvel appareil.

Le nouvel appareil vérifie l'intégrité cryptographique de la réponse APDU relative à la sécurité. Si l'essai échoue, l'APDU reçue est rejetée. Si l'essai réussit, alors la réponse relative à la sécurité est traitée par l'appareil, qui annule le temporisateur de rattachement JT_1.

La réponse de rattachement APDU non relative à la sécurité qui est générée par le DMSO du gestionnaire de système est transmise au gestionnaire de sécurité afin de protéger cryptographiquement les informations dans cette APDU. Une fois que le DMSO reçoit cette APDU protégée, il envoie en retour l'APDU protégée vers le routeur d'annonce qui, à son tour, la transmet au nouvel appareil. Le nouvel appareil vérifie l'intégrité cryptographique de cette APDU protégée avant d'utiliser les informations dans cette APDU pour parachever le processus de rattachement. L'APDU inclut des informations relatives au contrat initial que le gestionnaire de système a établi entre le nouvel appareil et le gestionnaire de système. Ce contrat est décrit en 6.3.11.2.6.7.

Comme partie intégrante de la dernière étape du processus de rattachement, le nouvel appareil doit renvoyer une confirmation de sécurité APDU au gestionnaire de sécurité qui comprend le défi issu du gestionnaire de sécurité, authentifié avec la nouvelle clé principale symétrique partagée. Cette confirmation de sécurité est envoyée au PSMO qui la transmet au gestionnaire de sécurité. La méthode du PSMO utilisé à cet effet est décrite en 7.4.5.2.

Le gestionnaire de sécurité vérifie le message de confirmation. Si l'essai échoue, la réponse de confirmation reçue, l'état de rattachement et les informations placées en cache pour le nouvel appareil doivent être abandonnés. Si l'essai réussit, alors le gestionnaire de sécurité annule le temporisateur JT_2 et envoie en retour une réponse de confirmation vers le nouvel appareil.

Si le nouvel appareil reçoit une réponse positive à la demande de confirmation, il annule alors le temporisateur JT_1.

Le contrat qui a été établi entre le nouvel appareil et le gestionnaire de système au cours du processus de rattachement est utilisé pour prendre en charge ces messages.

NOTE 2 En envoyant la réponse du défi authentifié avec la clé principale, le nouvel appareil prouve au gestionnaire de sécurité qu'il était capable d'extraire la clé principale, et donc qu'il avait la clé de rattachement.

L'ASL peut concaténer des ASDU résultantes d'appels de méthodes multiples vers une seule et même TSDU, garantissant ainsi que si l'une est reçue, toutes sont reçues. Par exemple, pour réduire le surdébit de trafic ou le temps de rattachement, la Proxy_Security_Sym_Join().Request et la Proxy_System_Manager_Contract().Request peuvent être concaténées dans la même TSDU envoyée au DMO du routeur d'annonce.

7.4.5.2 Méthodes d'objet de gestion d'appareil et d'objet proxy de gestion de service relatives au processus de rattachement à clés symétriques

7.4.5.2.1 Généralités

Le nouvel appareil doit utiliser la méthode Proxy_Security_Sym_Join définie pour le DMO du routeur d'annonce dans le routeur d'annonce pour envoyer ses informations de sécurité qui font partie intégrante de la demande de rattachement et pour obtenir ses informations de sécurité qui font partie intégrante de la réponse de rattachement.

NOTE 1 Pour atténuer une inondation de messages de rattachement, le gestionnaire de système limite les ressources sans fil (les intervalles de temps, par exemple) assignées dans des routeurs d'annonce pour recevoir les messages de rattachement. Les ressources sont décrites en 9.3.5.2.4.2.

Le Tableau 59 décrit la méthode Proxy_Security_Sym_Join. L'objet source pour invoquer la DMO.Proxy_Security_Sym_Join().Request doit être le DMO dans le DMAP de l'appareil se rattachant.

Tableau 59 – Méthode Proxy_Security_Sym_Join

Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)				
Identificateur du type d'objet normalisé: 127				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**

Identificateur du type d'objet normalisé: 127				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
	1	Join_ Response	Security_Sym_Join_Response; voir 7.4.5.2.3	Réponse de rattachement relative à la sécurité basée sur les clés symétriques du gestionnaire de sécurité devant être transmise au nouvel appareil. Cela est protégé grâce à la clé de rattachement

Le routeur d'annonce doit utiliser la méthode Security_Sym_Join définie pour le PSMO du gestionnaire de système pour envoyer les informations de sécurité qui font partie intégrante de la demande de rattachement pour le compte du nouvel appareil et pour obtenir les informations de sécurité qui font partie intégrante de la réponse de rattachement.

Le Tableau 60 décrit la méthode Security_Sym_Join.

Tableau 60 – Méthode Security_Sym_Join

Nom du type d'objet normalisé: Proxy security management object (PSMO, objet proxy de gestion de sécurité)				
Identificateur du type d'objet normalisé: 105				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
Security_Sym_Join	1	Méthode d'utilisation du PSMO dans le gestionnaire de système pour envoyer des demandes de rattachement relatives à la sécurité et recevoir des réponses de rattachement relatives à la sécurité		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Join_Request	Security_Sym_Join_Request; voir 7.4.5.2.2	Demande de rattachement relative à la sécurité d'un nouvel appareil au gestionnaire de système
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Join_Response	Security_Sym_Join_Response; voir 7.4.5.2.3	Réponse de rattachement relative à la sécurité du gestionnaire de sécurité au nouvel appareil protégé par l'utilisation de la clé de rattachement

Comme partie intégrante de la dernière étape du processus de rattachement, le nouvel appareil doit utiliser la méthode Security_Confirm définie pour le PSMO du gestionnaire de système pour envoyer une confirmation de sécurité au gestionnaire de sécurité.

Le Tableau 61 décrit la méthode Security_Confirm.

Tableau 61 – Méthode Security_Confirm

Nom du type d'objet normalisé: Proxy security management object (PSMO, objet proxy de gestion de sécurité)				
Identificateur du type d'objet normalisé: 105				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
Security_Confirm	2	Méthode utilisée par le nouvel appareil pour l'envoi de confirmation de sécurité au gestionnaire de sécurité par l'intermédiaire du PSMO.		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Security_Sym_Confirm	Security_Sym_Confirm; voir 7.4.5.2.4	Confirmation de sécurité du nouvel appareil au gestionnaire de sécurité
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	-	-	-	-

NOTE 2 Bien que la méthode Security_Confirm n'ait aucun argument de sortie, le message de réponse Execution dans la sous-couche application est retourné comme résultat de cette méthode.

7.4.5.2.2 Demande de rattachement à clés symétriques

La structure de données Security_Sym_Join_Request qui est utilisée pour former une demande de rattachement à clé symétrique est définie dans le Tableau 62.

Tableau 62 – Structure de données Security_Sym_Join_Request

Nom du type de données normalisé: Security_Sym_Join_Request		
Code du type de données normalisé: 410		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
New_Device_EUI64	1	Type: EUI64Address Classification: Constant Accessibilité: Read Only
128_Bit_Challenge_From_New_Device	2	Type: SymmetricKey Classification: Static Accessibilité: Read/write
Algorithm_Identifier	3	Type: Unsigned8 Classification: Static Accessibilité: Read Only Valeur par défaut: 1
MIC	4	Type: Unsigned32 Classification: Static Accessibilité: Read Only

Les champs comprennent:

- New_Device_EUI64 est l'adresse EUI64Address de l'appareil de rattachement. Cette adresse EUI64Address est utilisée par le routeur d'annonce lorsqu'il transmet le

message au gestionnaire de système pour identifier cet appareil de façon univoque, car il pourrait y avoir plusieurs nouveaux appareils qui se rattachent en même temps.

- 128_Bit_Challenge_from_new_device est un nouveau défi unique généré par le nouvel appareil pour vérifier que le gestionnaire de sécurité est vivant.
- L'identificateur d'algorithme doit être utilisé pour spécifier l'algorithme à clé symétrique utilisé dans le réseau-cible. La valeur 0x0 doit être réservée. Un algorithme à clé symétrique de 0x01 correspondant à AES_CCM* doit être le seul algorithme symétrique et le seul mode pris en charge pour le processus de rattachement.

NOTE Actuellement, seul AES_CCM* est défini comme étant un algorithme à clé symétrique. Cependant, ce champ est préparé pour des algorithmes pour usage futur ou réglementation nationale.

- Le MIC-32 se calcule sur les éléments 1 à 4, en utilisant la clé de rattachement et les 13 octets de poids fort du défi comme nonce.

7.4.5.2.3 Réponse de rattachement à clés symétriques

La structure de données Security_Sym_Join_Response qui est utilisée pour former une réponse de rattachement à clé symétrique est définie dans le Tableau 63.

Tableau 63 – Structure de données Security_Sym_Join_Response

Nom du type de données normalisé: Security_Sym_Join_Response		
Code du type de données normalisé: 411		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
128_Bit_Challenge_From_SecurityManager	1	Type: SymmetricKey Classification: Static Accessibilité: Read/write
128_Bit_Response_To_New_Device_Hash_B	2	Type: SymmetricKey Classification: Static Accessibilité: Read/write
Combined_Security_Level	3	Type: Unsigned8 (voir Tableau 64) Classification: Static Accessibilité: Read/write
Master_Key_HardLifeSpan	4	Type: Unsigned16 Classification: Static Accessibilité: Read/write
DL_Key_HardLifeSpan	5	Type: Unsigned16 Classification: Static Accessibilité: Read/write
Sys_Mgr_Session_Key_HardLifeSpan	6	Type: Unsigned16 Classification: Static Accessibilité: Read/write
DL_Key_ID	7	Type: Unsigned8 Classification: Static Accessibilité: Read/write

Nom du type de données normalisé: Security_Sym_Join_Response		
Code du type de données normalisé: 411		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
Encrypted_DL_Key	8	Type: SymmetricKey Classification: Static Accessibilité: Read/write
Encrypted_Sys_Mgr_Session_Key	9	Type: SymmetricKey Classification: Static Accessibilité: Read/write

Cette structure de données est constituée d'une section en texte clair et d'une section chiffrée. La section en texte clair doit être composée de l'en-tête, du défi d'origine issu du nouvel appareil et d'un nouveau défi issu du gestionnaire de sécurité qui est différent du défi généré par le nouvel appareil, et des politiques principales. La section chiffrée doit être composée de la clé D et de la clé T avec le gestionnaire de système.

- 128_Bit_Challenge_From_Security_Manager est un nouveau défi unique généré par le gestionnaire de sécurité pour vérifier que le nouvel appareil est vivant.
- 128_Bit_Response_To_New_Device_Hash_B doit être calculé comme étant:
  - Hash_B= HMAC-MMO$_{K_join}$[challenge_from_security_manager || challenge_from_new_device || adresse EUI64Address de new_device || adresse EUI64Address de security_manager || Message_Key_Transport]
  - Message_Key_Transport = Combined_Security_Level || Master_Key_HardLifeSpan || DL_Key_HardLifeSpan || Sys_Mgr_Session_Key_HardLifetime || DL_Key_ID || Encrypted D-key || Encrypted SysMan T-key
- Les Master_Key_HardLifeSpan, DL_Key_HardLifeSpan et Sys_Mgr_Session_Key_HardLifeSpan doivent être la HardLifeSpan, exprimée en heures. Les Key Type='001' et Key Usage peuvent être inférés implicitement à partir du Tableau 89 et du Tableau 90 par l'élément Identifier. Une granularité par défaut de 0x2='heures' doit être utilisée pour les politiques dans le message de réponse de rattachement.
- Le DL_Key_ID doit être le CryptoKeyIdentifier associé à la clé D envoyée dans la réponse de rattachement. Le CryptoKeyIdentifier de la clé principale et de la clé T peut être mis implicitement (pas émis, mais inféré) comme étant 0x00.
- Les 13 octets de poids fort du défi envoyé à partir du gestionnaire de sécurité doivent être utilisés comme étant le nonce pour chiffrer la clé-D et la clé-T. La clé-D et la clé-T sont chiffrées en même temps (opération unique de chiffrement AES-CCM* avec une longueur de MIC = 0).
- La réaction à un nouvel appareil doit être le hachage codé défini comme suit:
- La nouvelle clé principale doit être dérivée comme étant:
  - K_master = HMAC-MMOK_join[EUI64Addressnew_device || EUI64Address of security_manager || challenge_from_new_device || challenge_from_security_manager]
- La clé D et la clé T pour prendre en charge le contrat avec le gestionnaire de système doivent être chiffrées en utilisant la nouvelle clé principale.

NOTE 1 En incluant le défi issu du nouvel appareil et en calculant un MIC sur celui-ci, le gestionnaire de sécurité prouve qu'il est un appareil vivant avec connaissance de la clé de rattachement.

NOTE 2 La période de validité de 16 bits, avec les unités en heures, donne une plage de plus de 7 ans, qui est adéquate pour exprimer l'actuelle durée maximale de vie d'une clé.

Tableau 64 – Structure du champ niveau de sécurité compressé

Octet	Bits							
	7	6	5	4	3	2	1	0
1	DL_Security_Level			Sys_Mgr_Ses_Security_Level			Master_key_Sec_level	

Les champs comprennent:

- DL_Security_Level: Le niveau de sécurité appliqué à la clé D acheminée dans le message de réponse Security_Sym_Join. Le format de ce champ doit être spécifié conformément au Tableau 35. Le niveau de sécurité 0, None, et le niveau de sécurité 4, ENC, ne doivent pas être utilisés.
- Sys_Mgr_Ses_Security_Level: Le niveau de sécurité appliqué à la clé T avec le gestionnaire de système acheminée dans le message de réponse Security_Sym_Join. Le format de ce champ doit être spécifié conformément au Tableau 35. Le niveau de sécurité 4, ENC, ne doit pas être utilisé.
- Master_Key_Sec_Level: La taille de MIC appliquée à la clé principale générée dans le processus de rattachement. Le format de ce champ est défini dans le Tableau 65. Sachant que le facteur de chiffrement est différent dans chaque message protégé par la clé principale, seule la taille du MIC est spécifiée dans ce champ. Le niveau de sécurité réel doit être sélectionné dans le Tableau 65 avec une combinaison de conditions de chiffrement dans chaque message.

NOTE 3 Par exemple, sachant que les structures de données Security_New_Session_Request et Security_New_Session_Response n'ont aucun élément devant être chiffré, le Security_Level dans le champ Security_Control est mis à MIC-*n* avec la taille MIC spécifiée dans cette structure. Alors que la structure de données Security_Key_and_Policies a l'élément devant être chiffré, le Security_Level dans le champ Security_Control est mis à ENC-MIC-*n* avec la taille MIC spécifiée dans cette structure.

Tableau 65 – Niveau de sécurité de clé principale

Identificateur de niveau de sécurité	Master_Key_Sec_Level	Attributs de sécurité
0	0	Réservé
1	1	MIC-32
2	2	MIC-64
3	3	MIC-128

NOTE 4 Sachant qu'un MIC est toujours utilisé pour protéger les PDU de processus de rattachement avec la clé principale, l'identificateur de niveau de sécurité 0 est Reserved (réservé).

- ValidNotBefore = temps TAI où l'APDU est reçue;

NOTE 5 La ValidNotBefore peut être inférée comme étant le temps reconstruit utilisé dans l'authentification de la PDU et n'est pas incluse en raison des restrictions d'espace dans la PDU de réponse.

Le temps auquel l'APDU est reçue ne doit pas être supérieur à DSMO.pduMaxAge secondes après qu'elle a été créée. Cela donne un temps de début acceptable.

- HardLifeSpan: La durée valide de la clé est exprimée en heures. La saisie de la valeur 0x0000 doit interdire l'expiration de la clé.

Si la valeur de HardLifeSpan est zéro (effectivement infinie par exemple), alors la durée de vie de la clé inférée doit être:

– ValidNotAfter = 0xFFFF FFFF. Ainsi, cette clé sera perçue par la logique d'expiration de clé comme une clé qui n'expire jamais;

– SoftExpirationTime = ValidNotAfter.

Si la valeur de HardLifeSpan est différente de zéro (finie par exemple), alors la durée de vie de la clé inférée doit être:

– ValidNotAfter = ValidNotBefore + (HardLifeSpan x 3 600);

– SoftExpirationTime = ValidNotBefore + (SoftLifeSpanRatio x HardLifeSpan x 3 600).

Un SoftLifeSpanRatio de 50 % doit être utilisé comme valeur par défaut pour les clés envoyées avec un champ Key_HardLifeSpan.

7.4.5.2.4 Confirmation de la sécurité à clés symétriques

La structure de données Security_Sym_Confirm qui est utilisée pour former une confirmation de sécurité à clé symétrique est définie dans le Tableau 66. L'objet source pour invoquer la PSMO.Proxy_Security_Sym_Confirm().Request doit être le DMO dans le DMAP de l'appareil se rattachant.

Tableau 66 – Structure de données Security_Sym_Confirm

Nom du type de données normalisé: Security_Sym_Confirm		
Code du type de données normalisé: 412		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
128_Bit_Response_To_Security_Manager	1	Type: SymmetricKey Classification: Static Accessibilité: Read/write

128_Bit_Response_To_Security_Manager doit être calculé comme étant:

HMAC-MMOK_join[challenge_from_new_device || challenge_from_security_manager || EUI64Address of new_device || EUI64Address of security_manager || MIC_1 || MIC_2]

où

MIC_1 est la valeur MIC 32 bits dans la réponse in System_Manager_Join et MIC_2 est la valeur MIC 32 bits dans la réponse System_Manager_Contract.

NOTE 1 La confirmation de rattachement dit au gestionnaire de sécurité que l'appareil était capable de récupérer la clé principale en utilisant la clé de rattachement, fournissant ainsi la preuve qui l'appareil, qui connaît la clé de rattachement, est vivant.

NOTE 2 La construction du hachage pour le protocole de réponse au défi était modélisée d'après le protocole décrit par Menezes et al.:1996, 10.17 (voir Bibliographie).

7.4.6 Processus de rattachement à clés asymétriques

7.4.6.1 Vue d'ensemble

Le processus de rattachement à clés asymétriques, tout comme le processus de rattachement à clés symétriques, spécifie la séquence des étapes par lesquelles et les conditions dans lesquelles un appareil peut devenir une partie du réseau et avoir accès aux informations exigées pour communiquer au sein du réseau, tant avec des appareils immédiatement voisins qu'avec des appareils d'infrastructure particulière, tels que les appareils jouant le rôle de gestionnaire de système ou de gestionnaire de sécurité du réseau. A ce titre, cela nécessite les sous-processus décrits ci-dessous. Noter que la distribution du support de codage et les étapes d'allocation de ressources sont identiques pour les processus de rattachement à clés asymétriques et à clés symétriques. La table des rôles et leur assignation de carte de bits respective sont définies dans l'Annexe B.

Le processus d'inscription comprend:

- Inscription d'adhésion comme membre de réseau. Un appareil et un gestionnaire de sécurité s'engagent dans un protocole mutuel d'authentification d'entité basé sur des techniques à clés asymétriques. Ce protocole fournit la preuve relative à la véritable identité d'appareil tant de l'appareil se joignant que du gestionnaire de sécurité, sur la

base de clés asymétriques authentiques. En outre, l'admission peut être basée sur des critères d'acceptabilité autres que cryptographiques (par exemple, par l'intermédiaire d'un essai d'adhésion comme membre de l'appareil par l'intermédiaire d'une liste de contrôle d'accès). Si l'appareil a été catégoriquement authentifié et est autorisé à rejoindre le réseau, il peut être admis dans le réseau. Le protocole d'authentification d'entité conduit également à l'établissement d'une clé partagée entre l'appareil se joignant et le gestionnaire de sécurité, facilitant ainsi des communications sécurisées et authentiques en cours entre ces appareils.

- Distribution de support de codage. Un gestionnaire de sécurité alloue le support de codage à un appareil nouvellement admis, afin de faciliter des communications ultérieures et l'authentification continue de l'appareil auprès d'autres membres du réseau comme étant un appareil légitime de réseau. Le support de codage peut inclure des clés D, qui sont utilisées pour prouver l'adhésion comme membre de réseau parmi des appareils dans le réseau, et des clés T, qui sont utilisées pour sécuriser et authentifier des communications en cours entre un appareil nouvellement admis et un gestionnaire de système.

Le processus de rattachement suppose que des appareils ont été dotés d'informations suffisantes pour permettre l'authentification correcte de l'appareil. Un appareil se joignant peut tout aussi bien avoir été doté d'informations non relatives à la sécurité.

Le plan d'agrément de clé à clés asymétriques est spécifié en 7.4.6.2, le plan de distribution de clé est spécifié en détail en 7.4.6.3, le plan d'allocation de ressources est spécifié en détail en 6.3.9, et le protocole de rattachement à clés asymétriques est spécifié en 7.4.6.3.5. Les nombres entiers, les octets et les entités utilisés dans le protocole de rattachement à clés asymétriques sont définis dans l'Annexe F. Les blocs modules de base cryptographiques à clés asymétriques sont définis dans l'Annexe H.

7.4.6.2 Plan d'agrément de clé à clés asymétriques

7.4.6.2.1 Vue d'ensemble

7.4.6.2.1.1 Généralités

L'inscription d'adhésion comme membre de réseau est basée sur l'exécution du plan d'agrément de clé à clés asymétriques spécifié en H.4.2 et comporte l'authentification d'appareil basée sur des certificats implicites, tels que spécifiés en H.5.1. Les deux plans impliquent des techniques à clés asymétriques utilisant des courbes elliptiques.

7.4.6.2.1.2 Format de certificat implicite

Le certificat implicite est une preuve d'identité et est utilisé dans le processus de rattachement à clés asymétriques. Il peut acheminer une structure de données arbitraire; cependant, pour permettre l'interfonctionnabilité entre les appareils, le format du certificat implicite, utilisé dans la présente norme, est défini dans le Tableau 67.

Tableau 67 – Format de certificat implicite

Nom de l'élément	Identificateur de l'élément	Type de l'élément
PublicKey_reconstruction_data	1	Type: OctetString37
Sujet	2	Type: EUI64Address
Issuer	3	Type: EUI64Address
Usage_serial_number	4	Type: Structure Usage_Serial (voir Tableau 68)
ValidNotBefore	5	Type: TAITimeRounded
ValidNotAfter	6	Type: TAITimeRounded

- PublicKey_reconstruction_data: Paramètre pour générer une clé publique en utilisant la clé publique de CA.

- Subject: Adresse EUI64Address d'un appareil dont la clé publique/privée est associée à Publickey_Reconstruction_Data
- Issuer: Adresse EUI64Address d'un appareil qui a généré ce certificat.
- Usage_serial_number: Indiquant un usage de certification et un numéro de série.
- ValidNotBefore: Temps TAI absolu (en secondes) où ce certificat devient valide.
- ValidNotAfter: Temps TAI absolu (en secondes) où ce certificat devient non valide.

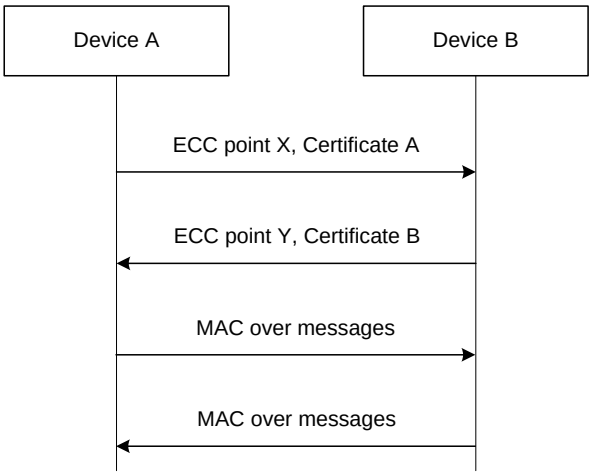
Tableau 68 – Structure d'Usage_serial_number

Octet	Bits							
	7	6	5	4	3	2	1	0
1	Reserved	Issuable	Serial_number					

- Reserved: Il convient que le champ Reserved soit 0.
- Issuable: Si ce champ est 0, la paire de clés correspondant à ce certificat ne doit pas être utilisée pour signer un autre certificat. Autrement, la paire de clé peut être utilisée pour signer un autre certificat.
- Serial_number: Numéro de série de ce certificat géré par l'émetteur.

7.4.6.2.2 Description du plan

La Figure 46 montre la messagerie impliquée dans le plan d'agrément de clé à clés asymétriques utilisé avec la présente norme.



Légende

Anglais	Français
Device A	Appareil A
Device B	Appareil B
ECC point X, certificate A	Point X sur ECC, certificat A
ECC point Y, certificate B	Point Y sur ECC, certificat B
MAC over messages	Messages au-dessus de MAC

Figure 46 – Plan d'agrément de clé à clés asymétriques

Dans le contexte du protocole de rattachement, le plan d'agrément de clé implique une messagerie entre un appareil se joignant et un gestionnaire de sécurité, par laquelle l'appareil se joignant lance le protocole et par laquelle le gestionnaire de sécurité agit comme ledit répondeur. Donc, dans les termes de la Figure 46, l'appareil se joignant joue le rôle d'appareil A et le gestionnaire de sécurité joue le rôle d'appareil B.

Le protocole inclut les composantes séquentielles suivantes:

a) Contributions de clé. Chaque partie prenante génère au hasard une paire de clés publiques de court terme (éphémères) et communique la clé publique éphémère (mais pas la clé privée) à l'autre partie prenante. En outre, chaque partie prenante communique le certificat de sa clé publique (statique) à long terme à l'autre partie prenante.

b) Etablissement de clé. Chaque partie prenante calcule la clé partagée en se basant sur les points de courbes elliptiques statiques et éphémères qu'elle a reçus en provenance de l'autre partie prenante, et également en se basant sur les clés privées statiques et éphémères qu'elle génère elle-même. En raison des propriétés des courbes elliptiques, l'une ou l'autre partie prenante arrive à la même clé partagée.

c) Authentification de clé. Chaque partie prenante vérifie l'authenticité de la clé statique à long terme de l'autre partie prenante, pour obtenir la preuve que la seule partie prenante qui peut être capable de calculer la clé partagée est effectivement la partie prenante communicante perçue.

d) Confirmation de clé. Chaque partie prenante calcule et communique une valeur de contrôle d'authentification de message sur des chaînes communiquées par l'autre partie prenante, pour prouver la possession de la clé partagée à l'autre partie prenante. Cela confirme à chaque partie prenante la véritable identité de l'autre partie prenante et prouve que l'autre partie prenante a calculé avec succès la clé partagée. Ce message de confirmation de clé peut authentifier une chaîne complémentaire communiquée par la partie prenante elle-même. Les chaînes et les opérations sur les chaînes sont définies dans l'Annexe F.

Le protocole suppose que chaque partie prenante a accès à la clé racine de l'autorité de certification (CA[7]) qui a signé le certificat reçu en provenance de l'autre partie prenante.

7.4.6.2.3 Propriétés de sécurité du plan

L'exécution réussie du plan complet conduit à des propriétés de sécurité, y compris ce qui suit:

- Authentification mutuelle d'entité. Chaque partie prenante a des assurances quant à la véritable identité de l'autre partie prenante et quant au fait que cette partie prenante était vivante pendant l'exécution du protocole.
- Authentification de clé implicite mutuelle. Chaque partie prenante a des assurances que la seule partie prenante qui a pu avoir été capable de calculer la clé partagée est effectivement la partie prenante communicante prévue.
- Confirmation de clé mutuelle. Chaque partie prenante a la preuve que sa partie prenante communicante prévue a calculé avec succès la clé partagée.
- Secret direct parfait. La compromission de la clé statique ne compromet pas les clés partagées passées.
- Aucune commande de clé unilatérale. Chaque partie prenante a l'assurance qu'aucune partie prenante n'était capable de commander ou prédire la valeur de la clé partagée.
- Propriétés de sécurité complémentaires, telles que la résilience de partage de clé inconnue et sécurité de clé connue. Pour des détails, voir la norme ANSI X9.63:2011, Tableau H.2.

Les services de sécurité fournis par chaque plan sont assurés après l'achèvement réussi du plan complet en question (et si les conditions préalables du plan sont respectées). A partir des plans, il n'est pas a priori clair quelles propriétés sont fournies pendant l'exécution des étapes de protocole du plan. Les services de sécurité fournis incluent:

– Le traitement des contributions de clé aléatoires n'offre aucun service de sécurité, car ces messages sont indépendants.

_____

[7] CA = *certificate authority*.

– A partir de la perspective de l'appareil se rattachant A, le protocole est fini après l'achèvement des étapes de traitement résultant de la réception du message de confirmation de clé MAC_B, alors qu'à partir de la perspective du gestionnaire de sécurité B, le protocole est seulement fini après l'achèvement des étapes de traitement résultant de la réception du message de confirmation de clé MAC_A. En particulier, le gestionnaire de sécurité B n'a aucune assurance avant la réception et le traitement du message de confirmation clé MAC_A. Ainsi, toutes les éventuelles actions par B déclenchées avant l'achèvement du protocole entier avec A sont prématurées, en ce sens qu'elles ne peuvent pas être logiquement basées sur d'éventuelles assurances de sécurité (car il n'y en a aucune). En revanche, toutes les éventuelles actions par B déclenchées après que l'achèvement réussi du protocole entier avec A peuvent être bien fondées, en ce sens qu'elles peuvent être basées sur les services de sécurité résultant de l'achèvement du protocole.

NOTE Cela souligne de nouveau l'importance de la prise en considération de l'effet des plans cryptographiques dans leur intégralité.

7.4.6.3 Plan de distribution de clé

7.4.6.3.1 Vue d'ensemble

La distribution de clé est basée sur la clé partagée résultant du plan d'agrément de clé à clés asymétriques, tel que décrit en 7.4.6.2, exécuté entre l'appareil se joignant et le gestionnaire de sécurité.

7.4.6.3.2 Description du plan

Le mécanisme pour la distribution du support de codage du gestionnaire de sécurité vers l'appareil nouvellement rattaché et le gestionnaire de système est le même que celui décrit dans le processus de rattachement à clés symétriques. Pour les détails, voir 7.4.4.

7.4.6.3.3 Propriétés de sécurité du plan

L'exécution réussie du plan de distribution de clé conduit à des propriétés de sécurité, y compris ce qui suit:

- Transfert sécurisé et authentique de la clé D et des informations de codage associées du gestionnaire de sécurité vers l'appareil nouvellement rattaché.
- Transfert sécurisé et authentique de la clé T et des informations de codage associées du gestionnaire de sécurité vers l'appareil nouvellement rattaché et vers le gestionnaire de système sélectionné par le gestionnaire de sécurité.
- Dans un cas comme dans l'autre, le support de codage distribué est généré par le gestionnaire de sécurité, offrant donc la commande de clé unilatérale.

7.4.6.3.4 Formats de messagerie de protocole

Le mécanisme pour la distribution du support de codage du gestionnaire de sécurité vers l'appareil nouvellement rattaché et le gestionnaire de système est le même que celui décrit dans le processus de rattachement à clés symétriques. Pour les détails, voir 7.4.4.

7.4.6.3.5 Protocole de rattachement à clés asymétriques

Le protocole de rattachement à clés asymétriques peut être vu comme un protocole qui combine le plan d'agrément de clé à clés asymétriques débattu en 7.4.6.2 et le plan de distribution de clé débattu en 7.4.6.3, la différence principale résidant dans l'organisation réelle de la messagerie en trames.

Le protocole de rattachement à clés asymétriques et le protocole de rattachement à clés symétriques diffèrent seulement dans l'utilisation d'un plan d'agrément de clé à clés asymétriques, plutôt que d'un plan d'agrément de clé à clés symétriques. Ainsi, tous autres

aspects de la spécification du protocole de rattachement à clés symétriques (voir 7.4.4) s'appliquent également au protocole de rattachement à clés asymétriques.

7.4.6.4 Messages de processus de rattachement à clés asymétriques

7.4.6.4.1 Généralités

La Figure 47 et la Figure 48 illustrent la messagerie impliquée dans le processus de rattachement à clés asymétriques par lequel un nouvel appareil doit rejoindre un réseau en fonctionnement dans lequel il n'a pas été récemment un participant. Le flux montre le cas normal dans lequel il ne se produit pas d'erreur ou de temporisation. Les temporisations sont spécifiées en 7.4.7.3.

Security join reply	Réponse de rattachement de sécurité
Security join confirm request	Demande de confirmation de rattachement de sécurité
Security join confirm response	Réponse de confirmation de rattachement de sécurité

Figure 48 – Exemple: Vue d'ensemble du processus de rattachement à clés asymétriques d'un appareil dorsal

Sur l'appareil se rattachant, le processus de rattachement à clés asymétriques doit être initié par l'émission d'une DMO.Proxy_Security_Pub_Join().Request et finalisé par la réception d'une PSMO.Network_Information_Confirmation().Response valide. Sur le gestionnaire de sécurité, le processus de rattachement à clés asymétriques doit être initié par la réception d'un message valide dérivé à partir d'une PSMO.Security_Pub_Join().Request et finalisé par un message d'émission dérivé pour être une PSMO.Network_Information_Confirmation().Response.

Comme montré à la Figure 48, un nouvel appareil doit utiliser les méthodes définies pour le DMO de routeur d'annonce pour envoyer et recevoir les messages de demande de rattachement et de réponse de rattachement. Les méthodes relatives aux informations autres que de sécurité sont décrites en 6.3.9.2. Les méthodes de DMO relatives aux informations de sécurité pour la méthode de rattachement asymétrique sont décrites en 7.4.6.4.2.

Le routeur d'annonce doit utiliser les méthodes définies pour le DMSO du gestionnaire de système pour envoyer et recevoir les messages de demande et de réponse relatifs à la non-sécurité. Ces méthodes de DMSO sont décrites en 6.3.9.5. Les méthodes définies pour l'objet proxy de gestion de sécurité (PSMO) du gestionnaire de système doivent être utilisées par le routeur d'annonce pour envoyer et recevoir les messages de demande et de réponse relatifs à la sécurité. Les méthodes du PSMO relatives aux informations de sécurité sont décrites en 7.4.5.2.

7.4.6.4.2 Méthodes d'objet de gestion d'appareil et d'objet proxy de gestion de sécurité relatives au processus de rattachement à clés asymétriques

Le nouvel appareil doit utiliser la méthode Proxy_Security_Pub_Join définie pour le DMO de routeur d'annonce dans le routeur d'annonce pour envoyer ses informations de sécurité qui font partie intégrante de la demande de rattachement et pour obtenir ses informations de sécurité qui font partie intégrante de la réponse de rattachement. Après émission de la DMO.Proxy_Security_Pub_Join().Request, le nouvel appareil doit démarrer le temporisateur de rattachement JT_1. Après réception de la DMO.Proxy_Security_Pub_Join().Request, le gestionnaire de sécurité doit démarrer le temporisateur de rattachement JT_2.

Le Tableau 69 décrit la méthode Proxy_Security_Pub_Join.

Tableau 69 – Méthode Proxy_Security_Pub_Join

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Device management object (DMO, objet de gestion d'appareil)</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 127</th></tr>
<tr><th>Nom de la méthode</th><th>ID de la méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="8">Proxy_Security_Pub_Join</td><td>6</td><td colspan="3">Méthode d'utilisation du routeur d'annonce en tant que proxy afin d'envoyer des demandes de rattachement relatives à la sécurité et d'obtenir des réponses de rattachement relatives à la sécurité</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>Join_Request</td><td>Security_Pub_Join_Request; voir 7.4.6.4.3</td><td>Demande de rattachement relative à la sécurité basée sur les clés publiques à partir d'un nouvel appareil devant être transmise au gestionnaire de sécurité</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>Join_Response</td><td>Security_Pub_Join_Response; voir 7.4.6.4.3</td><td>Réponse de rattachement relative à la sécurité basée sur les clés publiques du gestionnaire de sécurité devant être transmise au nouvel appareil. Cela est protégé grâce à la clé de rattachement</td></tr>
</table>

Le routeur d'annonce doit utiliser la méthode Security_Pub_Join définie pour le PSMO du gestionnaire de système pour envoyer les informations de sécurité qui font partie intégrante de la demande de rattachement pour le compte du nouvel appareil et pour obtenir les informations de sécurité qui font partie intégrante de la réponse de rattachement.

L'objet source de la DMO.Proxy_Security_Pub_Join().Request doit être le DMO dans le DMAP de l'appareil se rattachant.

Le Tableau 70 décrit la méthode Security_Pub_Join.

Tableau 70 – Méthode Security_Pub_Join

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Proxy security management object (PSMO, objet proxy de gestion de sécurité)</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 105</th></tr>
<tr><th>Nom de la méthode</th><th>ID de la méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="6">Security_Pub_Join</td><td>3</td><td colspan="3">Méthode d'utilisation du PSMO dans le gestionnaire de système pour envoyer des demandes de rattachement relatives à la sécurité et recevoir des réponses de rattachement relatives à la sécurité</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>Join_Request</td><td>Security_Pub_Join _Request; voir 7.4.6.4.3</td><td>Demande de rattachement relative à la sécurité d'un nouvel appareil au gestionnaire de système</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>Join_Response</td><td>Security_Pub_Join _Response; voir 7.4.6.4.3</td><td>Réponse de rattachement relative à la sécurité du gestionnaire de sécurité au nouvel appareil protégé par l'utilisation de la clé de rattachement</td></tr>
</table>

Après avoir reçu le message Proxy_Security_Pub_Join().Response, le nouvel appareil doit utiliser la méthode Proxy_Security_Pub_Confirm() définie pour le DMO de routeur d'annonce pour envoyer une confirmation de sécurité au routeur d'annonce. Le Tableau 71 décrit cette méthode. L'objet source de la DMO.Proxy_Security_Pub_Join().Request doit être le DMO dans le DMAP de l'appareil se rattachant.

Le routeur d'annonce doit utiliser la méthode Security_Pub_Confirm définie pour le PSMO du gestionnaire de système pour envoyer ces informations de sécurité au gestionnaire de sécurité. Le Tableau 72 décrit cette méthode.

Le gestionnaire de sécurité est responsable de vérifier le message de confirmation. Si l'essai échoue, l'état de rattachement et les informations placées en cache pour le nouvel appareil doivent être initialisés ou abandonnés. Si l'essai réussit, alors le gestionnaire de sécurité arrête le temporisateur de rattachement JT_2 et envoie une réponse de confirmation et les réponses d'informations autres que de sécurité au nouvel appareil.

Si le nouvel appareil reçoit une réponse valide à sa demande de confirmation, alors le nouvel appareil arrête le temporisateur JT_1.

Après avoir reçu la réponse DMO.Proxy_System_Manager_Join() et DMO.Proxy_System_Manager_Contract(), l'appareil de rattachement invoque la méthode PSMO.Network_Information_Confirmation(). Le Tableau 73 décrit la méthode.

Le champ Confirm dans la PSMO.Network_Information_Confirmation().Request est le MACTag généré avec l'opération suivante:

$$MACTag = HMAC\text{-}MMOK\_join[MIC_1 \,||\, MIC_2 \,||\, Challenge_{joining\_device}]$$

où:

MIC_1: Champ MIC dans la DMO.Proxy_System_Manager_Join().Response (voir Tableau 19);

MIC_2: Champ MIC dans la DMO.Proxy_System_Manager_Contract().Response (voir Tableau 20).

7.4.6.4.3 Formats de messagerie de protocole

7.4.6.4.3.1 Format de la structure interne de la demande de rattachement (PK-join-1)

Le type de données Security_Pub_Join_Request utilisé dans la méthode de Security_Pub_Join et dans la méthode Proxy_Security_Pub_Join a la structure suivante et représente le premier flux de message du plan d'agrément de clé à clés asymétriques (7.4.6.2). Ce type de données est utilisé par le nouvel appareil et son routeur proxy dans les méthodes correspondantes du DMO du routeur proxy et du PSMO du gestionnaire de système respectivement. Les données PK-join-1 doivent être formatées telles que montrées dans le Tableau 74.

Tableau 74 – Format de la structure interne de la demande de rattachement asymétrique

Nom du type de données normalisé: Security_Pub_Join_Request (PK-Join-1)		
Code du type de données normalisé: 415		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
New_Device_EUI64	1	Type: EUI64Address Classification: Constant Accessibilité: Read Only
Champ de contrôle de protocole	2	Type: Unsigned8 Classification: Constant Accessibilité: Read Only Valeur par défaut: 1000 0000
Point X de courbe elliptique éphémère	3	Type: OctetString37 Classification: Static Accessibilité: Read Only
Certificat implicite du nouvel appareil	4	Type: OctetString SIZE(37..66) Classification: Static Accessibilité: Read/write
NOTE 1 Le format du certificat implicite utilisé dans la présente norme est défini en 7.4.6.2.1.2. NOTE 2 La taille totale de la demande de rattachement à clés asymétriques se situe dans la plage de 83..112 octets. Si l'utilisateur emploie cette approche, la demande exigera parfois plus d'une DPDU d'acheminement.		

Le champ commande de protocole a une taille de 1 octet et spécifie l'algorithme qui est utilisé pour le protocole de rattachement à clés asymétriques et l'étape du protocole qui est actuellement exécutée. Ce sous-champ doit être formaté comme spécifié dans le Tableau 75.

Tableau 75 – Format du champ commande de protocole

7	6	5	4	3	2	1	0
ID de l'algorithme = "10"		Réservé				Phase du sous-protocole de rattachement	

L'ID de l'algorithme a une taille de 2 bits et indique l'algorithme de rattachement à clé asymétrique en cours d'utilisation. L'algorithme défini dans la présente norme a pour ID 0b'10'.

La phase du sous-protocole de rattachement a une taille de 2 bits et indique la phase en cours du protocole:

0: Demande de rattachement à clés asymétriques;

1: Réponse de rattachement à clés asymétriques;

2: Demande de confirmation de rattachement à clés asymétriques;

3: Réponse de confirmation de rattachement à clés asymétriques.

7.4.6.4.3.2 Format de la structure interne de la réponse de rattachement asymétrique (PK-join-2)

Le type de données Security_Pub_Join_Response utilisé dans la méthode de Security_Pub_Join et dans la méthode Proxy_Security_Pub_Join a la structure suivante et représente le premier flux de message du plan d'agrément de clé à clés asymétriques

(7.4.6.2). Les données PK-join-2 doivent être formatées telles que montrées dans le Tableau 76.

Tableau 76 – Format de la structure interne de la réponse de rattachement asymétrique

Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
New_Device_EUI64	1	Type: EUI64Address Classification: Constant Accessibilité: Read Only
Champ de contrôle de protocole	2	Type: Unsigned8 Classification: Constant Accessibilité: Read Only Valeur par défaut: 1000 0001
Point Y de courbe elliptique éphémère	3	Type: OctetString37 Classification: Static Accessibilité: Read Only
Certificat implicite du gestionnaire de sécurité	4	Type: OctetString SIZE(37..66) Classification: Static Accessibilité: Read/write
NOTE 1 Le format du certificat implicite utilisé dans la présente norme est défini en 7.4.6.2.1.2. NOTE 2 La taille totale de la demande de rattachement à clés asymétriques se situe dans la plage de 83..112 octets. Si l'utilisateur emploie cette approche, la demande exigera parfois plus d'une DPDU d'acheminement.		

7.4.6.4.3.3 Format de la première structure interne de la confirmation de rattachement (PK-join-3)

Le type de données Security_Pub_Confirm_Request utilisé dans la méthode de Security_Pub_Confirm et dans la méthode Proxy_Security_Pub_Confirm a la structure suivante et représente le troisième flux de message du plan d'agrément de clé à clés asymétriques (7.4.6.2). Les données PK-join-3 doivent être formatées telles que montrées dans le Tableau 77.

Tableau 77 – Format de la première structure interne de la confirmation de rattachement

Nom du type de données normalisé: Security_Pub_Confirm_Request (PK-Join-3)		
Code du type de données normalisé: 417		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
New_Device_EUI64	1	Type: EUI64Address Classification: Constant Accessibilité: Read Only
Champ de contrôle de protocole	2	Type: Unsigned8 Classification: Constant Accessibilité: Read Only Valeur par défaut: 1000 0010
Message_authentication_tag_MAC	3	Type: OctetString16 Classification: Static Accessibilité: Read Only
Taille du texte	4	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 0 Plage valide: 0..31
Texte	5	Type: OctetStringN (SIZE: voir élément 4) Classification: Static Accessibilité: Read/write

Le Message_authentication_tag_MAC est généré par la formule suivante.

$$\text{Message\_authentication\_tag\_MAC} = \text{MACmackey}(02_{16} \,||\, U \,||\, V \,||\, QEU \,||\, QEV)$$

où:

U est l'adresse EUI64Address du nouvel appareil;

V est l'ID de 8 octets du gestionnaire de sécurité;

QEU est la chaîne d'octets de la clé publique éphémère du nouvel appareil;

QUV est la chaîne d'octets de la clé publique éphémère du gestionnaire de sécurité.

Cela fait partie du plan d'agrément de clé ECMQV. La MACmackey est définie dans l'ANSI X9.63:2011, 5.7. Dans la présente spécification, la fonction de hachage codé HMAC-MMO avec la clé principale doit être utilisée pour la fonction MACmackey.

Le champ texte est utilisé pour stocker n'importe quelle information qui a besoin d'être authentifiée. Les utilisateurs peuvent utiliser ce champ pour n'importe quelle information qui requiert une protection au cours du processus de rattachement à clés asymétriques.

7.4.6.4.3.4 Format de la seconde structure interne de confirmation de rattachement

Le type de données Security_Pub_Confirm_Response utilisé dans la méthode de Security_Pub_Confirm et dans la méthode Proxy_Security_Pub_Confirm a la structure de données suivante et représente le quatrième flux de message du plan d'agrément de clé à clés asymétriques (7.4.6.2). Les données PK-join-4 doivent être formatées telles que montrées dans le Tableau 78.

Tableau 78 – Format de la structure interne de la réponse de confirmation de rattachement

Nom du type de données normalisé: Security_Pub_Confirm_Response (PK-Join-4)		
Code du type de données normalisé: 418		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
Champ de contrôle de protocole	1	Type: Unsigned8 Classification: Constant Accessibilité: Read Only Valeur par défaut: 1000 0011
Message_authentication_tag_MAC	2	Type: OctetString16 Classification: Static Accessibilité: Read Only
Taille du texte	3	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 0
Texte	4	Type: OctetString (SIZE: voir élément 3) Classification: Static Accessibilité: Read/write
Master_Key_HardLifeSpan	5	Type: Unsigned16 Classification: Static Accessibilité: Read/write
Encrypted D-key (clé D chiffrée)	6	Type: SymmetricKey Classification: Static Accessibilité: Read/write
DL CryptoKeyIdentifier (Identificateur de clé crypto DL)	7	Type: Unsigned8 Classification: Static Accessibilité: Read/write
DL_Key_HardLifeSpan	8	Type: Unsigned16 Classification: Static Accessibilité: Read/write
Encrypted system manager T-key (clé T chiffrée de gestionnaire de système)	9	Type: SymmetricKey Classification: Static Accessibilité: Read/write
System_Manager_Session_Key_HardLifeSpan	10	Type: Unsigned16 Classification: Static Accessibilité: Read/write

Le Message_authentication_tag_MAC est généré par la formule suivante:

$$\text{Message\_authentication\_tag\_MAC} = \text{MACmackey}(03_{16} \,||\, U \,||\, V \,||\, QEU \,||\, QEV)$$

où:

U est l'adresse EUI64Address du nouvel appareil;
V est l'ID de 8 octets du gestionnaire de sécurité;

QEU est la chaîne d'octets de la clé publique éphémère du nouvel appareil;

QUV est la chaîne d'octets de la clé publique éphémère du gestionnaire de sécurité.

Cela fait partie du plan d'agrément de clé ECMQV. La MACmackey est définie dans l'ANSI X9.63:2011, 5.7. Dans la présente spécification, HMAC-MMO avec la clé principale doit être utilisée pour la fonction MACmackey.

Le champ texte est utilisé pour stocker les informations déterminées par un utilisateur qui ont besoin d'être authentifiées. Les utilisateurs peuvent utiliser ce champ pour n'importe quelle information devant être protégée au cours du processus de rattachement à clés asymétriques.

Les champs "key material" (support de clé) et "policy" (politique) sont les mêmes que pour le processus de rattachement à clés symétriques. Spécifiquement, les suivants doivent être les mêmes qu'en 7.4.5:

- Master Key compressed policy (politique compressée de clé principale)
- Encrypted D-key (clé D chiffrée)
- DL CryptoKeyIdentifier (Identificateur de clé crypto DL)
- D-key compressed policy (politique compressée de clé D)
- Encrypted system manager T-key (clé T chiffrée de gestionnaire de système)
- System manager T-key compressed policy (politique compressée de clé T de gestionnaire de système)

7.4.7 Rétablissement après défaillance de processus de rattachement et de durée de vie d'appareil

7.4.7.1 Généralités

A un point quelconque au cours du processus de rattachement, il y a une possibilité qu'une PDU soit abandonnée. Dans ce cas, il convient que le système soit capable de récupérer et continuer. La définition d'état et la transition d'état suivantes décrivent les grandes lignes du mécanisme de rétablissement, avec les effets secondaires déclenchés.

7.4.7.2 Etats d'appareil pendant le processus de rattachement et la durée de vie d'appareil

Les états de l'appareil au cours du processus de rattachement sont:

- Provisioned (configuré): Aucune clé principale, n'est pas en train d'obtenir une clé principale.
- Joining (se rattachant): Aucune clé principale, est en train d'obtenir une clé principale.
- Joined (rattaché): Ayant une clé principale courante, n'est pas en train d'obtenir la clé principale suivante.
- Updating (se mettant à jour): Ayant une clé principale courante, est en train d'obtenir la clé principale suivante.
- Overlapped (superposé): Ayant à la fois la clé principale courante et la clé principale suivante.

7.4.7.3 Transitions d´état

Les transitions d'état pour un appareil rejoignant le réseau doivent être telles que présentées dans le Tableau 79 et dans la Figure 49. Les valeurs de temporisation pour le processus de rattachement join_timeout (ID 4) dans le Tableau 92, doivent être configurables en utilisant des annonces de DL. Il convient que l'effacement de clés soit au moins l'équivalent du nettoyage de données confidentielles, conformément à la NIST SP 800-88:2012, Tableau 2-1.

Tableau 79 – Diagramme d'états du processus de rattachement et de la durée de vie d'appareil

Transition	Etat actuel	Evénement(s)	Action(s)	Etat suivant
T1	Provisioned (configuré)	DMO initialise le processus de rattachement	Routeur d'annonce DMO.Proxy_Security_Sym_ Join().Request or DMO.Proxy_Security_Pub_ Join().Request	Joining (se rattachant)
T2	Joining (se rattachant)	DMO.Proxy_Security_Sym_Join ().Response or DMO.Proxy_Security_Pub_Join ().Response reçue et vérification cryptographique ok	Entrée appropriée peuplée dans le DSMO et le KeyDescriptor Appel PSMO.Security_Confirm(). Request (peut être retardée), ou Appel PSMO.Network_Information_ confirmation().Request	Joined (rattaché)

Figure 49 – Transitions d'états d'appareil pour processus de rattachement et durée de vie d'appareil

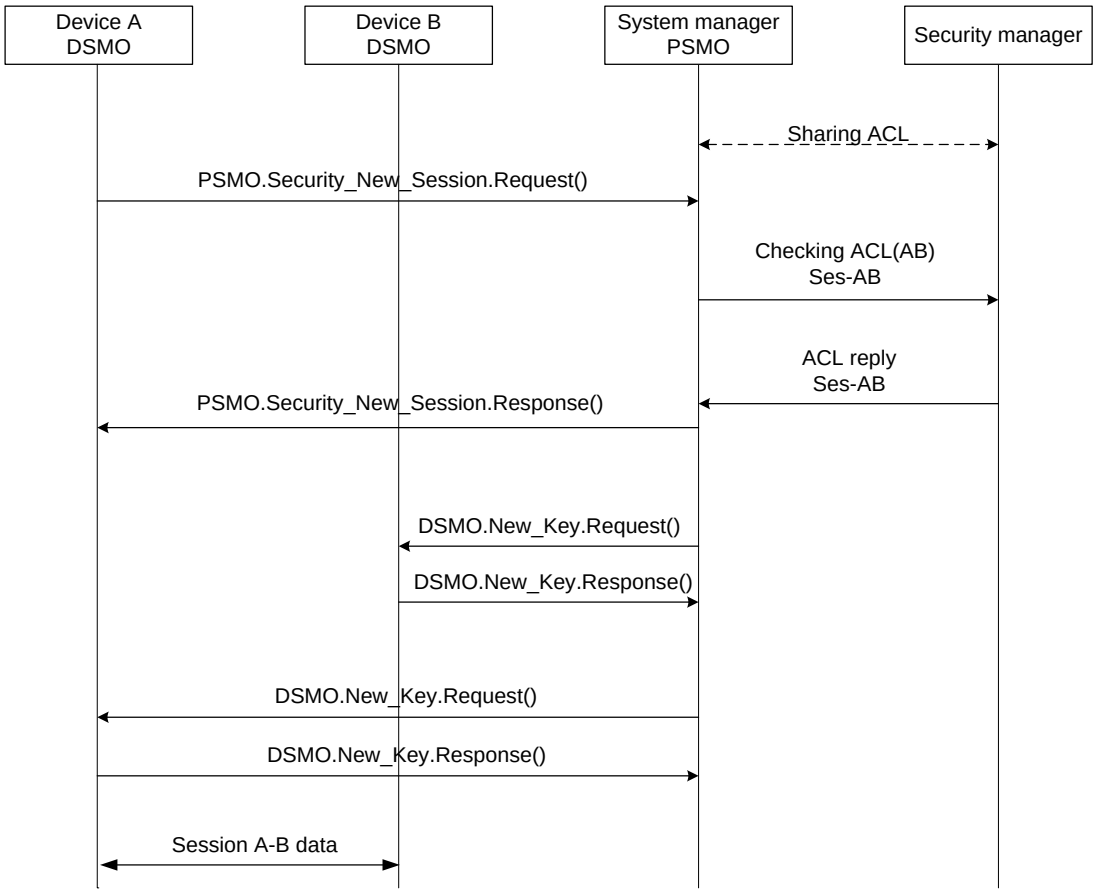
7.5 Etablissement de session

7.5.1 Généralités

L'établissement de session se produit à l'appui d'une communication sécurisée de bout en bout entre deux UAP. Le point d'extrémité d'une session est défini comme étant la concaténation de l'adresse IPv6Adress et du port de transport. Le gestionnaire de sécurité est responsable d'octroyer ou de refuser le support cryptographique utilisé pour établir la voie sécurisée de bout en bout entre les deux appareils.

7.5.2 Description

La Figure 50 fournit un exemple de haut niveau de l'établissement de session.



Légende

Anglais	Français
Device A DMSO	DMSO appareil A
Device B DMSO	DMSO appareil B
System manager PSMO	PSMO Gestionnaire de système
Security manager	Gestionnaire de sécurité
Sharing ACL	Partage ACL
Checking ACL(AB)	Vérification ACL(AB)
ACL reply	Réponse ACL
Session A-B data	Données de session A-B

Figure 50 – Exemple de haut niveau d'établissement de session

Dans l'exemple de haut niveau montré à la Figure 50, un UAP sur un appareil A établit une session avec un UAP sur un appareil B. Le DSMO de l'appareil A envoie la demande au gestionnaire de sécurité par l'intermédiaire de l'objet PSMO du gestionnaire de système. Le gestionnaire de système transmet alors la demande au gestionnaire de sécurité, qui authentifie la demande et peut accomplir une vérification pour vérifier si la session est autorisée. Si la session est accordée, le gestionnaire de sécurité génère une seule clé T pour les deux points d'extrémité, chiffre une copie pour l'appareil A et une autre copie pour l'appareil B, et transmet les messages au PSMO du gestionnaire de système. Le PSMO du gestionnaire de système peut alors envoyer la réponse à la demande de session. Le PSMO du gestionnaire de système appelle ensuite la méthode du DSMO pour ajouter une nouvelle clé T sur l'appareil A et l'appareil B.

L'établissement de session peut être initié par un appareil de terrain ou par le gestionnaire de sécurité/système.

- L'appareil de terrain initie un établissement de session en utilisant la méthode PSMO.Security_New_Session() dans le Tableau 80.
- Le gestionnaire de sécurité/système initie un établissement de session en utilisant la méthode de DSMO.New_Key() dans le Tableau 83.

Le gestionnaire de sécurité doit assigner les mêmes clé et CryptoKeyIdentifier parmi les appareils qui participent à la session sécurisée. Dans le cas des clés superposées, l'en-tête de sécurité doit acheminer le CryptoKeyIdentifier de la clé sélectionnée pour protéger la PDU. Au destinataire, l'appareil recherche le KeyDescriptor avec le CryptoKeyIdentifier spécifié dans l'en-tête de sécurité de la PDU entrante. Si la valeur de CryptoKeyIdentifier n'a pas de correspondance, l'appareil de réception ne sera pas capable de déchiffrer et/ou d'authentifier la PDU entrante.

7.5.3 Protection d'unité de données de protocole d'application en utilisant la clé principale

7.5.3.1 Généralités

La demande est faite à partir du DSMO de l'appareil au PSMO du gestionnaire de système agissant comme proxy du gestionnaire de sécurité. L'APDU doit être protégée avec l'utilisation du mécanisme de sécurité de PDU presque le même que la TL. La clé cryptographique doit être la clé principale, et le nonce doit être construit de la même manière que la TL en 7.3.3.7, mais la valeur de TAITimeRounded doit être utilisée pour le champ de création de temps TAI nominal. Voir le Tableau 363 pour les règles de codage appliquées aux valeurs de TAITimeRounded.

NOTE 1 Le processus de rattachement étant accompli à l'AL, il n'y a aucune sécurité à la TL au cours du processus en question, excepté des messages de confirmation.

La granularité du champ Time_Stamp étant exprimée en secondes, deux opérations cryptographiques utilisant la clé principale ne doivent pas être autorisées dans la même seconde.

NOTE 2 Si le débit de message utilisant la clé principale est supérieur au débit d'une fois par seconde, il y aura une collision de nonce.

7.5.3.2 Protection contre le rejet pour unité de données de protocole d'application protégée avec la clé principale

A la réception de l'APDU protégée avec la clé principale, la procédure de sécurité doit effectuer une vérification pour déceler tous les éventuels doublons de nonces avec un MIC valide dans le cache de nonces avec le KeyDescriptor correspondant. Si un nonce en double est détecté, la procédure doit rejeter la PDU avant de traiter l'ASDU, autrement la procédure doit stocker le nonce dans le cache de nonces dans le KeyDescriptor.

7.5.4 Méthodes d'objet proxy de gestion de sécurité relatives à l'établissement de session

Le Tableau 80 décrit la méthode Security_New_Session.

Tableau 80 – Méthode Security_New_Session

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Proxy security management object (PSMO, objet proxy de gestion de sécurité)</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 105</th></tr>
<tr><th>Nom de la méthode</th><th>ID de la méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="6">Security_New_Session</td><td>6</td><td colspan="3">Méthode d'utilisation du PSMO dans le gestionnaire de système pour envoyer une demande de session de sécurité et recevoir une réponse de session de sécurité</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>New_Session_Request</td><td>Security_New_Session_Request; voir Tableau 81</td><td>Demande de la nouvelle session de sécurité d'un appareil au gestionnaire de sécurité</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>New_Session_Response</td><td>Security_New_Session_Response; voir Tableau 82</td><td>Réponse de la nouvelle session de sécurité du gestionnaire de sécurité à l'appareil demandeur, protégé par l'utilisation de la clé principale</td></tr>
</table>

La structure de données Security_New_Session_Request qui est utilisée pour former une demande de session est définie dans le Tableau 81.

Tableau 81 – Structure de données Security_New_Session_Request

Nom du type de données normalisé: Security_New_Session_Request		
Code du type de données normalisé: 420		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
Originator_IPv6Adress	1	Type: IPv6Adress Classification: Static Accessibilité: Read/write
Originator_Port	2	Type: Unsigned16 Classification: Static Accessibilité: Read/write
Destination_IPv6Adress	3	Type: IPv6Adress Classification: Static Accessibilité: Read/write
Destination_Port	4	Type: Unsigned16 Classification: Static Accessibilité: Read/write
Algorithm_Identifier	5	Type: Unsigned8 Classification: Static Accessibilité: Read Only Valeur par défaut: 1 = AES_CCM*
Protocol_Version	6	Type: Unsigned8 Classification: Static Accessibilité: Read Only Valeur par défaut: 1 = IEC 62734 Ed. 1.0 (la présente norme, par exemple)
Security_Control	7	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Crypto_Key_Identifier	8	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Time_Stamp	9	Type: TAITimeRounded Classification: Static Accessibilité: Read Only
MIC	10	Type: OctetString (SIZE = 4, 8, 16) Classification: Static Accessibilité: Read Only

Cette structure de données est constituée d'une section en texte clair uniquement protégée en utilisant la clé principale partagée entre le demandeur de la session et le gestionnaire de sécurité. L'adresse EUI64Address du demandeur doit être utilisée dans la construction de nonce pour protéger cette structure.

- Originator_IPv6Adress doit être l'adresse IPv6Adress du premier appareil d'extrémité (habituellement la source) dans la session.
- Originator_Port doit être le port T du premier UAP d'extrémité (habituellement la source) dans la session.

- Destination_IPv6Adress doit être l'adresse IPv6Adress du second appareil d'extrémité (habituellement la destination) dans la session.
- Destination_Port doit être le port T du second UAP d'extrémité (habituellement la destination) dans la session.
- Algorithm_Identifier définit l'algorithme et le mode de fonctionnement pris en charge dans cette session. Dans la version courante, il est mis à 0x1 = AES_CCM*.
- La version de protocole identifie le protocole utilisé pour cette association de sécurité. Dans la présente norme, cet octet doit être 0x01.
- Security_Control doit être tel que défini en 7.3.1.2. Le niveau de sécurité est sélectionné dans MIC-32, MIC-64 et MIC-128 avec le niveau de sécurité de clé principale assigné dans le processus de rattachement. Le CryptoKeyIdentifierMode doit être '01' correspondant à la taille du champ Crypto_Key_Identifier de 1 octet.
- Crypto_Key_Identifier doit être le Crypto_Key_Identifier de la clé principale utilisée dans la protection de cette structure.
- Time_Stamp doit être la représentation tronquée de 32 bits du temps TAI utilisée dans la construction de nonce T.
- MIC doit être le code d'intégrité généré par le calcul de l'AES_CCM*. La taille du MIC est assignée dans le champ Security_Control .

Le nonce utilisé pour générer le MIC est formé conformément au Tableau 57 avec:

– EUI64Address: Adresse EUI64Address de l'appareil transmettant le message de demande Security_New_Session.

– Temps TAI nominal: Le champ Time_Stamp dans le message Security_New_Session Request.

La structure de données Security_New_Session_Response qui est utilisée pour former une nouvelle réponse de session est définie dans le Tableau 82.

Tableau 82 – Structure de données Security_New_Session_Response

Nom du type de données normalisé: Security_New_Session_Response		
Code du type de données normalisé: 421		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
Status	1	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Security_Control	2	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Crypto_Key_Identifier	3	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Time_Stamp	4	Type: TAITimeRounded Classification: Static Accessibilité: Read Only
MIC	5	Type: OctetString (SIZE = 4, 8, 16) Classification: Static Accessibilité: Read Only

Les champs comprennent:

- Status doit être le statut de la session où 0x1 = SECURITY_SESSION_GRANTED et 0x0 = SECURITY_SESSION_DENIED.
- Security_Control doit être tel que défini en 7.3.1.2. Le niveau de sécurité est sélectionné dans MIC-32, MIC-64 et MIC-128 avec le niveau de sécurité de clé principale assigné au cours du processus de rattachement. Le CryptoKeyIdentifierMode doit être '01' correspondant à une taille du champ CryptoKeyIdentifier de 1 octet.
- Crypto_Key_Identifier doit être le Crypto_Key_Identifier de la clé principale utilisée dans la protection de cette structure.
- Time_Stamp doit être la représentation tronquée de 32 bits du temps TAI utilisée dans la construction de nonce.
- MIC doit être le code d'intégrité généré par le calcul de l'AES_CCM*. La taille du MIC est assignée dans le champ Security_Control.

Le nonce utilisé pour générer le MIC est formé conformément au Tableau 57 avec:

– EUI64Address: Adresse EUI64Address de l'appareil transmettant le message de demande Security_New_Session.
– Temps TAI nominal: Le champ Time_Stamp issu du message Security_New_Session Request.

Si la session est accordée, le gestionnaire de sécurité par le truchement du PSMO du gestionnaire de système doit appeler la méthode New_Key du DSMO définie en 7.6.3 pour écrire une nouvelle clé T dans les appareils spécifiés dans la demande de session.

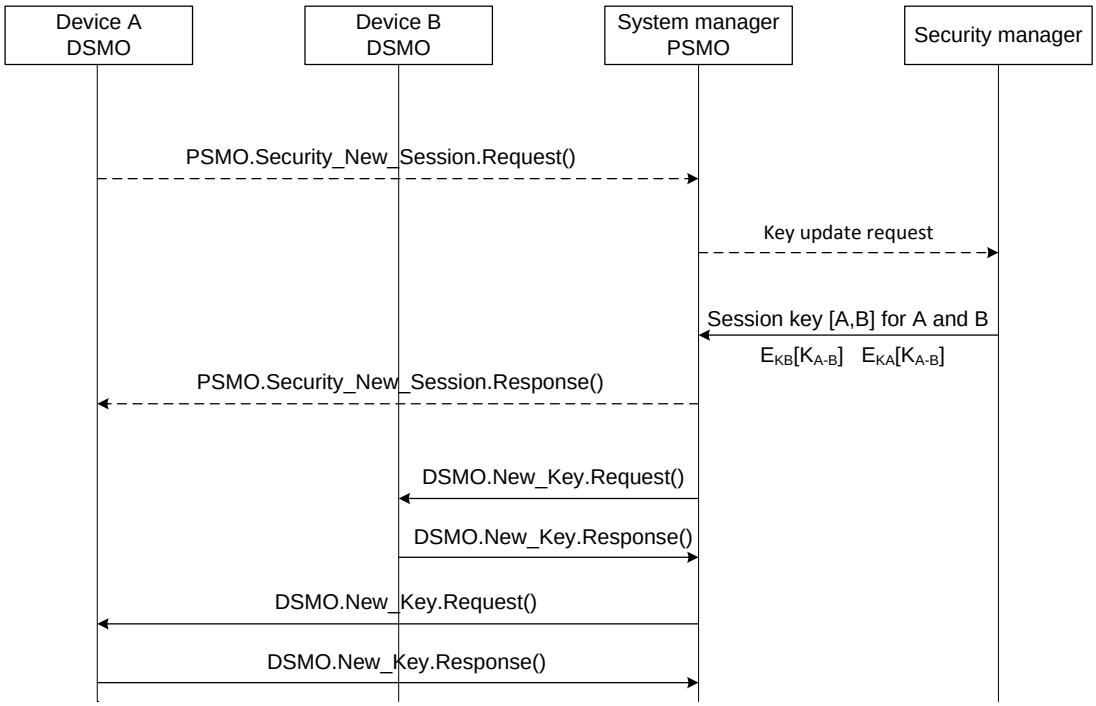
7.6 Mise à jour de clé

7.6.1 Généralités

Les clés T ont une durée de vie limitée et sont mises à jour périodiquement pour assurer que la session est maintenue vivante. Le processus de mise à jour de clé peut être initié par un appareil, même s'il convient qu'il soit poussé à partir du gestionnaire de sécurité entre le SoftExpirationTime et le HardExpirationTime d'une clé T.

7.6.2 Description

Le processus de mise à jour de clé est résumé à la Figure 51. Une TLE peut demander que le gestionnaire de sécurité mette à jour une clé T. Le gestionnaire de sécurité émet alors un appel au DSMO des TLE de point d'extrémité, par l'intermédiaire du PSMO du gestionnaire de système, pour mettre à jour la clé T pour ces TLE. Chaque message de ce type est protégé avec la clé principale active partagée entre le gestionnaire de sécurité et le DSMO de la TLE spécifique.



Légende

Anglais	Français
Device A DMSO	DMSO appareil A
Device B DMSO	DMSO appareil B
System manager PSMO	PSMO gestionnaire de système
Security manager	Gestionnaire de sécurité
Key update request	Demande de mise à jour de clé
Session key [A, B] for A and B	Clé de session [A, B] pour A et B

Figure 51 – Vue d'ensemble du protocole de mise à jour de clé

Une TLE participant à une session peut initier le processus de mise à jour de clé en faisant un appel à la méthode de Security_New_Session du PSMO. La demande est transmise du PSMO du gestionnaire de système vers le gestionnaire de sécurité, qui authentifie la demande en utilisant la clé principale de l'appareil demandeur. Si la vérification est couronnée de succès, le gestionnaire de sécurité reconnaît que la session existe déjà et continue simplement avec le protocole de mise à jour de clé exactement comme si le SoftExpirationTime de la clé T a expiré. La construction de nonce pour protéger l'APDU utilisant la clé principale est décrite en 7.5.3.

Si le SoftExpirationTime d'une clé T active a passé, le gestionnaire de sécurité doit appeler la méthode New_Key sur le DSMO des appareils d'extrémité pour écrire une nouvelle clé et les politiques d'accompagnement.

Les méthodes de Key Update (mise à jour de clé) peuvent également être utilisées pour mettre à jour la clé de DL et la clé principale.

7.6.3 Méthodes de l'objet de gestion de sécurité d'appareil relatives à la mise à jour de clé T

Le Tableau 83 décrit la méthode New_Key.

Tableau 83 – Méthode New_Key

Nom du type d'objet normalisé: Device security management object (DSMO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 125				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
New_Key	1	Méthode d'utilisation du DSMO dans l'appareil pour l'envoi d'une clé de sécurité protégée et des politiques d'accompagnement		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Key_And_Policies	Security_Key_and_Policies; voir Tableau 84	Les clés de sécurité et les politiques doivent être authentifiées, décryptées et stockées par un appareil participant à la session

Key_Material	11	Type: SymmetricKey Classification: Static Accessibilité: Read Only
MIC	12	Type: OctetString (SIZE = 4, 8, 16) Classification: Static Accessibilité: Read Only

Cette structure de données est constituée d'une section en texte clair uniquement protégée en utilisant la clé principale partagée entre le demandeur de la session et le gestionnaire de sécurité. L'adresse EUI64Address du demandeur doit être utilisée dans la construction de nonce pour protéger cette structure.

Les champs comprennent:

- 128_Bit_Address_remote doit être l'adresse IPv6Adress de la TLE de point d'extrémité distante dans cette session. Dans le cas de la clé D ou de la clé principale, ce champ doit être élidé.
- End_Port_remote doit être le port T de l'UAP de point d'extrémité distante dans cette session. Dans le cas de la clé D ou de la clé principale, ce champ doit être élidé.
- Algorithm_Identifier définit l'algorithme et le mode de fonctionnement pris en charge dans cette session. Dans la version courante, il est mis à 0x1 = AES_CCM*.
- Security_Control doit être tel que défini en 7.3.1.2. Le niveau de sécurité est sélectionné dans ENC-MIC-32, ENC-MIC-64 et ENC-MIC-128 avec le niveau de sécurité de clé principale assigné dans le processus de rattachement. Le CryptoKeyIdentifierMode doit être '01' correspondant à la taille du champ Key Index de 1 octet.
- Crypto_Key_Identifier doit être le Crypto_Key_Identifier de la clé principale utilisée dans la protection de cette structure.
- Time_Stamp doit être la représentation tronquée de 32 bits du temps TAI utilisée dans la construction de nonce.
- Key_Policy doit être tel que décrit dans le Tableau 88 et peuplé par le gestionnaire de sécurité sur la base de ses politiques de sécurité pour cette session.
- New_Key_ID doit être le Crypto_Key_Identifier de 8 bits assigné pour ce support de clé par le gestionnaire de sécurité.
- Key_Material doit être une clé symétrique pour cette session.
- MIC doit être le code d'intégrité généré par le calcul de l'AES_CCM*. La taille du MIC est spécifiée dans le champ Security_Control.

Le niveau de sécurité pour la clé principale doit être mis au moins à la force de la clé la plus élevée utilisée.

La structure de données Security_Key_and_Policies est protégée par AES-CCM* avec les paramètres suivants:

- partie authentification: élément 1..10
- partie cryptage: élément 11
- clé: clé principale
- nonce: formé avec la structure du Tableau 57 avec:
  - EUI64Address: Adresse EUI64Address du gestionnaire de sécurité
  - temps TAI nominal: Elément Time Stamp acheminé dans Security_Key_and_Policies

A la réception de l'appel de la méthode DSMO.New_Key().Request, le DSMO de l'appareil d'extrémité doit déchiffrer et faire une vérification d'intégrité sur la PDU en utilisant la même étape de traitement de PDU entrante telle que définie dans la TL (voir 7.3.3.9) avec le nonce construit avec l'adresse EUI64Address du gestionnaire de sécurité et les 32 bits de temps inclus dans la PDU. La clé utilisée doit être la clé principale courante telle qu'identifiée par le CryptoKeyIdentifier.

A l'achèvement réussi de la vérification, le KeyDescriptor approprié doit être peuplé en utilisant les champs dans la structure de données Security_Key_and_Policies. Dans la présente version, l'émetteur est toujours le gestionnaire de sécurité.

Le DSMO doit alors produire un message de statut tel que défini dans le Tableau 85 pour notifier au gestionnaire de sécurité le statut de l'appel de méthode.

La structure de données Security_Key_Update_Status qui est utilisée pour former la réponse à la demande de mise à jour de clé est définie dans le Tableau 85.

Tableau 85 – Structure de données Security_Key_Update_Status

Nom du type de données normalisé: Security_Key_Update_Status		
Code du type de données normalisé: 423		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
Status	1	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Security_Control	2	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Crypto_Key_Identifier	3	Type: Unsigned8 Classification: Static Accessibilité: Read/write
Time_Stamp	4	Type: TAITimeRounded Classification: Static Accessibilité: Read Only
MIC	5	Type: OctetString (SIZE = 4, 8, 16) Classification: Static Accessibilité: Read Only

Les champs comprennent:

- Status doit être le statut de la session où 0x1 = SECURITY_KEY_UPDATE_FAILURE et 0x0 = SECURITY_KEY_UPDATE_SUCCESS.
- Security_Control doit être tel que défini en 7.3.1.2. Le niveau de sécurité est sélectionné dans MIC-32, MIC-64 et MIC-128 avec le niveau de sécurité de clé principale assigné au cours du processus de rattachement. Le CryptoKeyIdentifierMode doit être '01' correspondant à une taille du champ CryptoKeyIdentifier de 1 octet.
- Crypto_Key_Identifier doit être le Crypto_Key_Identifier de la clé principale utilisée dans la protection de cette structure.
- Time_Stamp doit être la représentation tronquée de 32 bits du temps TAI utilisée dans la construction de nonce.
- MIC doit être le code d'intégrité généré par le calcul de l'AES_CCM*. La taille du MIC est assignée dans le champ Security_Control.

Le nonce utilisé pour générer le MIC est formé conformément au Tableau 57 avec:

– EUI64Address: Adresse EUI64Address de la DLE émettant le message de réponse New_Key.

– Temps TAI nominal: L'élément Time_Stamp issu du message Security_Key_Update_Status.

7.6.4 Rétablissement après défaillance

7.6.4.1 Généralités

A un point quelconque au cours de l'établissement de session ou du processus de mise à jour de clé, il y a une possibilité qu'une PDU soit abandonnée. Dans ce cas, il convient que le système soit capable de récupérer et continuer. Les définitions d'états et les transitions d'états suivantes décrivent les grandes lignes du mécanisme de rétablissement, avec les effets secondaires déclenchés.

7.6.4.2 Etats de la clé T et de la clé D

Les états de clé T et de clé D comprennent:

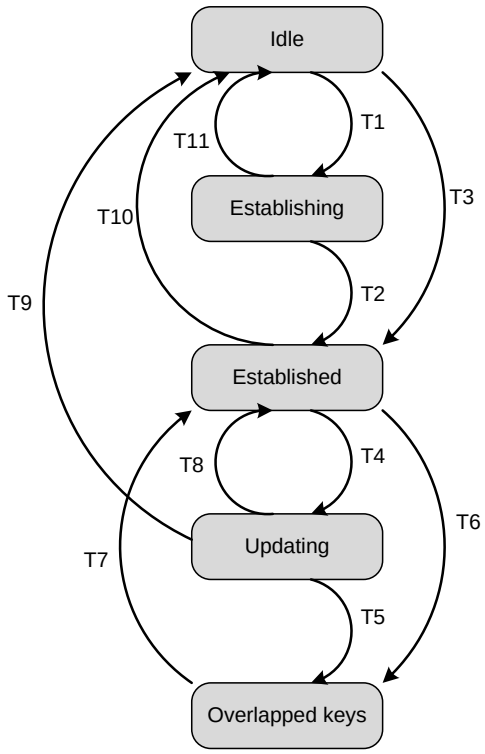
- Idle (inactif): Aucune clé, n'est pas en train d'obtenir la clé T courante.
- Establishing (s'établissant): Aucune clé, est en train d'obtenir la clé T courante.
- Established (établi): Ayant la clé courante, n'est pas en train d'obtenir la clé suivante.
- Updating (se mettant à jour): Ayant la clé courante, est en train d'obtenir la clé suivante.
- Overlapped (superposé): Ayant la clé courante et la clé suivante

7.6.4.3 Transition d'état de clé T et de clé D

Les transitions d'état montrées dans le Tableau 86 et à la Figure 52 montrent l'état de l'appareil initiant une récupération de clé T ou de clé D, et celui de son homologue acceptant la demande. Toutes les deux commencent dans l'état "idle", et toutes les deux finissent dans l'état "established" avec une session ou clé D valide et les éléments cryptographiques pertinents.

Tableau 86 – Transition d'états de clé T et de clé D

Transition	Etat actuel	Evénement(s)	Action(s)	Etat suivant
T1	Inactif	DSMO a demandé une nouvelle session	Appel de la méthode suivante sur le gestionnaire de système: PSMO.Security_New_Session. Request()	Establishing (s'établissant)
T2	Establishing (s'établissant)	PSMO.Security_New_Session() .Response && crypto check ok	Enregistrer le support de clé, l'indice de politique et d'emplacement, l'adresse distante, le port distant, l'adresse locale, le port local, selon les besoins	Established (Etablie)
T3	Inactif	DSMO.New_Key().Request du gestionnaire de sécurité via le PSMO et vérification cryptographique ok	Enregistrer le support de clé, l'index de politique et d'emplacement, l'adresse distante, le port distant, l'adresse locale, le port local, selon les besoins. Retourner une DSMO.New_Key.Response()	Established (Etablie)
T4	Established (Etablie)	Session ou SoftExpirationTime de la clé D expirés	Appel de la méthode suivante sur le gestionnaire de système: PSMO.Security_New_Session. Request()	Updating (se mettant à jour)
T5	Updating (se mettant à jour)	DSMO.New_Key().Request du gestionnaire de sécurité via le PSMO et vérification cryptographique ok	Enregistrer le support de clé, l'index de politique et d'emplacement, l'adresse distante, le port distant, l'adresse locale, le port local, selon les besoins. Retourner une DSMO.New_Key.Response()	Clés superposées
T6	Established (Etablie)	DSMO.New_Key().Request du gestionnaire de sécurité via le PSMO et vérification cryptographique ok	Stocker les nouvelles clés dans la mémoire	Clés superposées
T7	Clés superposées	ValidNotAfter de la session courante ou de la clé D expirés	Supprimer la clé expirée	Established (Etablie)
T8	Updating (se mettant à jour)	Timeout OR PSMO.Security_New_Session. Response() && crypto check ok && SESSION_DENIED	Définir le moment du prochain essai	Established (Etablie)
T9	Updating (se mettant à jour)	ValidNotAfter de la dernière session ou de la clé D expiré	Supprimer la clé expirée	Inactif
T10	Established (Etablie)	ValidNotAfter de la dernière session ou de la clé D expirés	Supprimer la clé expirée	Inactif
T11	Establishing (s'établissant)	Timeout	Diagramme d'états de réinitialisation et définir le moment du prochain essai si nécessaire	Inactif



Légende

Anglais	Français
Idle	Inactif
Establishing	S'établissant
Established	Etabli
Updating	Se mettant à jour
Overlapped keys	Clés superposées

NOTE 1 Si un appareil reçoit la demande DSMO.New_Key() alors qu'il est dans l'état Updating ou Overlapped, l'appareil rejette la clé principale, qui n'est pas utilisée pour chiffrer la nouvelle clé principale.

NOTE 2 Si l'appareil reçoit par une demande de DSMO.New_Key() une nouvelle clé principale qui a été chiffrée en utilisant une clé principale inconnue, l'appareil est capable d'interroger le gestionnaire de sécurité pour la clé principale nécessaire pour le déchiffrement avec la demande de PSMO.New_Session_Request(), afin de resynchroniser les clés principales. Le gestionnaire de sécurité a les informations nécessaires pour inférer, sélectionner et utiliser la clé principale appropriée.

Figure 52 – Etablissement de clé d'appareil et transition d'états de mise à jour de clé

7.7 Fonctionnalité du rôle de gestionnaire de sécurité

7.7.1 Proxy security management object (objet proxy de gestion de sécurité)

Les attributs du PSMO sont donnés dans le Tableau 87.

Tableau 87 – Attributs du PSMO dans le gestionnaire de système

Nom du type d'objet normalisé: Proxy security management object (PSMO, objet proxy de gestion de sécurité)				
Identificateur du type d'objet normalisé: 105				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Réservé pour les éditions futures de la présente norme	1..63	-	-	-

Note Un objet a des attributs, ou des méthodes, ou les deux. Cet objet n'utilise que des méthodes normales; aucun attribut normal n'a été identifié comme étant nécessaire. Par conséquent, dans cette édition de la présente norme, le Tableau 87 est vide (null).

7.7.2 Autorisation des appareils de réseau et génération ou dérivation de clés principales initiales

Le gestionnaire de sécurité maintient une base de données contenant:

- une liste d'appareils dont les authentifiants ont été établis par un processus de configuration ou à la première tentative de rattachement au réseau, et qui n'ont pas été révoqués; et
- une liste de clés de rattachement valides et de leurs durées de vie associées qui ont été émises aux appareils d'agent de configuration, qui pourrait être fournie par de nouveaux appareils qui tentent de rejoindre le réseau.

Lorsqu'un nouvel appareil tente de rejoindre le réseau et sa demande vient du gestionnaire de sécurité par l'intermédiaire du PSMO du gestionnaire de système selon la procédure décrite en 7.4.5, le gestionnaire de sécurité examine les deux premières listes pour une décision rapide d'acceptation/rejet. Autrement, la procédure doit être telle que décrite en 7.4.6.

7.7.3 Interaction avec des objets de gestion de sécurité d'appareil

Un gestionnaire de sécurité interagit avec le DSMO d'un appareil par l'intermédiaire du PSMO:

- au cours du processus de rattachement;
- lorsqu'il distribue de nouvelles clés;
- lorsqu'il reçoit de nouvelles clés qui ont été établies par d'autres appareils par le biais de l'utilisation de protocoles d'agrément de clé;
- au cours d'un processus de rattachement comme décrit en 7.4.4; et
- au cours de la récupération de clé lorsqu'un nouveau gestionnaire de sécurité réseau en remplace un qui a échoué.

NOTE Seul le gestionnaire de sécurité génère de nouvelles clés une fois qu'un appareil est rattaché au réseau.

7.7.4 Gestion de clés opérationnelles

7.7.4.1 Généralités

Le gestionnaire de sécurité maintient la clé principale courante et les attributs associés de génération de clés et de politique pour chaque appareil qu'il gère.

Toutes les clés symétriques sont maintenues dans le stockage opérationnel du gestionnaire de sécurité et il convient que dans les mises en œuvre de plus haute sécurité celui-ci soit physiquement protégé au sein du module cryptographique du gestionnaire de sécurité.

Lorsque les appareils participants ne mettent pas tous les deux en œuvre le jeu de primitives cryptographiques asymétriques spécifiées en 7.4.6, qui est une option de construction pour chaque appareil, le gestionnaire de sécurité peut également générer des clés de données symétriques de secrets partagés pour les associations de DL et de TL en monodiffusion.

NOTE De nombreux appareils n'ont pas une source de bits aléatoires d'entropie élevée. Sans une telle source, n'importe quelle composante de clé générée par l'appareil est potentiellement sensible aux interférences.

7.7.4.2 Archivage de clé

La réglementation ou la politique peut exiger que les clés soient archivées pour permettre le déchiffrement, simultané ou ultérieur, de la messagerie chiffrée.

7.7.4.3 Récupération de clé

Il convient que le gestionnaire de sécurité prenne en charge deux formes de récupération de clé:

- récupération par un appareil de terrain qui a perdu des clés qui étaient maintenues dans le stockage volatil (RAM, par exemple) en raison d'une panne de courant ou d'une erreur mémoire non corrigée; et
- récupération par un nouveau gestionnaire de sécurité réseau des clés opérationnelles actuellement en utilisation dans le réseau.

Chaque appareil de terrain qui prend en charge la cryptographie à clés asymétriques doit conserver dans le stockage non volatil:

– son adresse EUI64Address; et
– sa paire de clés publique/privée, avec cette dernière comme un certificat signé si disponible.

Chaque appareil de terrain qui ne prend en charge que la cryptographie à clés symétriques doit conserver dans le stockage non volatile:

– son adresse EUI64Address;
– sa clé de rattachement; et
– sa clé de rattachement courante et ses informations de codage connexes, s'il a précédemment été un membre du réseau.

Toutes les autres informations de codage opérationnelles peuvent être conservées dans le stockage volatil, susceptibles d'être perdues en cas de panne de courant d'appareil ou corruption de mémoire, car ces informations peuvent être régénérées par un gestionnaire de sécurité une fois que le gestionnaire de sécurité a déterminé l'adresse EUI64Address de l'appareil.

7.7.4.4 Administration de politique de sécurité

Les principales options de déploiement affectant la politique de sécurité à l'échelle du réseau sont sélectionnées pendant l'installation initiale du gestionnaire de sécurité pour un réseau. D'autres options de déploiement de politique peuvent être sélectionnées à un moment ultérieur.

7.8 Politiques de sécurité

7.8.1 Définition de politique de sécurité

Dans la présente norme, la politique de sécurité est définie comme étant une combinaison des paramètres suivants:

- Key Type (type de clé) défini dans le Tableau 89;

- Key Usage (utilisation de clé) définie dans le Tableau 90;
- Key Lifetime (durée de vie de clé) définie en 7.2.2.4; et
- Security Level (niveau de sécurité) défini en 7.3.1.1.

Les clés sont distribuées avec les paramètres spécifiés ci-dessus de façon explicite ou reconstruits de façon implicite au destinataire. Un KeyDescriptor correspondant est généré avec ces paramètres.

7.8.2 Etendue de politique

Les politiques de sécurité limitent les choix de sécurité que les programmes et appareils individuels peuvent faire. Ces politiques existent aux niveaux suivants:

- à l'échelle de sous-réseau, à travers tous les appareils participant à un sous-réseau D donné, qui peut englober le système réseauté entier;
- à l'échelle d'appareil, à travers tous les programmes d'application et les couches communications d'appui au sein de l'appareil;
- à l'échelle de clé, à travers toutes les PDU sécurisées avec une clé donnée; et
- à l'échelle de liaison, à travers toutes les PDU émises sur une connexion donnée définie par une source et une destination, qui peuvent inclure des ports d'UAP, fournissant ainsi des politiques à l'échelle d'UAP, à travers toutes les invocations de service par une application donnée.

Certaines politiques à l'échelle du système doivent être établies avant que l'exploitation du système ne commence; d'autres peuvent être modifiées de façon dynamique pendant que le système fonctionne, sans interrompre les sessions en cours.

7.8.3 Choix de politiques de sécurité non contraintes

Des choix de politique de sécurité de système peuvent être faits pendant l'exploitation du système. La nouvelle politique entrera en vigueur avec le prochain recodage des appareils affectés effectué par un gestionnaire de sécurité. Ainsi, l'opération avec une clé symétrique donnée a toujours un jeu fixé d'attributs.

7.8.4 Structures de politique

Le format des politiques est présenté dans le Tableau 88.

Tableau 88 – Structure de champ "policy"

Octet	Bits							
	7	6	5	4	3	2	1	0
0	Key_Type			Key_Usage			Granularité	
1..4	ValidNotBefore nominal							
5..6 (7, 8 opt)	HardLifeSpan							
9	Security_Level			Réservé				

Les champs comprennent:

- Key_Type: type de clé défini dans le Tableau 89.
- Key_Usage: utilisation de clé définie dans le Tableau 90.
- Granularité: unité en laquelle la Nominal HardLifeSpan est interprétée, telle que définie dans le Tableau 91.

- ValidNotBefore nominal en secondes: temps TAI absolue sous la forme TAITimeRounded, où le destinataire de la clé peut commencer à utiliser la clé.
- HardLifeSpan: durée pendant laquelle cette clé est valide. La durée valide de la clé commence à ValidNotBefore. Si le champ ValidNotAfter est rempli avec 0x00 pour une granularité quelconque, cette clé a une durée de vie infinie et la clé n'expirera donc jamais. A moins que ValidNotAfter soit infini, la durée réelle de la KeyHardLifeSpan ne doit excéder 48,5 jours (voir 7.3.2.4.10) dans aucune granularité.
- Security_Level: niveau de sécurité pour chaque clé, tel que défini dans le Tableau 35.
- Reserved: il convient que le champ Reserved soit 0.

Les valeurs possibles pour les types de clé sont présentées dans le Tableau 89.

Tableau 89 – Key_Type

Valeur Key_type	Description
0	Réservé
1	Support de codage de clé symétrique, cryptage
2	Certificat manuel ECC
3	Certificat implicite ECC
4..7	Réservé

Les valeurs possibles pour l'utilisation de la clé sont présentées dans le Tableau 90.

Tableau 90 – Key_Usage

Valeur Key_Usage	Description
0	Clé de groupe pour traitement de PDU (clé D par exemple)
1	Clé de lien pour traitement de PDU (clé T par exemple)
2	Clé principale pour l'établissement de session
3	Clé de rattachement
4	Clé publique pour plan ECMQV
5	Clé racine CA pour plan ECQV
6	Réservé
7	Clé non secrète globale fixe

La granularité de la HardLifeSpan dans la politique de clé est présentée dans le Tableau 91.

Tableau 91 – Granularité

Granularité	Unité de temps SI [a]	Nom commun	Facteur d'échelle	HardLifeSpan (octets)
0	s	Seconde	1 s	4
1	Min	Minute	60 s	3
2	h	Heure	3 600 s	2
3	d	Day	86 400 s	2

[a] Bien que "s" soit la seule unité de temps SI officielle, l'utilisation des autres unités listées dans la seconde colonne est acceptée avec le système SI.

Les politiques suivantes doivent être disponibles à un réseau spécifié par la présente norme. La variable *k* indique une variable qui peut être établie par le gestionnaire de sécurité d'un réseau donné.

- Alertes et journalisation:

  Un appareil garde la trace du nombre de calculs cryptographiques défaillants sur une période de temps. Si un seuil configurable est franchi, une alerte est générée. Les alertes incluent "taux d'échecs de données DPDU excédé", "taux d'échecs de TPDU excédé", et "taux d'échecs de mise à jour de clé dépassé". Voir les alertes en 7.11.4.

- Politique d'appareil:

  L'authentification D doit toujours être active avec une taille d'étiquette d'authentification de 32 bits. La clé par défaut utilisée par un appareil se joignant est la K_global bien connue, utilisée pour détecter seulement des erreurs aléatoires. Une clé secrète protège l'APDU de niveau plus haut au cours d'un rattachement sécurisé. Voir 7.4.

  NOTE 1 La taille du MIC de DL est spécifiée en 7.3.1.1 et les contraintes pour le DMIC sont spécifiées en 7.3.2.

- Politique de clé:

  La liaison, l'association de sécurité et la politique de PDU sont appliquées par le biais de la politique de clé. Tous les utilisateurs d'une clé donnée doivent avoir la même politique; voir Tableau 88. Les éléments configurables incluent:

  – les types de clés; voir Tableau 89;
  – la granularité du temps TAI utilisé dans la durée de vie de la clé; voir Tableau 91;
  – la taille de MIC (32 bits, 64 bits ou 128 bits); voir Tableau 35;
  – la taille de DMIC de 32 bits, 64 bits ou 128 bits, mise à 32 par défaut, définie dans le DMXHR; voir 7.3.2.2;
  – la taille de TMIC de 0, 32, 64, ou 128 est mise à 0 si la sécurité est désactivée, et mise à 32 si la sécurité est activée. Durée de vie Soft; voir Tableau 93;
  – chiffrement de charge utile activé/désactivé;
  – chiffrement de DL activé/désactivé, désactivé par défaut, mis dans le DMXHR; voir 7.3.2.2;
  – chiffrement de TL activé/désactivé, désactivé si la sécurité est désactivée, activé si la sécurité est activée;
  – HardLifeSpan (voir Tableau 88), exprimée comme une valeur absolue de temps TAI, limitée par la durée maximale à partir du temps de génération de clé qui empêchera un passage par zéro du nonce;

    NOTE 2 Cette question est liée à la granularité du temps de TAI dans le nonce (voir 6.3.10); 48,5 jours si utilisé à 1 024 PDU/s.

  – key originator: adresse EUI64Address du générateur d'une clé donnée (habituellement le gestionnaire de sécurité) qui doit établir la politique pour une clé donnée;
  – sessions autorisées dans le gestionnaire de sécurité.

- Politique de contrôle d'accès:

  La fonction de contrôle d'accès pour un établissement de session n'est exigée que dans le gestionnaire de sécurité. Le gestionnaire de sécurité décide d'accorder ou de refuser une session dans la phase d'établissement de session. Le résultat est retourné par la méthode PSMO.Security_New_Session(). Si un gestionnaire de sécurité a à la fois une liste Allowed et une liste Disallowed, le gestionnaire de sécurité peut indiquer laquelle de ces deux listes est prioritaire.

  – Liste Allowed: Le gestionnaire de sécurité peut avoir une liste d'appareils autorisés identifiés par des informations valides (par exemple: adresse EUI64Address et nom de TAG) énumérées dans le Tableau 372.

– Liste Disallowed: Le gestionnaire de sécurité peut avoir une liste d'appareils autorisés identifiés par des informations valides (par exemple: adresse EUI64Address et nom de TAG).

7.9 Fonctions de sécurité disponibles à l'AL

7.9.1 Paramètres sur les demandes de service de transport qui se rapportent à la sécurité

Les UAP sont autorisés à établir des associations d'applications de façon dynamique en demandant une session devant être établie. Voir 6.3.11.2.5.2. Après qu'une session est établie, toutes les communications issues de cet UAP avec ces homologues sont traitées en toute sécurité jusqu'à une période de non-utilisation ou jusqu'à ce qu'un besoin de réutiliser le stockage pour les informations d'état de sécurité amène la TL à mettre fin à l'association de sécurité de transport antérieure. Si une demande ultérieure de service de transport émise de l'UAP vers ces homologues se produit après que l'association de sécurité de transport a été interrompue, cette demande ultérieure doit être traitée comme une nouvelle demande, conduisant à une nouvelle association de sécurité de transport.

Il n'y a intentionnellement aucune aptitude de porter des TPDU non sécurisées sur l'association de sécurité de transport une fois qu'elle a été établie, car un tel mécanisme serait trivialement facile à attaquer en altérant simplement des TPDU authentifiées sélectionnées pour indiquer qu'elles n'utilisaient aucune authentification.

Pour prendre en charge des services d'AL sans état, la politique la moins récemment utilisée peut être appliquée par des couches sous-jacentes pour recycler tous les éventuels engagements de ressource (état de connexion de sécurité, par exemple) qu'elles pourraient prendre.

Cela aiderait à l'exploitation efficace du système de sécurité si chaque demande de service de transport sur une association avait la capacité de faire allusion à l'intervalle prévu avant la prochaine utilisation de l'association. Une telle allusion fournit des conseils quant à la gestion des connexions implicites de sécurité de transport exigées pour des communications de transport sécurisées, permettant un placement intelligent en cache des connexions de sécurité établies et réduisant au maximum la dégradation qui se produit lorsqu'une connexion de sécurité implicite est fermée puis rouverte après qu'une nouvelle clé a été établie à tous les participants d'association.

Les niveaux de sécurité permis (voir 7.3.1.1) sur une demande de service de transport sont:

- chiffrement de charge utile de couche supérieure de TPDU: on/off;
- authentification de la TPDU avec un TMIC de taille 32 bits, 64 bits ou 128 bits.

Dans un API, ceux-ci peuvent être acheminés conjointement sous la forme d'un seul nombre entier signé (un Integer8, par exemple), où le signe a été utilisé pour désigner le chiffrement (–) ou pas (+), et la grandeur a été utilisée pour spécifier la taille demandée nn, avec la valeur zéro représentant une demande pour "aucune authentification" et "aucun chiffrement".

7.9.2 Accès direct aux primitives cryptographiques

7.9.2.1 Généralités

Les UAP peuvent utiliser n'importe lesquels des services cryptographiques disponibles pour un appareil. Ceux-ci comprennent notamment:

- fonctions de hachage non codées et codées;
- génération de chaîne de bits pseudo aléatoire ou aléatoire;
- cryptographie à clés symétriques;
- chiffrement par blocs chiffrants;

NOTE 1 L'exclusion du déchiffrement par blocs chiffrants rend plus probable la capacité d'une mise en œuvre à utiliser l'assistance d'un matériel.

- fonctions de chiffrement continu pour traiter les chaînes de données qui incluent l'authentification, le chiffrement, l'authentification étendue avec chiffrement, déchiffrement, et le déchiffrement avec authentification étendue.

Les primitives cryptographiques disponibles peuvent également inclure une seule option de construction:

- cryptographie à clés asymétriques:
  - chiffrement avec une clé publique et déchiffrement avec une clé privée d'une paire de clés privée/publique;
  - signature avec une clé publique et authentification de signature avec une clé publique d'une paire de clés privée/publique;
  - génération de paires de clés;
  - génération de certificat, signature et autosignature;
  - agrément de clé de Menezes-Qu-Vanstone à deux parties;
  - signatures numériques de Pintsov-Vanstone.

NOTE 2 L'option de construction de cryptographie à clés asymétriques seule fournit l'ensemble de ces capacités.

Les définitions des services abstraits pour l'ensemble de toutes les primitives de 7.9.2 sont spécifiées en 6.2.3.

7.9.2.2 Fonctions de hachage non codées

Une fonction sécurisée de hachage à sens unique non codée (ou à clé fixe) doit être fournie.

Le hachage non codé par défaut doit être celui de Matyas-Meyer-Oseas (MMO) tel que spécifié dans l'ISO/IEC 10118-2, basé sur le chiffrement par blocs de 7.9.3.2.

NOTE L'utilisation de l'algorithme MMO rend plus probable la capacité d'une mise en œuvre à utiliser l'assistance d'un matériel.

D'autres fonctions de hachage non codées peuvent être utilisées lorsque cela est nécessaire, soit en raison de la réglementation nationale, soit parce qu'une plus grande taille de hachage de sortie est exigée pour une certaine application ou pour contrer une menace.

Un paquetage alternatif d'algorithmes cryptographiques peut être exigé pour les systèmes gouvernementaux des USA, parce que la construction MMO n'est pas autorisée pour l'utilisation par le gouvernement des USA. D'autres gouvernements peuvent avoir des politiques semblables.

7.9.2.3 Bits aléatoires

Chaque appareil doit fournir une source de haute qualité de bits aléatoires issus d'un générateur déterministe de bits aléatoires. Celui-ci peut être un générateur à germe correct qui est conforme à l'ANSI X9.82 ou au FIPS 186-3. Lorsqu'elle est disponible, il convient que la source d'entropie élevée soit un générateur non déterministe de bits aléatoires.

Une source de haute qualité de bits aléatoires doit être utilisée dans le rattachement à clés asymétriques. Un générateur déterministe de bits aléatoires à germe correct peut être utilisé pour générer des valeurs de défi dans le rattachement à clés symétriques.

NOTE 1 Les générateurs déterministes de bits aléatoires ne sont pas adaptés pour une utilisation directe en raison de l'incapacité de prouver des propriétés statistiques d'une telle source autres que son non-déterminisme. Au contraire, ils sont utilisés pour semer et fournir une entrée continue à haute entropie à des générateurs déterministes de bits aléatoires, dont les propriétés statistiques sont quantifiables. La certification de la source

d'entropie (comme la certification de la mise en œuvre de sécurité), étant une fonction hautement spécialisée, est mieux déléguée à une entité accréditée. La NIST SP 800-22 est utile pour soumettre à essai les générateurs non déterministes et déterministes de bits aléatoires.

NOTE 2 Dans le processus de rattachement à clés symétriques, il est possible de générer un germe en utilisant le chiffrement par blocs (dont la valeur par défaut est AES) pour chiffrer le temps TAI avec la clé de rattachement (à savoir Seed = Encrypt[K_join, TAI]). Une telle clé de rattachement est présumée provenir d'une source de haute entropie, après avoir été générée dans le gestionnaire de sécurité et distribuée au cours de la phase de configuration.

7.9.3 Cryptographie à clés symétriques

7.9.3.1 Fonctions de hachage codées

Le hachage codé par défaut doit être HMAC, basé sur le hachage non codé de 7.9.2.1 (voir FIPS 198).

7.9.3.2 Fonctions de chiffrement et de déchiffrement par blocs chiffrants

Le chiffrement par blocs par défaut doit être l'AES-128, qui a une taille de bloc B de 16 et une taille de clé de 16 (voir FIPS 197).

Des chiffrements par blocs alternatifs peuvent être utilisés avec l'identificateur d'algorithme approprié lorsque cela est nécessaire, soit en raison de la réglementation nationale, soit parce qu'une plus grande taille de clé ou taille de bloc est exigée pour une certaine application ou pour contrer une certaine menace.

7.9.3.3 Fonctions de chiffrement continu pour le chiffrement, le déchiffrement, l'authentification, l'authentification étendue avec chiffrement et le déchiffrement avec authentification étendue

La sécurité de ce système est basée en partie sur la disponibilité d'un mode de fonctionnement en chiffrement continu d'un chiffrement par blocs qui fournit le chiffrement/déchiffrement, l'authentification, ou les deux. Lorsque tous les deux sont fournis, l'authentification peut s'étendre aux données qui ne sont pas incluses dans le processus de chiffrement/déchiffrement.

NOTE Le chiffrement/déchiffrement sans authentification est évité au sein des TPDU et des DPDU parce qu'il y a un certain nombre d'attaques cryptanalytiques éditées qui s'appliquent à tous les plans de ce type. Cependant, les modes chiffrement seul et déchiffrement seul de CCM* sont disponibles aux UAP pour leur utilisation, tel que pour la protection des données en place.

Le mode de fonctionnement par défaut en chiffrement continu du chiffrement par blocs de 7.9.3.2 doit être CCM* (voir ISO/IEC 19772, mécanisme 3). CCM* peut être utilisé pour l'authentification seule, pour l'authentification étendue avec chiffrement, ou pour le déchiffrement avec authentification étendue.

7.9.3.4 Primitive de génération de clé secrète

Une primitive de génération de clé secrète (SKG) doit être utilisée par les plans d'agrément de clé à clés symétriques spécifiés dans la présente norme.

Cette primitive dérive une valeur secrète partagée à partir d'un défi possédé par une entité U_1 et d'un défi possédé par une entité U_2 lorsque tous les défis partagent les mêmes paramètres de domaine de défi. Si les deux entités exécutent correctement toutes les deux cette primitive avec des défis correspondants comme entrées, la même valeur secrète partagée sera produite.

La valeur secrète partagée doit être calculée comme suit:

- Conditions préalables: les conditions préalables pour l'utilisation de la primitive SKG sont:

  - chaque entité doit être liée à un identificateur unique (par exemple: l'adresse EUI64Address de l'appareil). Tous les identificateurs doivent être des chaînes de bits de la même taille. L'identificateur de l'entité U_1 sera désigné par la chaîne de bits U_1. L'identificateur de l'entité U_2 sera désigné par la chaîne de bits U_2;
  - un plan MAC spécialisé doit avoir été sélectionné, avec les informations d'étiquetage telles que spécifiées dans l'ANSI X9.63:2011, 5.7.1. La taille en bits des clés utilisées par le plan MAC spécialisé est désignée par macKeySize.

- Entrée: la primitive SKG prend comme entrée:
  - une chaîne de bits MacKey de taille macKeySize bits devant être utilisée comme la clé d'un plan MAC spécialisé établi;
  - une chaîne de bits QEU_1 fourni par U_1;
  - une chaîne de bits QEU_2 fourni par U_2.
- Actions: les actions suivantes sont entreprises:
  - former la chaîne de bits constituée de l'identificateur de U_1, de l'identificateur de U_2, la chaîne de bits QEU_1 correspondant au défi de U_1, et la chaîne de bits QEU_2 correspondant au défi de U_2.
- MacData = U_1 || U_2 || QEU_1 || QEU_2.
  - calculer l'étiquette MacTag pour MacData avec la clé MacKey en utilisant la transformation d'étiquetage du plan MAC spécialisé établi:
- MacTag = MACMacKey(MacData)
  - si la transformation d'étiquetage produit ”non valide", produire également ”non valide” et arrêter;
  - autrement, mettre Z=MacTag.
- Sortie: la chaîne de bits Z en tant que valeur secrète partagée.

7.10 Collecte des statistiques de sécurité, détection de menaces et rapports

Il convient que les événements majeurs relatifs à la sécurité consignés dans un journal par le gestionnaire de sécurité incluent:

- les autorisations de nouveaux appareils;
- le premier rattachement de nouveaux appareils au réseau; et
- la disparition prolongée des appareils du réseau, en particulier lorsqu'ils sont censés avoir une présence stationnaire.

NOTE La journalisation exigée d'autres événements de sécurité est un sujet potentiel de normalisation future.

Les événements relatifs à la sécurité suivants doivent tous deux faire l'objet d'une journalisation et d'alertes:

- les taux d'échecs de MIC sur les DPDU reçues qui apparaissent correctement formées spécifiant le correct ID de réseau, qui dépassent une plage spécifiée dans l'attribut 5 du DSMO;
- les taux d'échecs de MIC sur les TPDU reçues qui dépassent une plage spécifiée dans l'attribut 6 du DSMO; et
- tout échec d'intégrité détecté lors du déroulement d'une clé symétrique enveloppée qui excède une plage spécifiée dans l'attribut 9 du DSMO.

7.11 Fonctionnalité de DSMO

7.11.1 Généralités

L'objet de gestion de sécurité d'appareil (DSMO) est une partie intégrante du DMAP et est l'application locale de gestion de sécurité dans chaque appareil. Il est responsable de l'agrément et de l'échange du support cryptographique avec des politiques associées. Il

communique avec le DSMO du gestionnaire de sécurité par l'intermédiaire de l'objet proxy gestionnaire de sécurité (PSMO) du gestionnaire de système. Par conséquent, la sécurité de la TL doit être utilisée pour protéger le trafic du DSMO, sauf pendant le processus de rattachement qui exige des mesures spéciales alternatives.

7.11.2 Attributs du DSMO

Le Tableau 92 décrit le DSMO.

Tableau 92 – Attributs du DSMO

Nom du type d'objet normalisé: Device security management object (DSMO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 125				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
DPDU_MIC_Failure_Limit	1	Le seuil d'échec DPDU MIC par unité de temps au-delà duquel une alerte sera envoyée au gestionnaire de sécurité	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 5	La valeur est réinitialisée à 0 après la génération d'une alerte
DPDU_MIC_Failure_Time_Unit	2	Temps d'intervalle en secondes utilisé pour déterminer le taux d'échec du MIC DPDU	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 60 s	
TPDU_MIC_Failure_Limit	3	Seuil d'échec du MIC DPDU par unité de temps au-delà duquel une alerte sera envoyée au gestionnaire de sécurité	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 5 Plage valide: > 0	La valeur est réinitialisée à 0 après la génération d'une alerte
TPDU_MIC_Failure_Time_Unit	4	Temps d'intervalle en secondes utilisé pour déterminer le taux d'échec du MIC DPDU	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 5	
DSMO_KEY_Failure_Limit	5	Le seuil au-delà duquel une alerte sera envoyée au gestionnaire de sécurité	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 1	La valeur est réinitialisée à 0 après la génération d'une alerte
DSMO_KEY_Failure_Time_Unit	6	Le temps d'intervalle en heures utilisé pour déterminer le taux d'échec clé du DSMO	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 1	

Nom du type d'objet normalisé: Device security management object (DSMO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 125				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Security_DPDU_Fail_Rate_Exceeded_AlertDescriptor	7	Utilisé pour changer la priorité de l'alerte Security_DPDU_Fail_Rate_Exceeded appartenant à la catégorie de sécurité. Cette alerte peut également être activée ou désactivée	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 6]	Voir la définition d'alerte
Security_TPDU_Fail_Rate_Exceeded_AlertDescriptor	8	Utilisé pour changer la priorité de l'alerte Security_TPDU_Fail_Rate_Exceeded appartenant à la catégorie de sécurité. Cette alerte peut également être activée ou désactivée	Type: Descripteur de rapports d'alertes Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 6]	Voir la définition d'alerte
Security_Key_Update_Fail_Rate_Exceeded_AlertDescriptor	9	Utilisé pour changer la priorité de l'alerte Security_Key_Update_Fail_Rate_Exceeded appartenant à la catégorie de sécurité. Cette alerte peut également être activée ou désactivée	Type: Alert report descriptor Classification: Static Accessibilité: Read/write Valeur par défaut: [false, 6]	Voir la définition d'alerte
pduMaxAge	10	Durée de temps maximale en secondes durant laquelle il est permis pour une PDU de rester sur le réseau. Si une PDU est reçue dans une fenêtre temporelle excédant cette période, il doit être rejeté au récepteur	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 510 Plage valide: 0..600	Mis sur 510 s par défaut

7.11.3 KeyDescriptor

7.11.3.1 Généralités

Les informations associées à une clé sont résumées dans le Tableau 93.

Tableau 93 – KeyDescriptor

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
KeyLookupData*	1	Type: OctetString36 Classification: Static Accessibilité: Read/write Voir Tableau 94
KeyUsage	2	Type: Unsigned8 Classification: Static Accessibilité: Read/write Plage valide: 0..7 Voir Tableau 90
ValidNotBefore	3	Type: TAITimeRounded Classification: Static Accessibilité: Read/write
SoftExpirationTime	4	Type: TAITimeRounded Classification: Static Accessibilité: Read/write
ValidNotAfter	5	Type: TAITimeRounded Classification: Static Accessibilité: Read/write
Issuer	6	Type: Adresse IPv6Adress ou EUI64Address Classification: Static Accessibilité: Read/write
CryptoKeyIdentifier	7	Type: Unsigned8 ou Unsigned64 Classification: Static Accessibilité: Read/write
KeyMaterial	8	Type: OctetString Classification: Static Accessibilité: Read/write
SecurityLevel	9	Type: Unsigned8 Classification: Static Accessibilité: Read/write Plage valide: 0..7 Voir Tableau 35
Compteur	10	Type: Unsigned8 Classification: Static Accessibilité: Read/write
NonceCache	11	Type: OctetString Classification: Dynamic Accessibilité: Read/write

Nom de l'élément	Identificateur de l'élément	Type de l'élément scalaire
MICFailures	13	Type: Unsigned16 Classification: Static Accessibilité: Read/write
NOTE * indique un champ d'indice.		

Les champs T-keyLookupData OctetString sont énumérés dans le Tableau 94.

Tableau 94 – Champs T-keyLookupData OctetString

Nom de champ	Type du champ scalaire
SourceAddress	Type: IPv6Address
SourcePort	Type: Unsigned16
DestinationAddress	Type: IPv6Address
DestinationPort	Type: Unsigned16

NOTE 1 Puisque la représentation interne du Key Descriptor n'est pas observable, tous les éventuels aspects de représentation dans ce qui suit sont purement donnés pour l'exposé.

Les champs Key Descriptor incluent:

- KeyLookupData:
  - à la TL, utilisé comme indice pour trouver une clé pour une association donnée;
  - à la DL, ce champ n'est pas utilisé et doit être mis à 0x00 partout;
- KeyUsage: permet d'identifier si la clé est utilisable en tant que clé D, clé T ou les deux;

NOTE 2 L'utilisation d'une carte de bits à 2 bits permet à une clé d'être définie pour être utilisée comme clé de DL et clé de T en même temps, si cela est permis par la politique de clé.

- ValidNotBefore: temps (TAI) auquel la clé devient valide;
- SoftExpirationTime: temps (TAI) auquel une clé mise à jour est nécessaire;
- ValidNotAfter: temps (TAI) auquel la clé devient non valide;
- Issuer: adresse de l'émetteur de la clé; cela peut être une adresse IPv6Adress ou une adresse EUI64Address;
- CryptoKeyIdentifier: CryptoKeyIdentifier, mis par l'émetteur de clé, utilisé pour distinguer des clés lorsque plusieurs clés sont valides simultanément;
- KeyMaterial: données de clé pour chiffrement/déchiffrement et/ou génération de MIC;
- SecurityLevel: similaire à ce qui est décrit en Tableau 88;
- Counter: si le KeyUsage bit0 est 0 (cette clé n'est pas une clé D), ce champ n'est pas utilisé, donc il est mis à 0;
- Noncecache: si le KeyUsage bit1 est 0 (cette clé n'est pas une clé T), ce champ n'est pas utilisé, donc il est mis à NULL;
- MICFailure: nombre d'échecs d'authentification de MIC après lequel il convient de générer une alarme.

7.11.3.2 Méthodes complémentaires d'objet de gestion de sécurité d'appareil pour prendre en charge la gestion de clé

Le Tableau 95 décrit la méthode de suppression de clé. Le résultat de l'invocation de méthode est stocké dans ServiceFeedbackCode dans l'en-tête de sous-couche d'application

et retourné à l'appareil demandeur. La construction de nonce pour protéger l'APDU utilisant la clé principale est décrite en 7.5.3.

Tableau 95 – Méthode Delete_key

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Device security management object (DSMO, objet de gestion de sécurité d'appareil)</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 125</th></tr>
<tr><th>Nom de la méthode</th><th>ID de la méthode</th><th colspan="3">Description de la méthode:</th></tr>
<tr><td rowspan="12">Delete_key</td><td>2</td><td colspan="3">Cette méthode est utilisée pour effacer une clé symétrique d'un appareil. Cette méthode est évoquée par le PSMO du gestionnaire de sécurité. Cette méthode doit être protégée par la clé principale courante partagée par l'appareil et le gestionnaire de sécurité</td></tr>
<tr><td></td><td colspan="3">Arguments d'entrée</td></tr>
<tr><td></td><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td></td><td>1</td><td>KeyUsage</td><td>Unsigned8</td><td>KeyUsage défini dans le Tableau 90</td></tr>
<tr><td></td><td>2</td><td>Crypto_Key_Identifier</td><td>Unsigned8</td><td>Le Crypto_Key_Identifier utilisé pour identifier de façon unique les clés superposées au cours de la période de validité</td></tr>
<tr><td></td><td>3</td><td>Source_Port</td><td>Unsigned16</td><td>Port source; si KeyUsage n'est pas 0x01 (une clé T par exemple), il convient d'élider ce champ</td></tr>
<tr><td></td><td>4</td><td>Destination_Address</td><td>IPv6Adress</td><td>Adresse de destination; si KeyUsage n'est pas 0x01 (une clé T par exemple), il convient d'élider ce champ</td></tr>
<tr><td></td><td>5</td><td>Destination_Port</td><td>Unsigned16</td><td>Port de destination; si KeyUsage n'est pas 0x01 (une clé T par exemple), il convient d'élider ce champ</td></tr>
<tr><td></td><td>6</td><td>MasterKeyID</td><td>Unsigned8</td><td>CryptoKeyIdentifier pour la clé principale utilisée pour la génération de MIC</td></tr>
<tr><td></td><td>7</td><td>Time_Stamp</td><td>Unsigned32</td><td>Temps de création de ce message sous la forme TAITimeRounded. Cet argument est la portion de temps du nonce utilisé pour la génération de MIC pour la protection de cet appel de méthode</td></tr>
<tr><td></td><td>8</td><td>MIC</td><td>OctetString (SIZE = 4, 8, 16)</td><td>La vérification de l'intégrité utilisant AES_CCM*. La taille de MIC est sélectionnée dans MIC-32, MIC-64 et MIC-128 avec le niveau de sécurité de clé principale assigné dans le processus de rattachement</td></tr>
<tr><td></td><td colspan="3">Arguments de sortie</td></tr>
<tr><td></td><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td></td><td>-</td><td>-</td><td>-</td><td>-</td></tr>
</table>

Le MIC est généré par une opération de l'AES-CCM* avec les paramètres suivants:

- partie authentification: élément 1..7;
- partie cryptage: aucune;
- clé: clé principale, qui a CryptoKeyIdentifier = MasterKeyID;
- nonce: formé avec la structure du Tableau 57 avec:
  - EUI64Address: Adresse EUI64Address du gestionnaire de sécurité;
  - temps TAI nominal: champ Time Stamp acheminé dans la demande de Delete_Key().

La méthode Key_Policy_Update est décrite dans le Tableau 96. Le résultat de l'invocation de méthode est stocké dans ServiceFeedbackCode dans l'en-tête de sous-couche d'application et retourné à l'appareil demandeur. La construction de nonce pour protéger l'APDU utilisant la clé principale est décrite en 7.5.3.

Tableau 96 – Méthode Key_Policy_Update

Nom du type d'objet normalisé: Device security management object (DSMO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 125				
Nom de la méthode	**ID de la méthode**	**Description de la méthode**		
Key_Policy_Update	3	Cette méthode est utilisée pour mettre à jour une politique associée à une clé symétrique sur un appareil. Cette méthode est évoquée par le PSMO du gestionnaire de sécurité. Cette méthode doit être protégée par la clé principale courante partagée par l'appareil et le gestionnaire de sécurité		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	KeyUsage	Unsigned8	KeyUsage défini dans le Tableau 90
	2	Crypto_Key_Identifier	Unsigned8	Le Crypto_Key_Identifier utilisé pour identifier de façon unique les clés superposées au cours de la période de validité
	3	Source_Port	Unsigned16	Port source; si KeyUsage n'est pas 0x01 (une clé T par exemple), il convient d'élider ce champ
	4	Destination_Address	IPv6Adress	Adresse de destination; si KeyUsage n'est pas 0x01 (une clé T par exemple), il convient d'élider ce champ
	5	Destination_Port	Unsigned16	Port de destination; si KeyUsage n'est pas 0x01 (une clé T par exemple), il convient d'élider ce champ
	6	SoftLifeSpanRatio	Unsigned8	Le pourcentage de HardLifeSpan à partir duquel une mise à jour de la clé sera initiée
	7	Security_Level	Unsigned8	Security Level (niveau de sécurité) spécifié dans le Tableau 35
	8	MasterKeyID	Unsigned8	CryptoKeyIdentifier pour la clé principale utilisée pour la génération de MIC

Nom du type d'objet normalisé: Device security management object (DSMO, objet de gestion de sécurité d'appareil)				
Identificateur du type d'objet normalisé: 125				
	9	Time_Stamp	Unsigned32	Temps de création de ce message sous la forme TAITimeRounded. Cet argument est la portion de temps du nonce utilisé pour la génération de MIC pour le cryptage et la protection de cet appel de méthode
	10	MIC	OctetString (SIZE = 4, 8, 16)	La vérification de l'intégrité utilisant AES_CCM*. La taille de MIC est sélectionnée dans MIC-32, MIC-64 et MIC-128 avec le niveau de sécurité de clé principale assigné dans le processus de rattachement
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	-	-	-	-

Le MIC est généré par une opération de l'AES-CCM* avec les paramètres suivants:

- partie authentification: élément 1..7;
- partie cryptage: aucune;
- clé: clé principale, qui a CryptoKeyIdentifier = MasterKeyID;
- nonce: formé avec la structure du Tableau 57 avec:
  - EUI64Address: Adresse EUI64Address du gestionnaire de sécurité;
  - temps TAI nominal: Champ Time Stamp acheminé dans la demande de Key_Policy_Update().

Le SoftExpirationTime dans le Key Descriptor est mis à jour après un contrôle de MIC réussi sur les paramètres de cet appel de méthode. Tous les paramètres doivent être concaténés du premier élément à celui situé avant le dernier élément (excluant ainsi la vérification d'intégrité). La SoftLifeSpanRatio de clé est le pourcentage de la différence entre les temps ValidNotAfter et ValidNotBefore. Par exemple, une SoftLifeSpanRatio de 50 % causerait une mise à jour de clé à mi-chemin entre la ValidNotBefore et la ValidNotAfter.

7.11.4 Alertes de DSMO

Le Tableau 97 décrit les alertes de DSMO.

Tableau 97 – Alertes de DSMO

Nom du type d'objet normalisé: Device security management object (DSMO, objet de gestion de sécurité d'appareil)					
Identificateur du type d'objet normalisé: 125					
Description de l'alerte: Alertes de sécurité sur l'état de la communication					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alertes (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: urgent, haut, moyen, faible, journal)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = événement	2 = sécurité	0 = Security_DPDU_Fail_Rate_Exceeded	6 = Moyen	Type: Unsigned16 Valeur par défaut: 0	Alerte générée après le dépassement du seuil du taux d'échec DPDU préconfiguré. La valeur indique le nombre d'échecs au cours de la période de temps
0 = événement	2 = sécurité	1 = Security_TPDU_Fail_Rate_Exceeded	6 = Moyen	Type: Unsigned16 Valeur par défaut: 0	Alerte générée après le dépassement du seuil du taux d'échec TPDU préconfiguré. La valeur indique le nombre d'échecs au cours de la période de temps
0 = événement	2 = sécurité	2 = Security_Key_Update_Fail_Rate_Exceeded	6 = Moyen	Type: Unsigned16 Valeur par défaut: 0	Alerte générée après le dépassement du seuil du taux d'échec de mise à jour de clé de sécurité préconfiguré. La valeur indique le nombre d'échecs au cours de la période de temps

8 Couche physique

8.1 Généralités

La couche physique (PhL) est responsable de convertir les informations de données numériques vers, et à partir de, l'énergie radioélectrique émise, et capturée, par une antenne d'appareil. L'Article 8 spécifie également les fréquences opérationnelles, les niveaux de puissance d'émission et les méthodes de modulation utilisées. Comme décrit en 5.2.6.2, la présente norme utilise l'étalement du spectre en séquence directe DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4 comme la couche PhL par défaut, à laquelle elle se réfère comme le moyen de terrain de Type A. (voir 5.2.6.4). Les futures versions de la présente norme peuvent définir des couches physiques alternatives.

La PhL fournit deux services, le service de données de PhL et le service de gestion de PhL. Ces services sont collectivement accessibles par l'intermédiaire du PhSAP. Le service de données de PhL (PhD) permet l'émission et la réception des données utilisateur réelles (les PhPDU) à travers le canal radio physique. Le service de gestion de PhL est utilisé pour

commander les fonctions opérationnelles de la radio telles que le choix de canal, la sélection de la puissance d'émission, etc.

La structure des PhPDU utilisées par la présente norme est définie dans IEEE 802.15.4. Chaque PhPDU est constituée d'un en-tête de synchronisation PHY (PSH), d'un en-tête de codage PHY (PCH), et d'une charge utile de PHY qui est une PhSDU unique. Un délimiteur de début de trame (SFD) dans le SHR est communément utilisé comme référence de temporisation observable.

Un appareil employant une radio DSSS dans la bande de 2,4 GHz certifiée conforme à l'IEEE 802.15.4, sera généralement autorisé à fonctionner sans licence de site dans la plupart des pays dans le monde. Un contrat de licence de l'appareil acceptable pour le(s) pays dans le(s)quel(s) l'appareil est destiné à être utilisé peut être exigé.

8.2 Couche physique par défaut

8.2.1 Exigences générales

La couche physique par défaut doit être la PhL de Type A (voir 5.2.6.4), qui doit être basée sur DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4 avec des exigences et des exceptions complémentaires telles que spécifiées dans le présent document.

Les appareils sur les plates-formes mobiles telles que des navires et des trains et même des camions peuvent se déplacer entre différentes juridictions réglementaires. Dans tous les cas, les réglementations pour le lieu courant de l'appareil s'appliquent. Un des paramètres de configuration d'appareil, dlmo.CountryCode (9.1.15.6), fournit les conseils relatifs au lieu et aux contraintes de réglementation exigées pour piloter la conformité aux réglementations pertinentes; ainsi, pour les plateformes mobiles, la valeur de ce paramètre doit être changée au cours de l'exploitation du système, en temps utile, selon les besoins, pour être conforme aux réglementations pertinentes. Voir 5.2.5.3 et l'Annexe V.

Le fournisseur d'appareil et l'utilisateur final sont responsables de certifier que ces appareils sont conformes à la présente norme et à toutes les éventuelles réglementations spécifiques à un pays ou à une région.

8.2.2 Exigences complémentaires de l'IEEE 802.15.4

8.2.2.1 Débit de données par liaison radio

La PhL doit prendre en charge un débit de données brut (par liaison radio) de 250 kbit/s.

8.2.2.2 Exigences relatives à la temporisation

La présente norme exige que la PhLE prenne en charge le changement de canal pour chaque PhPDU émise. Les exigences relatives à la temporisation sont spécifiées dans le Tableau 98.

Tableau 98 – Exigences relatives à la temporisation

Evénement	Exigence
Temps de changement des voies RF	< 200 µs
Temps de commutation de réception à émission (avec la PA activée)	< 200 µs
Temps de commutation d'émission (avec la PA activée) à réception	< 200 µs
Temps de préparation d'inter-réception	< 200 µs
NOTE PA fait référence à tout amplificateur de puissance RF dans l'appareil.	

8.2.2.3 Détection de porteuse sélection du mode

La couche physique DSSS 2,4 GHz de l'IEEE 802.15.4 prend en charge l'utilisation d'un plan CSMA/CA pour réduire les collisions et augmenter la coexistence. Ce plan peut retarder de façon excessive l'émission d'une PhPDU, en raison de retards de replis aléatoires répétitifs pendant l'acquisition de canal.

La PhLE doit sélectionner le mode de fonctionnement CSMA/CA sur une base de transaction D à transaction D conformément à la demande faite par la DLE, selon la configuration de système, y compris le régime de réglementation dans lequel le système sans fil fonctionne, tel que contraint par dlmo.CountryCode (9.1.15.6).

8.2.2.4 Nombre de canaux

La PhLE doit prendre en charge à tout le moins les canaux 11..25 de DSSS 2,4 GHz de l'IEEE 802.15.4. La prise en charge du canal 26 de l'IEEE 802.15.4 est facultative lorsque son utilisation est permise par des contraintes réglementaires, et interdite lorsque les réglementations interdisent son utilisation.

NOTE L'utilisation du canal 26 est facultative en raison des contraintes réglementaires communément rencontrées près de la frontière de bande.

8.2.2.5 Limites de puissance d'émission

Comme spécifié par IEEE 802.15.4, la PhLE doit prendre en charge un niveau minimal de pleine puissance de -3 dBm, mesuré conformément aux réglementations par rapport auxquelles l'appareil est certifié.

La PhLE doit fournir une puissance d'émission réglable de -5 dBm à la puissance maximale de l'appareil, en des incréments spécifiés par l'attribut TXPowerTolerance de la PhE, tel que spécifié dans l'IEEE 802.15.4 PHY PIB.

Conformément aux exigences de l'IEEE 802.15.4:2011, 8.1.5, le niveau maximal de puissance rayonnée ne doit pas dépasser les exigences réglementaires qui s'appliquent à l'endroit où l'appareil est déployé, comme contraint par dlmo.CountryCode (9.1.15.6).

8.2.3 Exceptions à la couche physique de l'IEEE 802.15.4

8.2.3.1 Généralités

Les exigences de la présente norme qui sont des écarts ou des omissions par rapport à la couche physique de l'IEEE 802.15.4 sont énumérées ici.

8.2.3.2 Limitation de bandes de fréquence et classes de modulation

Bien que la couche physique de l'IEEE 802.15.4 prenne en charge plusieurs bandes de fréquence et classes de modulation, un appareil conforme à la présente norme doit fonctionner dans la bande de 2 400..2 483,5 MHz sans licence utilisant la modulation DSSS (et le codage à 250 kbit/s), qui est spécifiée dans l'IEEE 802.15.4:2011, Tableau 66, comme étant DSSS 2 450. La présente norme ne prend en charge aucune des autres bandes de fréquences, aucun des autres débits de données et aucune des autres techniques de modulation et de codage spécifié(e)s dans l'IEEE 802.15.4.

9 Couche liaison de données

9.1 Généralités

9.1.1 Vue d'ensemble

La couche liaison de données (DL) dans la présente norme est conçue dans le but général de contraindre la gamme des options reconnues de construction pour un appareil de terrain, tout en permettant des solutions de système flexibles et innovantes.

La spécification de DL fournit un ensemble de capacités qui sont bien définies et vérifiables pour chaque appareil qui participe à un sous-réseau D. La DLE peut être conceptualisée comme étant un diagramme d'état à base de tableaux qui fonctionne indépendamment sur chaque appareil. Un sous-réseau D est un groupe de DLE équipées d'un jeu assorti de configurations à base de tableaux par le gestionnaire de système.

Les blocs modules de base de la DL comprennent des intervalles de temps, des supertrames, des liaisons et des graphes. Le gestionnaire de système peut assembler ces blocs modules de base pour configurer une DLE en l'une de trois variantes opérationnelles générales, à savoir le saut de voie discrétisé (slotted-channel-hopping), le saut de voie lent (slow-channel-hopping), et le saut de voie hybride discrétisé/lent (hybrid slotted/slow-channel-hopping). (Voir 9.1.7.2 pour un débat relatif au saut de voie.)

Un intervalle de temps est une seule période de temps non répétitive. Les durées d'intervalle de temps dans la présente norme sont configurables à une valeur fixe telle que 10 ms ou 12 ms. Une fois qu'une durée d'intervalle de temps est choisie, tous les intervalles de temps ont généralement la même durée et ils sont réalignés sur un cycle de 4 Hz à chaque intervalle d'horloge de 250 ms. (Voir 9.1.9 pour un débat relatif au chronométrage de la DLE.)

Une supertrame est une collection d'intervalles de temps se répétant sur un programme cyclique. Le nombre d'intervalles de temps dans une supertrame donnée détermine la fréquence de répétition de chaque intervalle de temps, établissant ainsi un cycle de communication pour les DLE qui utilisent la supertrame. La supertrame a également un modèle de saut de voie de référence qui lui est associé. (Voir 9.1.8 pour un débat relatif aux supertrames.)

Les liaisons sont des connexions entre des DLE. Lorsque le gestionnaire de système définit des chemins entre des DLE, les DLE reçoivent des attributions de liaison. Une attribution de liaison se répète sur un programme cyclique, par le biais de sa connexion à une supertrame sous-jacente. Chaque liaison se réfère à un intervalle de temps ou à un groupe d'intervalles de temps au sein d'une supertrame, à son type (émission et/ou réception), à des informations relatives au voisin de la DLE (la DLE sur l'autre extrémité de la liaison), à un décalage de voie par rapport au modèle de saut de voie sous-jacent de la supertrame, et à des alternatives d'émission/réception.

La présente norme prend en charge le routage par graphe ainsi que le routage de source. Un graphe orienté est un ensemble de liaisons orientées qui est utilisé pour acheminer des DPDU Data au sein d'un sous-réseau D. Chaque graphe orienté au sein du sous-réseau D est identifié par un ID de graphe. Dans le routage de source, la DLE émettrice désigne le chemin saut par saut que la DPDU Data emprunte à travers un sous-réseau D. Le routage par graphe et le routage par source peuvent être mélangés. (Voir 9.1.6 pour un débat relatif au routage.)

9.1.2 Stratégies de coexistence dans la DL

La présente norme incorpore plusieurs stratégies qui sont utilisées simultanément pour optimiser la coexistence avec d'autres utilisateurs du spectre radio de 2,4 GHz, tel que décrit en 4.6.10. La plupart de ces stratégies sont traitées de manière adaptative par la DLE conjointement avec le gestionnaire de système.

9.1.3 Allocation de largeur de bande numérique

La DLE est un diagramme d'états à base de tableaux qui fournit l'accès hiérarchisé par ordre de priorité à la largeur de bande numérique pour la communication directionnelle parmi des DLE au sein d'un sous-réseau D. La machine à états fonctionne sur un seul intervalle de temps à la fois.

La largeur de bande numérique est allouée par une fonction de gestion de système. Par exemple, un appareil de terrain peut avoir besoin de faire rapport toutes les 10 s. Un niveau de service est configuré par le biais de la fonction de gestion de système, pour assurer que la largeur de bande numérique est disponible en cas de besoin. La fonction de gestion de système, à son tour, configure la largeur de bande numérique disponible pour la DLE de l'appareil de terrain et de toutes les éventuelles DLE de routeurs intermédiaires exigées.

Une liaison est l'unité de base de service au sein de la DL. Une liaison peut être entrante, sortante, ou bidirectionnelle. Elle peut être en monodiffusion ou en diffusion (voir 9.1.9.4.2).

La largeur de bande numérique de DL peut être allouée pour délivrer un niveau moyen de service, par exemple, 10 DPDU Data de largeur de bande numérique disponible (multi-saut) par minute. En variante, la largeur de bande numérique de DL peut être allouée pour prendre en charge un intervalle de production de rapports et un niveau de service, par exemple, une DPDU Data (y compris les répétitions de tentatives) toutes les 15 s, avec une latence maximale de 2 s à une connexion dorsale.

La largeur de bande numérique de DL peut être organisée comme un pot commun qui peut être partagé par un ensemble de DLE utilisant les liaisons correspondantes. Un niveau de service peut être fourni en assurant qu'une capacité partagée en mode contention suffisante est disponible.

Pour une allocation de voie plus granulaire, les liaisons peuvent être attachées à des groupes particuliers de DPDU Data.

Un niveau de service peut être fourni avec une combinaison d'allocations spécifiques de liaison et de largeur de bande numérique partagée généralement disponible. Par exemple, pour chaque rapport, une liaison spécialisée peut être allouée pour la première émission à chacun de deux voisins, avec des répétitions de tentative utilisant la largeur de bande numérique partagée.

9.1.4 Structure de la DPDU

La structure générale d'une unité de données de protocole de liaison de données (DPDU) dans la présente norme est montrée à la Figure 53.

Figure 53 – Suite de protocoles de DL et structure de PhPDU/DPDU

La DL spécifiée par la présente norme comprend:

- Un sous-ensemble de la couche MAC de l'IEEE 802.15.4, telle que décrite en 9.1.5. Celui-ci gère les mécanismes de bas niveau d'envoi et de réception de DPDU individuelles (dont toutes sont classifiées comme DPDU Data par l'IEEE 802.15.4). Les SHR, PHR, MHR, et séquence de contrôle de trame (FCS) de chaque DPDU sont tels que décrits et spécifiés dans l'IEEE 802.15.4.
- Une extension de la MAC, y compris les aspects de la DL qui ne sont pas spécifiés par l'IEEE mais sont logiquement des fonctions MAC.
- Un protocole de DL supérieur qui traite les aspects liaison et maille au-dessus du niveau MAC.

Des composants de l'en-tête de DPDU dans la présente norme sont décrits en 9.3.1.

9.1.5 La DL et la MAC de l'IEEE 802.15.4

La présente norme utilise la couche MAC de l'IEEE 802.15.4 (appelée IEEE MAC dans le présent document). Seules les trames de données de l'IEEE MAC sont utilisées par la DL. Les formats utilisés sont tels que spécifiés par l'IEEE 802.15.4. Deux exceptions sont explicitement énumérées en 9.1.5. Voir 9.3.3 pour plus d'informations.

L'IEEE MAC décrit diverses caractéristiques qui ne sont pas utilisées par la DL de la présente norme (appelée "DL" dans le présent document). En résumé, seules les trames de données de l'IEEE MAC sont utilisées par la DL.

Une DLE conforme à la présente norme ne s'associe jamais à un coordonnateur dans le sens défini par l'IEEE MAC. Aucune des fonctions de l'IEEE MAC impliquant des appareils pleines fonctions (FFD[8]) n'est utilisée par la présente norme.

Dans le contexte limité des DPDU de la présente norme, il y a quelques caractéristiques qui ne sont pas prises en charge pour les trames de données IEEE MAC. Ces caractéristiques sont mises en œuvre par l'intermédiaire de l'extension MAC de la présente norme, qui renforce l'IEEE MAC avec des caractéristiques qui sont logiquement des fonctions de MAC, mais qui ne sont pas incluses dans l'IEEE 802.15.4.

La DL et le MAC de l'IEEE 802.15.4 spécifient chacune une entité appelée une supertrame (voir 9.1.8), mais la DL n'utilise aucun aspect de la spécification de supertrames de l'IEEE 802.15.4 MAC.

Des DPDU ACK/NAK sont utilisées pour acheminer des informations relatives au temps pour une correction d'horloge, en plus de fournir un acquittement authentifié. Ces caractéristiques ne sont pas disponibles lors de l'utilisation d'une immédiate MPDU d'acquittement de l'IEEE 802.15.4 MAC. Pour cette raison, entre autres, les immédiates d'acquittement de niveau MAC spécifiées dans l' IEEE 802.15.4 ne sont pas utilisées. A la place, des acquittements immédiats de niveau MAC conformes à la présente norme sont ici fournis, tels que des trames de données IEEE 802.15.4 courtes qui utilisent habituellement une combinaison de structure de champ d'adresse non destinée à ces fins dans l'IEEE 802.15.4.

NOTE Les DPDU ACK/NAK sont des SCS (Short Control Signaling), tels que spécifiés dans l'ETSI EN 300 328.

L'IEEE 802.15.4 MAC inclut des balayages actifs et passifs, qui ne sont pas utilisés dans la présente norme. La présente norme a des balayages actifs et passifs alternatifs, utilisant des trames de données de l'IEEE 802.15.4.

Le mécanisme de repli et de répétition de tentative de l'IEEE 802.15.4 MAC n'est pas utilisé par la DL. Au lieu de cela, la DL met en œuvre ses propres répétitions de tentative, impliquant la diversité spatiale (répétitions de tentative à plusieurs DLE), la diversité de fréquence (répétitions de tentative sur plusieurs canaux radio), et la diversité de temps (retardant la DPDU Data). La façon et le degré de ces éléments de diversité ne sont pas fixes, mais ils sont configurés par le gestionnaire de système. Plus généralement, la DL de la présente norme utilise l'accès CSMA/CA, mais les détails sont différents de l'utilisation du CSMA/CA tel que défini dans l'IEEE 802.15.4. Divers aspects du comportement en CSMA/CA de l'IEEE 802.15.4 MAC ne sont pas utilisés, et les fonctions de CSMA/CA sont traitées dans la DL de la présente norme.

La présente norme comprend deux exceptions aux combinaisons d'adressage MAC-PDU spécifiées dans l'IEEE 802.15.4:

- Les DPDU Data de sollicitation et la plupart des DPDU ACK/NAK, qui sont techniquement des trames de données dans l'IEEE 802.15.4, utilisent un mode d'adressage de destination de 00 et un mode d'adressage de source de 00. Dans l'IEEE 802.15.4, cette combinaison se limite aux balises de l'IEEE 802.15.4 et aux immédiates d'acquittement trivialement brouillées de l'IEEE 802.15.4.
- Les DPDU Data d'annonce et les DPDU ACK/NAK secondaires en duodiffusion/N-diffusion qui sont techniquement des trames de données dans l'IEEE 802.15.4, utilisent un mode d'adressage de destination de 00 et un mode d'adressage de source de 10 (adresse DL16Address). Dans l'IEEE 802.15.4, cette combinaison implique que

[8] FFD = *full function device*.

la trame est dirigée vers le coordonnateur de réseau dans un local (PAN), ce qui n'existe pas dans la présente norme (et qui, par conséquent, ne s'applique pas).

9.1.6 Chemins et graphes

9.1.6.1 Généralités

Des chemins sont configurés par le gestionnaire de système, en se basant sur des rapports issus des DLE qui spécifient la qualité instantanée et historique de la connectivité sans fil vers leurs voisins immédiats. Le gestionnaire de système accumule ces rapports de qualité de signal pour prendre des décisions de routage. Les rapports de qualité de signal sont normalisés, mais le processus de décision de routage au sein du gestionnaire de système n'est pas normalisé. Une fois que le gestionnaire de système prend ses décisions de routage, il utilise des DPDU Data normalisées pour configurer les chemins au sein de chaque DLE dans le sous-réseau D. (Voir 9.1.13 et 9.1.14 pour une revue de la découverte de voisins).

Le routage de DL est adaptatif en deux niveaux:

- Les DLE prennent des décisions de transmission adaptatives instantanées. Les DLE sont normalement configurées avec la diversité de chemin et, de ce fait, si une liaison échoue quelque part le long du chemin, la DLE peut immédiatement envoyer la DPDU Data le long d'un chemin alternatif.
- Si, au fil du temps, certaines liaisons ont de constants problèmes de connectivité, cela est rapporté au gestionnaire de système, qui peut alors reconfigurer la DLE pour utiliser des liaisons différentes.

Dans chaque DPDU Data, des instructions de routage de DL sont placées dans le sous-en-tête DROUT de la DPDU Data (voir 9.3.3.6). Lorsque des DPDU Data sont adressées à un voisin immédiat, comme au cours du processus de rattachement au sous-réseau D, le chemin est simplement l'adresse du voisin en question. Lorsque les DPDU Data sont envoyées à une DLE plus distante, un simple numéro de graphe peut spécifier comment il convient d'acheminer la charge utile de la DPDU Data à travers le sous-réseau D pour atteindre l'adresse en question. Ces deux approches peuvent être combinées. Par exemple, un sous-en-tête DROUT peut contenir deux entrées, la première identifiant un voisin immédiat pour le premier saut, et la seconde indiquant un graphe utilisé pour le reste du chemin à travers le sous-réseau D.

Les chemins qui identifient des adresses D spécifiques, également connus comme routage de source, ne sont pas aussi adaptatifs que les chemins basés sur des graphes. Lorsqu'un chemin est basé sur une série d'adresses D, chaque DLE le long du chemin devient un point unique d'échec. D'autre part, il convient que les graphes soient configurés avec plusieurs branches à chaque saut, afin qu'en cas de problème de connectivité avec un voisin, la DLE puisse envoyer la charge utile de cette DPDU Data vers un voisin différent.

Le routage de source est utile pour des communications rapides et transitoires entre des DLE, comme au cours du processus de rattachement. Le routage de source peut également être utilisé lorsque les ressources des chemins de graphe sont rares.

Le sous-en-tête DROUT est construit par la DLE qui injecte la DPDU Data dans la DL à partir d'une NLE. Les chemins sont sélectionnés par une consultation de table basée sur l'ID de contrat, l'adresse D de destination D, ou par défaut. Une fois un chemin sélectionné, la charge utile acheminée de la DPDU Data suit ce chemin jusqu'à ce qu'elle arrive au point de terminaison du sous-réseau D, qui peut être sa destination finale, ou alternativement peut être un point de cheminement le long du chemin, tel qu'un routeur dorsal ou le gestionnaire de système. Au point de terminaison du sous-réseau D, la charge utile de la DPDU Data reçue est passée à la NLE contiguë.

Le sous-en-tête DROUT inclut un champ de limite de transmission qui est utilisé pour limiter le nombre de fois qu'une DPDU peut être transmise au sein d'un sous-réseau D. La limite de transmission est initialisée par la DLE initiatrice lorsque le chemin est assigné, et

décrémentée avec chaque saut jusqu'à ce qu'elle atteigne zéro, déclenchant le rejet de la DPDU Data si un saut ultérieur était exigé.

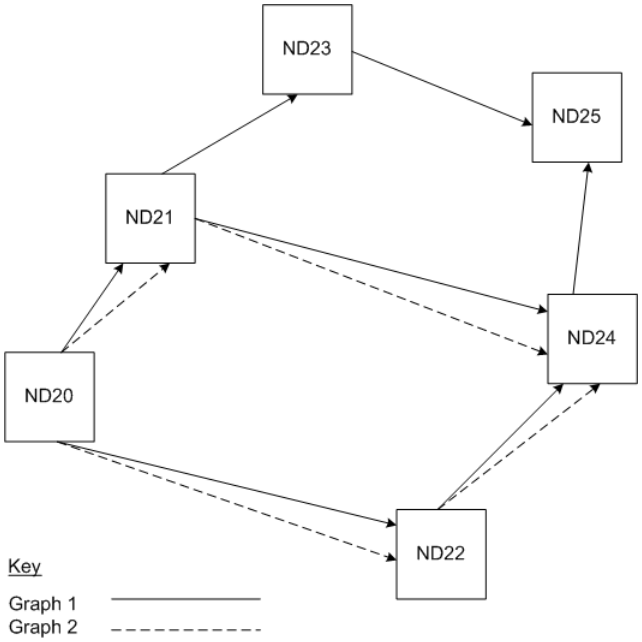
NOTE Cette limite de transmission s'assure que les DPDU Data ne peuvent pas circuler pour toujours par un chemin circulaire non intentionnel.

9.1.6.2 Routage par graphe

Un graphe est un ensemble de liaisons orientées qui est utilisé pour acheminer des messages au sein d'un sous-réseau D. Chaque graphe désigné par le gestionnaire de système pour le routage au sein d'un sous-réseau D est identifié par un identificateur de graphe (graph ID).

Les liaisons associées à chaque graphe sont configurées par le gestionnaire de système. Un sous-réseau D peut avoir plusieurs graphes, dont certains peuvent se chevaucher. Chaque DLE peut avoir plusieurs graphes passant par elle, voire vers les mêmes voisins.

La Figure 54 montre un exemple de routage par graphe.



Légende

Anglais	Français
Key	Légende
Graph 1	Graphe 1
Graph 2	Graphe 2

Figure 54 – Exemple de routage par graphe

Sur la Figure 54, ND20 communique avec ND25 en utilisant le graphe 1. Pour envoyer la charge utile d'une DPDU Data sur ce graphe, ND20 peut la transmettre à ND21 ou à ND22. A partir de ces DLE, la charge utile de la DPDU Data peut prendre plusieurs chemins alternés, mais toutefois, en suivant le graphe 1, la charge utile de la DPDU Data arrivera à ND25. De même, pour communiquer avec ND24, ND20 peut envoyer des DPDU Data sur le graphe 2 par ND21 ou ND22, dont l'un ou l'autre, à son tour, transmettra la charge utile de la DPDU Data à ND24.

La Figure 54 montre tous les graphes provenant de ND20, mais les mêmes graphes peuvent être utilisés par n'importe quel nœud. Par exemple, le gestionnaire de système peut configurer ND21 pour utiliser le graphe 1 pour sa communication avec ND25.

NOTE 1 Les informations de routage de DL dans la charge utile de la DPDU Data sont souvent mises à jour à mesure que cette charge utile passe à travers le sous-réseau de D.

Le Tableau 99 et le Tableau 100 reflètent le contenu des tables de graphes sur ND20 et ND21. Ces tables de graphes correspondent grossièrement à des structures de données au sein de chaque DLE pour la topologie montrée à la Figure 31. Par exemple, une DPDU Data suivant le graphe 2 cherchera l'ID de graphe 2 dans chaque routeur le long du chemin pour savoir quels voisins elle peut utiliser pour le prochain saut.

Tableau 99 – Table de graphes sur ND20

ID de graphe	Adresse du voisin
1	21, 22
2	21, 22

Tableau 100 – Table de graphes sur ND21

ID de graphe	Adresse du voisin
1	23, 24
2	24

Chaque graphe au sein du sous-réseau D est identifié par un ID de graphe. Une DPDU Data a habituellement son origine au sein du sous-réseau D, à un appareil de terrain ou à une passerelle, un gestionnaire de système ou un routeur dorsal. Pour envoyer un message sur un graphe, la DLE initiatrice inclut un ID de graphe dans le sous-en-tête DROUT de la DPDU Data. La DPDU Data suit les chemins correspondant à l'ID de graphe jusqu'à ce qu'elle atteigne sa destination ou soit rejetée.

Afin d'acheminer des DPDU Data sur un graphe, chaque DLE le long du chemin a besoin de maintenir une table de graphes contenant les entrées qui incluent l'ID de graphe et l'(les) adresse(s) D du(des) prochain(s) voisin(s). Une DLE acheminant une DPDU Data accomplit une consultation basée sur l'ID de graphe et envoie la DPDU Data vers n'importe lequel des voisins applicables. Une fois qu'un voisin acquitte la réception de la DPDU Data, la DLE la libère d'un tampon de transmission de DPDU Data.

Divers chemins de graphe (branches) peuvent être établis en configurant plus d'un voisin associé au même indice de graphe. Une branche peut être configurée avec un voisin préférentiel, indiquant qu'il convient que la DLE tente d'émettre la DPDU Data vers le voisin préférentiel d'abord, même s'il y a une occasion plus précoce d'émettre vers d'autres voisins. Si aucun voisin préférentiel n'est désigné, il convient que la DLE traite équitablement toutes les branches, en émettant la DPDU Data à la première occasion qui se présente. Si la première émission ne donne pas lieu à une DPDU ACK, la DLE est normalement configurée pour utiliser des branches de remplacement pour les répétitions de tentative.

La Figure 55 fournit des exemples de graphes de routage qui sont entrants (allant vers la dorsale) et sortants (s'éloignant de la dorsale). L'organisation de base des graphes de routage entrants et sortants peut être très similaire dans les deux cas, mais en pointant dans des sens opposés, conformément à la Figure 55. Le gestionnaire de système configure les relations de routage entre les DLE dans un sous-réseau D.

La moitié supérieure de la Figure 55 montre un graphe entrant dans une configuration de routage DL exemplaire. Un graphe entrant permet à un ensemble de DLE d'envoyer des DPDU Data vers la dorsale ou le gestionnaire de système. Un seul graphe peut être utilisé pour le routage entrant dans un petit sous-réseau D, comme montré à la moitié supérieure de la Figure 55. Il est possible et souvent souhaitable que le gestionnaire de système définisse plusieurs graphes entrants, en particulier lorsque le nombre des DLE dans le sous-réseau D augmente. Comme montré dans la moitié supérieure de la Figure 55, si des DLE ont plusieurs routeurs voisins, la diversité est souvent inhérente au graphe entrant.

Figure 55 – Graphes entrants et sortants

Le graphe entrant illustratif à la Figure 55 peut être problématique pour les NPDU fragmentées, car les fragments arrivant à différents routeurs dorsaux peuvent poser un défi de réassemblage. Les considérations suivantes s'appliquent:

a) Chaque contrat spécifie la taille de NPDU maximale. La plupart des contrats couvrant la communication vers la dorsale, y compris ceux généralement utilisés pour des trafics de plus haute priorité comme la communication P/S des variables de processus et la communication source/puits des alertes (alarmes de processus ou événements de l'appareil par exemple), spécifient une taille d'APDU maximale qui ne déclenche pas la fragmentation des NPDU. La plupart des communications s'adaptent dans une seule et même DPDU Data, qui peut être déterminée pour un flux particulier, en termes de taille maximale de charge utile prise en charge, lorsque le contrat est établi.

b) Les contrats qui permettent des NPDU de taille pouvant impliquer la fragmentation vers la dorsale sont généralement des transferts d'arrière-plan et de faible priorité de grands blocs d'informations, comme le chargement de formes d'ondes capturées. Un problème survient lorsque les fragments d'un NPDU fragmenté sont livrés à des BBR (routeurs dorsaux) différents.

   Ce problème (de livraison des fragments non coordonnée) peut être évité de deux manières différentes:

   1) Le contrat peut spécifier ou être attaché à un chemin qui se termine dans un BBR unique, évitant ainsi la livraison de différents fragments provenant d'un même NPDU à différents appareils.

   2) Le contrat peut spécifier ou être attaché à un chemin qui se termine dans des BBR multiples provenant du même fournisseur, connu par le gestionnaire de système pour avoir un protocole de réassemblage des fragments inter-BBR qui gère ce réassemblage via leurs réseaux dorsaux partagés.

      NOTE 2 Il est courant pour les propriétaires d'usine ou les opérateurs d'acquérir l'équipement des infrastructures remplissant la même fonction chez un seul fournisseur afin que les éventuels problèmes rencontrés avec cette catégorie d'équipement puissent être directement soumis au fournisseur responsable, évitant ainsi au personnel de l'usine d'avoir à déterminer le fournisseur spécifique en cause. Cette élimination de la "désignation de coupables" entre fournisseurs mène généralement à une résolution des problèmes accélérée et au retour à la productivité normale de l'usine plus rapide. Cela rend également plus utile toute caractéristique du fournisseur ou du propriétaire ou tout diagnostic pouvant être fourni par l'équipement des infrastructures.

   Pour les contrats de DLE prenant en charge les tailles de charge utile qui ne s'adaptent pas dans une seule et même DSDU, les graphes sélectionnés orientés vers la dorsale utilisent souvent une diversité de chemin réduite pour assurer qu'un jeu de NPDU fragmentées est livré dans sa totalité au même BBR (alternative a)) ou à un sous-ensemble de BBR multiples connus pour fournir conjointement une capacité partagée de réassemblage de fragments (alternative b)).

La moitié inférieure de la Figure 55 montre un ensemble de graphes sortants dans une configuration de routage exemplaire. Un graphe sortant est habituellement utilisé pour

envoyer des DPDU Data des DLE dorsales vers des DLE de terrain. Comme montré à la moitié inférieure de la Figure 55, plusieurs graphes peuvent être utilisés pour le routage sortant, avec chaque graphe sortant correspondant à un groupe de DLE dans la gamme radio du graphe.

Dans cet exemple, le routage de graphe de DL sortant finit à la dorsale, point auquel la NL prend les responsabilités de routage. La relation entre un sous-réseau D de WISN et un sous-réseau N de dorsale est décrite en 5.5.

Bien que tous les exemples ci-dessus montrent des graphes entrants et sortants, ceux-ci ne sont pas réellement des types de graphes différents, se sont seulement des graphes qui pointent dans des directions opposées. Le routage peer-to-peer est également pris en charge par la norme. Le gestionnaire de système peut configurer un graphe pour suivre n'importe quel chemin où la connectivité existe.

Une DSDU est transmise le long d'un graphe jusqu'à ce que le graphe soit terminé. Si l'adresse de destination de la DPDU Data correspond à l'adresse de la DLE, la DSDU a atteint sa destination et le graphe est terminé. En variante, si le numéro de graphe dans la DPDU Data n'a pas une entrée correspondante dans la table de consultation dlmo.Graph (voir 9.4.3.6), le graphe a atteint son point de fin.

9.1.6.3 Extensions de graphe

La moitié inférieure de la Figure 55 montre que les graphes sortants ne se prolongent pas nécessairement vers toutes les DLE à la périphérie d'un sous-réseau D. Néanmoins, de telles DLE sont implicitement couvertes par les graphes sortants, par le biais d'un mécanisme d'extension de graphe. Une DLE prolonge automatiquement des graphes en vérifiant l'adresse de destination de la DPDU Data comme une entrée de table de voisins, indiquant ainsi que la destination de la DPDU Data se situe à un saut de distance. Si tel est le cas, le routeur traite le voisin comme s'il était énuméré dans le graphe, prolongeant de ce fait le graphe pour la DPDU Data en question. Plus formellement, lorsque l'adresse de destination de la DPDU Data est dans la table de voisins d'une DLE, et la DPDU Data est en cours d'acheminement avec un graphe, la DLE doit traiter ce graphe comme comprenant ce voisin pour le besoin du routage de cette DPDU Data même si le graphe ne se réfère pas explicitement au voisin. Tous les routeurs doivent prendre en charge cette forme élémentaire d'extensions implicites de graphes.

Un champ explicite d'extension de graphe dans la table de voisins fournit un degré supplémentaire de commande. Si un graphe est spécifiquement désigné dans une table de voisins, telle que décrite en 9.4.3.4.2, le voisin est non seulement traité comme étant couvert par le graphe; le voisin reçoit également un traitement préférentiel. Si le voisin est désigné comme étant le dernier saut du graphe, une DPDU Data suivant ce graphe doit être transmise exclusivement à ce voisin. Si le voisin est désigné comme étant une branche préférentielle, il convient que la DLE tente de transmettre une DPDU Data applicable au voisin en question avant les autres voisins.

La prise en charge pour le champ d'extension de graphe explicite dans la table de voisins est une option de construction d'appareil; son statut de prise en charge est rapporté au gestionnaire de système par le biais de dlmo.DeviceCapability lorsque la DLE rejoint le sous-réseau D. Tous les routeurs prennent en charge la capacité d'extension de graphe implicite élémentaire, mais seuls certains routeurs sont censés prendre totalement en charge les indicateurs de dernier saut explicite et de branche préférentielle dans la table de voisins.

9.1.6.4 Routage de source

Le routage de source est une méthode générale de routage prise en charge par la présente norme. Dans le routage de source, la DLE émettrice peu être configurée pour désigner le chemin saut par saut à emprunter par une DPDU Data à travers un sous-réseau D. Une utilisation simple du routage de source correspond au fait de diriger une DPDU Data un saut plus loin à un voisin spécifique, comme pour le rattachement. Lorsqu'une DPDU Data

acheminée par routage de source arrive à une DLE intermédiaire, la DLE intermédiaire examine les informations de chemin contenues dans la DPDU Data pour déterminer le voisin auquel il convient qu'elle transmette la DPDU Data.

Un chemin de source est une liste d'entrées spécifiant le chemin qu'une DPDU Data doit suivre à travers le sous-réseau D. La première entrée dans la liste spécifie le prochain saut, et la liste raccourcit à mesure que la DPDU Data se déplace à travers le sous-réseau D. Les entrées de routage de source peuvent spécifier des graphes ou des adresses D, permettant ainsi à des graphes d'être chaînés. Les numéros de graphe de 12 bits au sein d'un chemin sont codés en binaire comme étant 0x1010 gggg gggg gggg.

L'en-tête de DPDU Data comprime un chemin de source en un seul octet dans le cas commun où un seul chemin de graphe est spécifié et le numéro de graphe est ≤ 255 (codé binaire comme étant 0x1010 0000 gggg gggg). Cela est communément appelé routage par graphe, mais formellement il s'agit d'un chemin de source contenant un seul graphe.

Dans le processus de configuration ou de rattachement, une adresse EUI64Address est utilisée pour adresser une DLE qui n'a pas encore reçu une adresse IPv6Address. Ce cas est codé comme un chemin avec un graphe de zéro et une adresse D de DADDR de zéro (voir 9.3.3.6 et 9.3.3.7), indiquant que l'adresse EUI64Address peut être trouvée dans l'en-tête de MAC (MHR) de la DPDU Data.

Lorsqu'une DPDU Data est reçue par la DLE par sa liaison sans fil, les étapes de traitement suivantes doivent être suivies, dans l'ordre, pour déterminer si le chemin de DL s'est terminé et pour mettre à jour le chemin de source dans l'en-tête de DPDU Data:

- L'adresse D de destination des sous-en-têtes de DADDR est vérifiée pour voir si elle concorde avec l'adresse D de la DLE de réception. S'il y a une concordance, la DSDU a atteint sa destination finale et la DSDU doit être passée à la NLE contiguë comme décrit en 9.2.4. (L'adresse D de destination de DADDR est codée comme étant zéro, dans le cas où l'adresse D de destination serait dupliquée dans le MHR. Voir 9.3.3.7. Dans ce cas, la concordance est indirecte, basée sur l'adresse D de la destination de MHR.)
- La première entrée dans le chemin de source est supprimée s'il y a lieu, raccourcissant donc le chemin de source en décalant la deuxième entrée et les suivantes (le cas échéant) vers les positions antérieures (décalage à gauche). La première entrée doit être supprimée, à moins qu'elle ne soit un numéro de graphe pour un graphe qui n'a pas atteint son point de fin.
- Si le chemin n'a aucune entrée restante, le chemin est terminé et la DSDU doit être passée à la NLE contiguë comme décrit en 9.2.4.

Si la DSDU n'est pas passée à la NLE contiguë, la DPDU Data doit être rejetée si la limite de transmission (dans le sous-en-tête DROUT) est zéro. Si la limite de transmission est positive, elle est décrémentée et la DPDU Data est placée sur la file d'attente de messages de transmission de la DLE.

Lorsqu'une DSDU est prévue pour être acheminée par la dorsale, il convient que le chemin de DL se termine au routeur dorsal. Si un chemin ne se termine pas dans un routeur dorsal contigu, elle est transmise par la DLE et n'est jamais traitée par la NLE contiguë du routeur dorsal, permettant donc à la messagerie peer-to-peer de se produire au sein du sous-réseau D sous les auspices d'un routeur dorsal.

Ces méthodes de routage sont des exemples de différentes manières de configurer la capacité de routage DL qui réside dans tous les routeurs de terrain conformes à la présente norme. Le gestionnaire de système doit configurer tous les graphes au sein d'un sous-réseau D. La capacité de configurer le routage de plusieurs manières différentes telles que le routage par graphe et/ou le routage de source permet l'interconnectabilité d'appareil.

9.1.6.5 Sélection de chemin

Le chemin à travers le sous-réseau D pour une DPDU Data est choisi lorsque le message pénètre dans la DL (voir 9.2.2). Le chemin est stocké dans le sous-en-tête DROUT pour être utilisé par d'autres DLE qui achemineront la DPDU Data. La sélection initiale d'un chemin est basée sur des règles de décision dans la DLE initiatrice. La liste suivante montre les critères de sélection de chemin, dans l'ordre, par lesquels le chemin doit être sélectionné en se basant sur la première condition qui s'applique:

- La DPDU Data a une adresse de destination EUI64Address. Une adresse de destination EUI64Address est utilisée seulement au cours du processus de rattachement, lorsqu'un routeur envoie une réponse à un voisin immédiat qui n'a pas encore reçu une adresse DL16Address issue du gestionnaire de système. Dans ce cas, l'adresse EUI64Address issue de l'IEEE MAC est utilisée, avec un ID de graphe (Graph ID) de 0 dans le chemin D.
- Le ContractID est associé à un chemin D particulier. Il peut être utilisé lorsqu'un graphe ou chemin D de source particulier est prévu pour fournir un niveau défini de service.
- L'adresse de destination DL16Address au sein du sous-réseau D est associée à un chemin particulier.
- L'adresse de destination DL16Address au sein du sous-réseau D est un voisin immédiat, comme au cours du processus de rattachement.
- Autrement, utiliser le chemin par défaut. Normalement, la valeur par défaut dirigera le message vers le routeur dorsal le plus proche, ou vers le gestionnaire de système s'il n'y a aucun routeur dorsal.

Un seul chemin peut être désigné comme étant la valeur par défaut par le gestionnaire de système, en désignant un chemin D particulier comme étant la valeur par défaut. Le chemin D par défaut est habituellement configuré pour acheminer des messages vers le gestionnaire de système, ou vers un routeur dorsal s'il n'y a aucun gestionnaire de système sur le sous-réseau D. Un chemin D par défaut peut raisonnablement être configuré conjointement avec l'établissement du contrat d'une DLE avec le gestionnaire de système. Des chemins complémentaires peuvent être configurés selon les besoins, comme pour fournir une qualité de service accrue ou pour acheminer des messages vers une DLE homologue sur le sous-réseau D.

9.1.7 Saut de voie discrétisé, saut de voie lent et intervalles de temps

9.1.7.1 Généralités

Trois variantes opérationnelles générales sont prises en charge par la DL:

– saut de voie discrétisé;

– saut de voie lent; et

– combinaisons hybrides de saut de voie discrétisé et de saut de voie lent.

Ces trois variantes opérationnelles sont différentes manières pour un gestionnaire de système de configurer une capacité de saut de voie discrétisé qui est prise en charge par chaque DLE dans un sous-réseau D. Des programmes de saut de voie sont configurés par le gestionnaire de système par l'intermédiaire des DPDU d'annonce et de l'attribut dlmo.Superframe.

Le saut de voie discrétisé et le saut de voie lent fournissent différentes manières de configurer une série d'intervalles de temps. Le gestionnaire de système détermine le mode de fonctionnement et assigne l'utilisation des supertrames, qui sont des collections cycliques d'intervalles de temps. (Voir 9.1.8 pour un débat plus poussé relatif aux supertrames.) Cela fournit la flexibilité et l'interopérabilité des fonctions de communication pertinentes (l'interconnectabilité par exemple) sans exiger une complexité excessive au sein des appareils.

De la perspective d'un appareil de terrain, la DLE peut être visualisée comme un piano avec plusieurs touches. Chaque touche correspond à une transaction D, qui spécifie une voie et un intervalle de temps spécifiques. Une touche est utilisée pour envoyer une DPDU Data en attente issue de la file d'attente sortante, une autre touche est utilisée pour être à l'écoute pour détecter une DPDU Data entrante, et ainsi de suite. Le gestionnaire de système fournit une bande perforée pour piano pour que la DLE joue sans cesse. Le style de jeu peut être saut de voie lent, saut de voie discrétisé, ou un hybride des deux. La DLE ne fait pas de différence; elle joue simplement mécaniquement chaque touche à un moment spécifié sur une voie spécifiée, en se basant sur les instructions contenues sur la bande perforée pour piano.

Les détails de note au sein d'un intervalle de temps sont configurables, en utilisant des modèles d'intervalles de temps fournis par le gestionnaire de système. Il y a une série contrainte d'opérations qui peuvent être accomplies au sein d'un intervalle de temps – émission, écoute, attente, temporisation et acquittement – mais ces blocs modules de base simples peuvent être assemblés en des temps différents. Ces définitions sont flexibles, sous le contrôle du gestionnaire de système.

La durée des intervalles de temps dans un sous-réseau D est mise à une valeur spécifique par le gestionnaire de système lorsqu'une DLE rejoint le sous-réseau D. Une durée d'intervalle de temps de 10 ms à 12 ms est censée être typique. La durée d'intervalle de temps est configurable pour permettre:

- la coexistence optimisée avec d'autres systèmes, tels que d'autres sous-réseaux D conformes à la présente norme, à l'IEC 62591, et à l'IEC 62601;
- de plus longs intervalles de temps pour prendre en charge des temps prolongés d'attente de message;
- de plus courts intervalles de temps pour tirer pleinement profit de mises en œuvre optimisées;
- de plus longs intervalles de temps pour prendre en charge des DPDU ACK/NAK DPDU en série issues de plusieurs appareils (par exemple: duodiffusion, N-diffusion);
- de plus longs intervalles de temps pour prendre en charge des accès CSMA/CA de longue durée au début d'un intervalle de temps (par exemple: pour l'accès hiérarchisé par ordre de priorité à des intervalles de temps partagés);
- de plus longs intervalles de temps pour prendre en charge des périodes de saut lent de durée prolongée;
- des intervalles de temps pour la synchronisation avec d'autres sous-réseaux non conformes et faciliter l'inter-routage.

La Figure 56 montre le fonctionnement du saut de voie discrétisé.

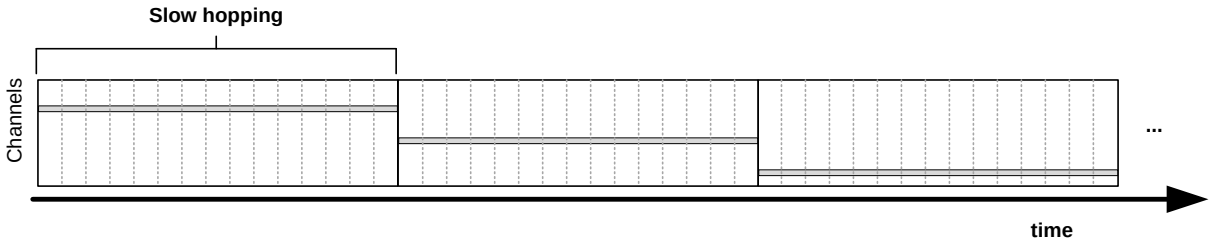
Figure 56 – Saut de voie discrétisé

Dans le saut de voie discrétisé, des intervalles de temps de saut de voie d'égale durée sont utilisés. Chaque intervalle de temps utilise une voie radio différente dans un modèle de saut de voie. Dans le saut de voie discrétisé, chaque intervalle de temps est prévu pour prendre en charge une seule transaction D constituée d'une DPDU Data et de son(ses) acquittement(s) de DPDU ACK/NAK.

La Figure 57 montre le fonctionnement du saut de voie lent.



Légende

Anglais	Français
Slow hopping	Saut lent
Channels	Voies
Time	Temps

Figure 57 – Saut de voie lent

Dans le saut de voie lent, un ensemble d'intervalles de temps contigus est groupé sur une seule voie radio réelle. Chaque ensemble d'intervalles de temps est traité comme une seule période de saut de voie lent; cependant, conformément à la Figure 57, les intervalles de temps sous-tendent encore le saut de voie lent. Les périodes de saut de voie lent sont configurables, habituellement sur une échelle d'environ 100 ms par saut à 400 ms par saut. De plus longues périodes de saut de voie lent, potentiellement d'une durée de plusieurs secondes, peuvent être utilisées pour prendre en charge des DLE avec un chronométrage imprécis et/ou des DLE qui ont temporairement perdu le contact avec le sous-réseau D. Pour permettre l'interopérabilité de DLE, toutes les DLE conformes à la présente norme doivent prendre en charge la configuration de la durée d'intervalle de temps, telle que désignée par le gestionnaire de système.

Dans certains domaines de réglementation, le saut de voie lent d'une radio dans la bande de 2,4 GHz selon l'IEEE 802.15.4 n'est pas autorisé à excéder 400 ms par saut. Cependant, dans d'autres domaines de réglementation, il n'y a aucune contrainte de ce type. La période de saut de voie lent est fixée par le gestionnaire de système, pas par la présente norme, mais son utilisation est contrainte dans chaque DLE par dlmo.CountryCode (9.1.15.6). Ainsi, cette contrainte de réglementation est explicitement appliquée où elle existe, comme d'autres contraintes de réglementation.

La structure, la durée, et l'assignation des intervalles de temps dans les périodes de saut de voie lent sont configurées par le gestionnaire de système, qui détermine le mode de fonctionnement et assigne l'utilisation des intervalles de temps. Cela fournit la flexibilité sans exiger une complexité excessive au sein des DLE, facilitant l'interfonctionnabilité des DLE.

La Figure 58 montre un mode de fonctionnement hybride.

Figure 58 – Fonctionnement hybride

Le fonctionnement hybride utilise de périodes de saut de voie discrétisé et de saut de voie lent dans une combinaison configurée. Par exemple, dans la Figure 58, un certain nombre d'intervalles de temps utilisant le saut de voie discrétisé est suivi d'une période de saut de voie lent.

9.1.7.2 Saut de voie

9.1.7.2.1 Généralités

Des communications de DL sont destinées à être distribuées à travers plusieurs voies radio. Le système utilise des modèles définis de saut de voie qui fournissent une séquence spécifique de voies pour la communication parmi des ensembles d'appareils. Le saut de voie commence à un décalage désigné dans le modèle de saut de voie, en continuant à travers le modèle séquentiellement jusqu'à la fin, puis en répétant le modèle indéfiniment.

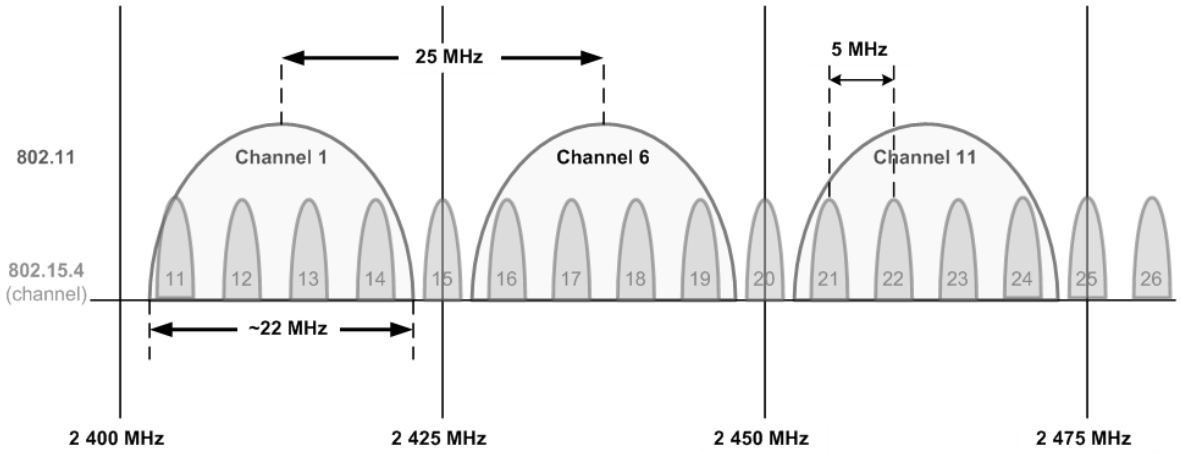
Les voies 11..26 DSSS selon l'IEEE 802.15.4 sont mappées à des numéros nominaux de voie 0..15 dans la présente norme. Cette vue d'ensemble leur fait référence par leur nomenclature de l'IEEE 802.15.4, comme voies 11..26.

La présente norme est basée sur les appareils qui utilisent une seule voie à la fois. Les radios multiples qui sont en copaquetage sont capables d'opérer plus d'instances de la PhLE et de la DLE simultanément sur différentes voies. Les détails d'une telle opération sur plusieurs voies ne sont pas spécifiés par la présente norme, mais une telle opération est intentionnellement prise en charge dans le nonce D.

9.1.7.2.2 Considérations de spectre radio

Pour la radiocommunication, la présente norme utilise les voies DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4. La couche physique de l'IEEE 802.15.4 (DSSS à 2,4 GHz) inclut seize voies, numérotées de 11 à 26.

La Figure 59 montre les seize voies DSSS selon l'IEEE 802.15.4 avec trois voies selon l'IEEE 802.11 communément utilisées qui se chevauchent.



Légende

Anglais	Français
802.15.4 (channel)	802.15.4 (voie)
Channel 1	Voie 1
Channel 6	Voie 6
Channel 11	Voie 11

NOTE Les numéros de voie montrés sont ceux de l'IEEE 802.11 et de l'IEEE 802.15.4, au lieu de ceux de la présente norme.

Figure 59 – Utilisation du spectre radio

A la Figure 59, les voies étroites 11..26 sont des voies DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4; ces voies sont essentiellement non superposées. Sont également montrées les voies plus larges 1, 6 et 11 de l'IEEE 802.11; ces trois voies sont des choix communs pour la communication selon l'IEEE 802.11 et chacune chevauche un certain nombre de voies DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4.

Comme la Figure 59 le montre, les voies 15, 20 et 25 DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4: ne chevauchent essentiellement aucune des trois voies communes de l'IEEE 802.11. Par conséquent, les voies 15, 20 et 25 DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4 peuvent raisonnablement être désignées comme étant des voies à saut de voie lent. Ces voies à saut de voie lent peuvent être configurées pour des besoins tels que la découverte de voisins. Par exemple, des informations relatives au sous-réseau D peuvent être annoncées par des routeurs de terrain sur des voies prédésignées à saut de voie lent, afin que toute DLE cherchant à rejoindre le sous-réseau D puisse limiter ses balayages actifs et passifs à ces voies lors de la découverte de routeurs de terrain limitrophes.

Cette illustration démontre comment des techniques de gestion de spectre prises en charge par la norme peuvent être utilisées pour rendre compte d'un scénario communément rencontré. Des configurations alternatives de WiFi, d'autres utilisateurs du spectre radio, et des restrictions de réglementation locales peuvent justifier des configurations alternatives dans les installations réelles.

La plupart des communications de DL sont destinées à être distribuées à travers toutes les voies (11..26) DSSS de l'IEEE 802.15.4 qui sont disponibles. La présente norme définit un certain nombre de modèles prédéfinis de saut de voie, chacun fournissant une séquence spécifique de voies à utiliser. D'autres modèles de saut de voie sont configurables par le gestionnaire de système. Les modèles de saut de voie qui sont prédéfinis dans la présente norme sont sélectionnés pour avoir certaines propriétés visant à réduire au maximum l'occurrence de collisions répétitives et non gérées avec des appareils sans fil contigus, en particulier des appareils IEEE 802.11.

9.1.7.2.3 Voie 26 et autres voies bloquées

La prise en charge de la voie 26 DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4 est facultative dans la présente norme, car certaines mises en œuvre peuvent rencontrer des restrictions réglementaires à la frontière supérieure de la bande. En outre, une DLE peut être empêchée d'utiliser d'autres voies en raison de restrictions réglementaires, mais pas pour d'autres raisons. Après la restriction ou une activation forcée pour le domaine de réglementation spécifié par dlmo.CountryCode (9.1.15.6), une liste de voies que la DLE prend en charge est rapportée au gestionnaire de système au cours du processus du rattachement de la DLE au sous-réseau D. Cela est accompli par le truchement de l'attribut dlmo.DeviceCapability.ChannelMap. Une DLE peut être configurée avec des liaisons qui utilisent de telles voies non prises en charge; dans ce cas, la DLE doit traiter ces liaisons comme étant non sélectionnables.

Sachant que la prise en charge de la voie 26 DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4 est facultative dans la norme, un gestionnaire de système peut raisonnablement limiter le fonctionnement de sous-réseau D aux voies 11..25 DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4. Les modèles de saut de voie prédéfinis par la présente norme incluent la voie 26 DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4, mais ces séquences prédéfinies de saut de voie sont conçues de sorte qu'elles puissent être raccourcies en excluant de la carte de voies dans chaque supertrame la voie 26 DSSS dans la bande de 2,4 GHz selon de l'IEEE 802.15.4.

9.1.7.2.4 Gestion de spectre et utilisation sélective de voie

Plusieurs méthodes sont disponibles pour limiter l'utilisation des voies radio occupées ou indésirables, y compris l'évaluation de voie libre (CCA), la gestion de spectre, et l'utilisation sélective de voie.

Des intervalles de temps sont normalement configurés pour vérifier l'existence d'une voie libre avant émission, en utilisant le mécanisme de la CCA défini dans l'IEEE 802.15.4. La CCA amène une DLE qui est sur le point d'initier une émission à abandonner un intervalle de temps si l'utilisation de la voie par une autre DLE est détectée avant l'émission. Voir 4.6.11, 9.1.9.4.3 et 9.1.9.4.8.

La gestion de spectre est une forme d'utilisation sélective de voie. La gestion de spectre limite la configuration de DL à un sous-ensemble de voies. Le fait de limiter le saut de voie lent aux voies 15, 20 et 25 de DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4 est un exemple de gestion de spectre. Un autre exemple est lorsqu'un gestionnaire de système bloque (place en liste noire) certaines voies radio qui ne fonctionnent pas bien ou sont interdites par la réglementation ou la politique locale, ou place en liste blanche des voies qui sont mandatées par la réglementation ou la politique locale. La gestion de spectre est traitée par le gestionnaire de système, par la manière dont il configure une DLE et la PhLE associée. Voir 9.1.8.4.7.

En plus, une DLE peut en toute autonomie traiter des liaisons d'émission sur des voies problématiques comme étant "idle", réduisant ainsi les interférences inutiles et l'énergie gaspillée sur des voies ayant des antécédents de connectivité médiocre. Il convient qu'une DLE sautant des liaisons de cette manière soumette périodiquement les liaisons à un essai afin de vérifier qu'elles restent problématiques. Une telle utilisation sélective de voie peut être désactivée par le gestionnaire de système sur une base liaison par liaison, par le biais de l'attribut dlmo.Link[ ].Type.SelectiveAllowed. Voir 9.4.3.7.2 et Tableau 182.

9.1.7.2.5 Modèles répétitifs de saut de voie

La présente norme prend en charge les modèles répétitifs prédéfinis de saut de voie de DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4:2011, qui doivent être pris en charge dans chaque DLE:

- pattern1 (modèle1): 19, 12, 20, 24, 16, 23, 18, 25, 14, 21, 11, 15, 22, 17, 13 (, 26);

- pattern 2: pattern1 dans l'ordre inverse;
- pattern3 (modèle3): 15, 20, 25 (destiné aux voies à saut de voie lent);
- pattern4 (modèle4): 25, 20, 15 (pattern3 dans l'ordre inverse);
- pattern5 (modèle5): 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 21. 22, 23, 24, 25 (, 26).

NOTE 1 La voie 26 de DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4 est montrée entre parenthèses, car elle est prise en charge par la présente norme, mais elle n'est pas nécessairement utilisée en raison de contraintes réglementaires communément rencontrées à la frontière de la bande. De la Figure 60 à la Figure 66 et de la Figure 70 à la Figure 74, les figures incluent pour la plupart la voie 26 bien que son utilisation soit généralement masquée par la supertrame qui utilise la séquence de sauts.

NOTE 2 Dans la présente norme, les voies sont numérotées 0..15, conformément à la description en 9.4.3.2. Cependant, pour des besoins tutoriaux et pour faciliter la comparaison avec l'IEEE 802.11 (WiFi) et d'autres utilisations de la même bande de fréquences, les modèles de saut de voie sont exprimés par leurs numéros de voies DSSS selon l'IEEE 802.15.4.

NOTE 3 Pattern5, qui est basé sur la IEC 62591, vise à faciliter la coexistence avec la norme IEC en question.

Le gestionnaire de système peut configurer une DLE pour utiliser l'un quelconque de ces modèles de saut de voie pour le saut de voie discrétisé, le saut de voie lent, ou le saut de voie hybride.

Une voie ou un ensemble quelconque de voies dans un modèle de saut de voie peut être déactivé(e) (masqué(e)) par la configuration de la supertrame qui utilise le modèle de saut de voie, avec l'effet de raccourcir le modèle de saut de voie pour la gestion de spectre.

Les modèles prédéfinis de saut de voie de la présente norme sont conçus pour avoir certaines propriétés, indépendamment du fait que la voie 26 soit incluse dans le modèle ou pas. Spécifiquement, des voies successives dans la plupart des modèles prédéfinis de saut de voie sont séparées d'au moins 15 MHz – trois voies DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4. Cette propriété atténue les effets des interférences et de l'évanouissement par trajets multiples dans les environnements industriels.

Comme montré dans l'exemple à la Figure 60, le modèle prédéfini pattern1 de saut de voie est configuré de façon que des sauts consécutifs ne chevauchent pas la même voie selon l'IEEE 802.11.

Time	Temps

Figure 60 – Modèle prédéfini de saut de voie 1

Au moins trois voies séparent chaque saut consécutif dans le modèle pattern1, conduisant à des décalages de fréquence d'au moins 20 MHz. Lorsque des répétitions de tentative se produisent en des sauts consécutifs, elles ne rencontreront pas ou ne causeront pas d'interférences dans la même voie IEEE 802.11.

Pour de groupes de DLE différents, il est souhaitable que les DLE sautent sur des modèles sans interférence.

Chaque modèle de saut de voie est combiné à un décalage de modèle de saut. Si le décalage de modèle de saut est zéro, le modèle spécifié de saut de voie de ligne de base est utilisé. Si le décalage de modèle de saut est 5, un décalage de 5 est utilisé pour indexer le modèle de saut de voie de ligne de base. La Figure 61 montre comment deux groupes de DLE avec des décalages de modèle de saut différents dans le modèle de saut de voie pattern1 peuvent être utilisés ensemble sans se disputer en même temps la même voie radio.

Channels	Voies
Time	Temps

NOTE Les numéros de voie montrés sont ceux de l'IEEE 802.15.4, au lieu de ceux de la présente norme.

Figure 61 – Deux groupes de DLE avec différents décalages de modèle de saut de voie

Le décalage de saut de voie d'une supertrame est déterminé indirectement à partir de l'attribut dlmo.Superframe[ ].ChBirth, appelé simplement ChBirth, qui donne la référence de début du modèle de saut de voie au temps TAI zéro. Cela fournit une séquence de saut de voie de ligne de base. Les décalages issus d'une séquence de saut de voie de ligne de base, spécifiés dans l'attribut de dlmo.Link[ ].ChOffset, appelé simplement ChOffset, sont tels que décrits ici et montrés à la Figure 61. Alors que le même résultat est réalisable en utilisant

ChBirth ou ChOffset, il convient de noter que les deux attributs sont essentiellement inverses. Les détails des calculs pour le décalage de modèle de saut de voie sont donnés en 9.4.3.5.3.

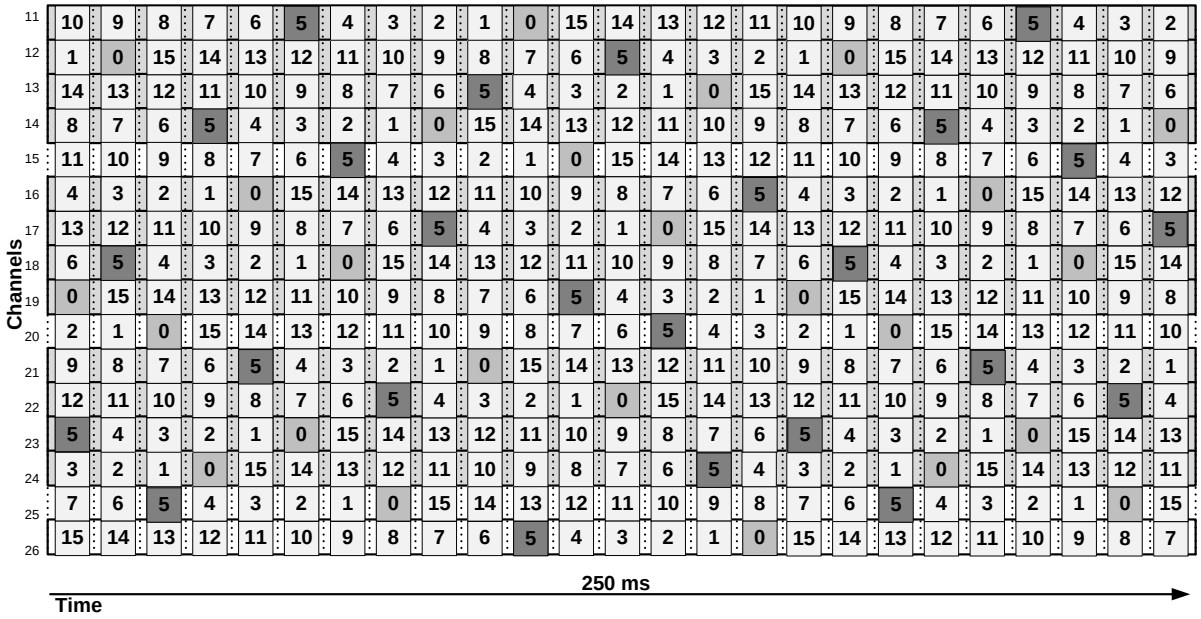
A la Figure 61, les cases numérotées 0 représentent un groupe de DLE utilisant le modèle prédéfini de saut de voie, pattern1; son modèle répétitif de saut de voie (avec la nomenclature de l'IEEE 802.15.4) est:

19, 12, 20, 24, 16, 23, 18, 25, 14, 21, 11, 15, 22, 17, 13, 26

Les cases numérotées 5 à la Figure 61 représentent un autre groupe de DLE utilisant le modèle de saut de voie pattern1 avec un décalage de modèle de saut de voie de 5. Un décalage de modèle de saut de voie de 5 a l'effet de tourner essentiellement la séquence de saut de voie vers la gauche de 5, conduisant à une séquence répétitive de saut de voie (avec la nomenclature de l'EEE 802.15.4) de:

23, 18, 25, 14, 21, 11, 15, 22, 17, 13, 26, 19, 12, 20, 24, 16

La Figure 62 étend le principe, montrant comment des décalages différents de modèle de saut de voie peuvent être utilisés pour un plus grand nombre de DLE.



Légende

Anglais	Français
Channels	Voies

NOTE Les numéros de voie montrés sont ceux de l'IEEE 802.15.4, au lieu de ceux de la présente norme.

Figure 62 – Pattern1 entrelacé de saut de voie avec seize différents décalages de modèle de saut de voie

A la Figure 62, seize voies sont disponibles. Par conséquent, le nombre maximal des DLE qui peuvent utiliser le pattern1 de saut de voie est 16, chacune avec un différent décalage de modèle de saut de voie de 0..15.

Comme montré à la Figure 62, un modèle donné de saut de voie peut être utilisé simultanément en assignant des décalages différents de modèle de saut de voie à diverses DLE, à diverses supertrames (voir 9.1.8) ou à divers groupes de DLE. A titre de simple exemple, chacun de deux groupes de DLE peut utiliser le même modèle de saut de voie avec différents décalages de modèle de saut de voie et, ainsi, les deux groupes peuvent partager le même spectre radio sans interférence mutuelle. Les groupes peuvent être situés dans le même sous-réseau D ou dans des sous-réseaux D différents; tant qu'ils partagent de façon

exacte une durée cohérente d'intervalle de temps et un sens synchronisé du temps, leurs modèles de saut de voie peuvent être entrelacés comme montré à la Figure 62.

Les cinq modèles prédéfinis de saut de voies doivent exister dans chaque DLE conforme à la présente norme. Cela permet à des routeurs d'annoncer avec concision le modèle de saut de voie qui est utilisé et le décalage de modèle de saut de voie courant, lorsqu'il est l'un de ces modèles. La présente norme prend également en charge les modèle personnalisés de saut de voie dans chaque DLE, en plus des cinq modèles prédéfinis, et le gestionnaire de système peut ainsi configurer des modèles complémentaires de saut de voie utilisables par les DLE déjà rattachées.

Chaque modèle de saut de voie prédéfini a la même taille que le nombre de voies utilisées. Ainsi, par exemple, le pattern1 de saut de voie utilise seize voies et a donc une longueur de seize sauts. Cette propriété permet au modèle de saut de voie d'être entrelacé à différents décalages, comme montré à la Figure 62.

NOTE 4 Sachant que certaines DLE pourraient ne pas prendre en charge la voie 26, qui est facultative, des systèmes limitent souvent le fonctionnement à quinze voies (11..25) avec essentiellement le même résultat.

9.1.7.2.6 Utilisation d'intervalle de temps et de voie

Un système doit utiliser le saut de voie discrétisé, le saut de voie lent ou une combinaison hybride des deux.

La Figure 63 montre l'utilisation du saut de voie discrétisé. Chaque intervalle de temps est utilisé avec la prochaine voie successive dans le modèle de saut de voie.

Figure 63 – Exemple d'allocation d'intervalles de temps pour le saut de voie discrétisé

La partie inférieure de la Figure 63 montre que le modèle de saut de voie peut être utilisé de façon répétitive au fil du temps. L'utilisation de la taille de supertrame et de l'intervalle de temps par la DLE n'est pas nécessairement liée à des constructions de DL cycliques inférieures telles que les modèles de saut de voies ou les intervalles d'alignement d'intervalles de temps de 250 ms. (V oir 9.1.9.1.3 pour un débat relatif aux intervalles d'alignement.)

La Figure 64 montre l'utilisation du saut de voie lent. Chaque voie est utilisée sur plusieurs intervalles de temps.

NOTE Les numéros de voie montrés sont ceux de l'IEEE 802.15.4, au lieu de ceux de la présente norme.

Figure 64 – Exemple d'allocation d'intervalles de temps pour le saut de voie lent

Les périodes de saut de voie lent peuvent s'étendre sur un intervalle d'alignement d'intervalles de temps de 250 ms. (Voir 9.1.9.1.3 pour un débat relatif à l'alignement des intervalles de temps.) Dans de tels cas, les périodes de saut de voie lent ne sont pas interrompues par des périodes "idle" c'est-à-dire, si une période de saut de voie lent traverse

la frontière d'un intervalle d'alignement d'intervalles de temps, la radio ne s'éteint pas au cours de la période "idle" autrement exigée.

La Figure 65 montre un système hybride qui combine le saut de voie discrétisé et le saut de voie lent. Dans cet exemple, au sein de chaque intervalle d'alignement de 250 ms, plusieurs intervalles de temps, chacun assigné à une voie différente, sont suivis d'une période saut de voie lent sur une seule voie.

Figure 65 – Mode hybride avec saut de voie discrétisé et saut de voie lent

L'ordre dans lequel le saut de voie discrétisé et le saut de voie lent peuvent être combinés est flexible; les périodes de saut de voie lent peuvent ne pas suivre des intervalles de temps de saut de voie discrétisé. Plutôt, les deux peuvent être utilisés dans n'importe quelle combinaison raisonnable. Par exemple, la Figure 66 montre une configuration exemplaire, où une DLE commute entre le saut de voie lent et le saut de voie discrétisé.

Figure 66 – Combinaison de saut de voie lent et de saut de voie discrétisé

Dans l'exemple de la Figure 66, le saut de voie discrétisé est utilisé lorsque des intervalles de temps de communication en diffusion/multidiffusion, duodiffusion/N-diffusion ou à base de conflits sont explicitement alloués. Lorsqu'une DLE n'a pas une allocation d'intervalle de temps, elle se met à l'écoute sur la voie 20, qui facilite la découverte de voisins. (Voir 9.1.9.4.7 pour un débat relatif à la duodiffusion/N-diffusion).

9.1.8 Supertrames

9.1.8.1 Généralités

Une supertrame est une séquence répétitive d'intervalles de temps. Le nombre d'intervalles de temps dans chaque cycle de supertrame (sa taille) et la durée de chacun de ces intervalles de temps déterminent la période du cycle de supertrame. Cela établit la structure du programme de communication pour les DLE qui utilisent la supertrame. Par exemple, une supertrame qui accomplit un cycle toutes les 500 ms permettra à chaque DLE qui utilise un seul intervalle de temps dans la supertrame de communiquer toutes les 500 ms.

Lorsqu'une supertrame est créée, il lui est donné un ID de supertrame. La Figure 67 montre comment des DLE peuvent communiquer dans un exemple de supertrame à trois intervalles de temps.

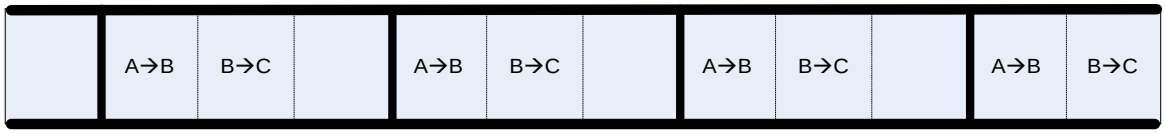

Figure 67 – Exemple de supertrame à trois intervalles de temps et comment elle se répète

A la Figure 67, la DLE A peut communiquer avec la DLE B pendant le premier intervalle de temps de chaque cycle de supertrame. La DLE B peut communiquer avec la DLE C pendant le deuxième intervalle de temps de chaque cycle. Le troisième intervalle de temps de chaque cycle est non assigné ("idle"). Le cycle se répète tous les trois intervalles de temps.

La Figure 67 montre des cycles de temporisation et des liaisons de communication au sein de la même structure, qui est une vue conceptuelle. Les cycles de supertrame et les liaisons de communication sont représentés sous la forme d'objets configurables distincts, mais connexes, au sein de la DLE. La Figure 68 montre cette structure de données, clarifiant la distinction entre supertrames et liaisons, pour la même supertrame à trois intervalles qu'à la Figure 67.

Figure 68 – Supertrames et liaisons

Comme montré à la Figure 68, les supertrames se réfèrent à un ensemble d'intervalles de temps. Les liaisons se réfèrent à l'utilisation des intervalles de temps de supertrame pour la communication entre une paire spécifique de DLE. Un intervalle de temps est une période de temps. Une supertrame est un programme cyclique d'intervalles de temps et de voies associées. Une liaison décrit une activité spécifique qui se répète au sein d'un programme cyclique de supertrames.

Le gestionnaire de système configure des jeux concordants de liaisons parmi un ensemble de DLE qui communiquent les unes avec les autres. Par exemple, une liaison sur la DLE A peut être configurée pour émettre des DPDU Data vers la DLE B sur un cycle particulier de supertrame. Sur le même cycle, il convient que la DLE B ait une liaison qui est configurée pour être à l'écoute afin de détecter une DPDU Data entrante. Ces deux liaisons sont

concordantes en ce sens que le gestionnaire de système a configuré ces deux opérations connexes de façon qu'elles se produisent simultanément sur la même voie.

Plusieurs paramètres de performance sont déterminés par la période de supertrame et par la manière dont les liaisons sont assignées aux supertrames. En général, les supertrames de plus courte période conduisent à une latence plus faible des DPDU Data et à une largeur de bande numérique accrue, aux dépens de la consommation accrue d'énergie et d'une allocation plus concentrée de la largeur de bande numérique. Les supertrames de plus longue période conduisent généralement à une latence plus élevée et à une largeur de bande numérique plus petite, mais avec une consommation d'énergie réduite et une allocation moins concentrée de largeur de bande numérique. Il convient d'envisager soigneusement ces compromis pour déterminer la période de supertrame et la densité de liaison au sein d'une supertrame.

Un DLE donnée peut être configurée pour utiliser simultanément plusieurs supertrames de différentes tailles. Une liaison avec un seul intervalle de temps au sein d'une supertrame de la longueur L intervalles de temps se répète deux fois plus fréquemment qu'une semblable liaison à un seul intervalle de temps au sein d'une supertrame de longueur $2 \times L$ intervalles de temps, permettant ainsi la prise en charge de deux fois la sortie par seconde.

Une DLE peut utiliser simultanément plus d'une supertrame. En outre, les DLE dans un sous-réseau D n'ont pas toutes besoin de participer à chaque supertrame. En configurant une DLE pour participer à plusieurs supertrames simultanées de longueurs différentes, il est possible d'établir plusieurs programmes de communication avec des périodes inégales qui opèrent toutes simultanément.

Les supertrames sont numérotées pour l'identification, mais la portée de ces numéros de supertrame est limitée à la DLE où la supertrame est utilisée. Sachant que la portée d'un numéro de supertrame est une seule DLE, une DLE voisine peut utiliser le même numéro de supertrame pour un besoin complètement différent. Les supertrames peuvent être ajoutées, retirées, activées et désactivées pendant que le sous-réseau D fonctionne.

La Figure 69 montre comment des intervalles de temps dans des supertrames différentes sont alignés, bien que les supertrames puissent accomplir un cycle à des fréquences indépendantes.

Légende

Anglais	Français
Superframe 0 5 slots	Supertrame 0 Cinq intervalles
Superframe 1 3 slots	Supertrame 1 Trois intervalles

Figure 69 – Plusieurs supertrames avec intervalles de temps alignés

NOTE L'alignement d'intervalle de temps est un résultat de la définition de tous les intervalles de temps comme ayant des durées identiques et du réalignement des intervalles de temps au temps TAI toutes les 250 ms (voir 9.1.9.1.3). Les supertrames avec des intervalles de temps de durées différentes sont utilisables simultanément au sein d'un sous-réseau D. Cependant, les concepteurs de la présente norme n'ont considéré que des configurations dans lesquelles une seule durée d'intervalle de temps est utilisée lors du fonctionnement d'un sous-réseau D donné (modifiable à la réinitialisation du sous-réseau D).

Une DLE avec plusieurs liaisons dans un intervalle de temps peut rencontrer des collisions de liaison lorsque deux liaisons ou plus de deux liaisons coïncident. Pour adresser de telles

situations, chaque liaison a une priorité assignée. Une priorité de liaison ayant un numéro plus élevé signifie que la liaison a la préséance sur une liaison ayant une priorité de numéro plus faible. En cas de collision de liaison, la liaison avec la priorité de numéro plus élevé est utilisée. Si deux liaisons ont la même priorité, une priorité de supertrame est utilisée. Voir 9.1.8.5.

En plus de la priorité de liaison, chaque DPDU Data a une priorité assignée par sa DLE d'origine. Une fois qu'une liaison est sélectionnée sur la base de la priorité de liaison, la priorité de la DPDU Data est utilisée pour pondérer l'importance relative de toutes les DPDU Data placées en file d'attente qui peuvent utiliser la liaison.

9.1.8.2 Repli exponentiel

Des liaisons peuvent être partagées ou dédiées. Du côté récepteur, il n'y a aucune différence structurelle entre liaisons partagées vs. dédiées. Du côté initiateur de transaction, un bit de repli exponentiel dans la spécification de la configuration de liaison indique si la liaison est partagée ou dédiée. Si une liaison est partagée, comme l'indique le fait que le bit de repli exponentiel de la liaison soit mis (à 1), l'initiateur de transaction doit utiliser le repli exponentiel pour des répétitions de tentative utilisant cette liaison. Si une liaison est dédiée, comme l'indique le fait que le bit de repli exponentiel de la liaison soit réinitialisé (à 0), l'initiateur de transaction ne doit pas utiliser le repli exponentiel dans la liaison en question.

Il est possible, et parfois raisonnable, pour un gestionnaire de système de configurer plusieurs DLE pour qu'elles émettent en même temps et sur la même voie radio, sans positionner un bit de repli exponentiel dans les liaisons applicables. Le terme "liaison dédiée" est utilisé simplement pour indiquer que le repli exponentiel n'est pas appliqué à de telles liaisons.

Le repli exponentiel doit être appliqué lorsque, et seulement lorsque, une DLE émet une DPDU Data en monodiffusion sur une liaison partagée et ne reçoit pas une DPDU ACK/NAK exempte d'erreur, ce qui implique une possible collision. Une émission en monodiffusion qui est prématurément arrêtée en raison de la détection de CCA doit être traitée comme étant l'équivalent d'une émission infructueuse dans le contexte du repli exponentiel. Le repli exponentiel vise à résoudre de telles collisions. Le repli exponentiel doit opérer sur une base voisin par voisin, appliquée à toutes les DPDU Data dans la file d'attente de message adressée au voisin en question, quelle que soit la priorité de la DPDU Data.

Pour chaque voisin, la DLE maintient un exposant de repli et un compteur de repli, appelés BackoffExponent[Neighbor] et BackoffCounter[Neighbor] dans la présente norme. BackoffExponent[ ] et BackoffCounter[ ] sont des parties internes à une mise en œuvre qui sont inaccessibles, et donc ne sont pas incluses dans le modèle d'objet de DL.

BackoffExponent[Neighbor] et BackoffCounter[Neighbor] sont mis à zéro chaque fois qu'une DPDU ACK/NAK est reçue pour une DPDU Data en monodiffusion qui avait été envoyée vers un voisin particulier dans une liaison partagée.

Une valeur de BackoffCounter[Neighbor] égale à zéro permet à la DLE d'envoyer une DPDU Data à la prochaine occasion d'émission de liaison partagée. A la suite d'une émission non réussie vers le voisin dans une liaison partagée, si la valeur courante de BackoffExponent[Neighbor] est inférieure à dlmo.MaxBackoffExp, la DLE incrémente BackoffExponent[Neighbor] et règle BackoffCounter[Neighbor] en sélectionnant une valeur uniformément dans l'intervalle $0..2^{(\text{BackoffExponent[Neighbor]})}-1$. Pour chaque occasion d'émission dans une liaison partagée, BackoffCounter[Neighbor] est décrémenté jusqu'à ce qu'il atteigne zéro. Si une occasion d'émission est dans une liaison dédiée (aucun indicateur de repli exponentiel), la DLE peut utiliser la liaison, quelle que soit la valeur de BackoffCounter[Neighbor]. L'attribut dlmo.MaxBackoffExp limite la valeur maximale de BackoffExponent[Neighbor].

Le comportement de répétitions de tentative peut être configuré par le gestionnaire de système. Les attributs de DLMO qui se rapportent aux répétitions de tentative comprennent:

- dlmo.MaxBackoffExp. La valeur maximale pour BackoffExponent[Neighbor].
- dlmo.MaxLifetime et dlmo.Graph.MaxLifetime: durée de vie maximale d'une DPDU Data. Une DPDU Data qui a été transmise doit être supprimée si elle est maintenue dans une file d'attente de message de DLE plus longtemps que MaxLifetime. L'attribut dlmo.MaxLifetime fournit une valeur par défaut pour la DLE. Une valeur non vide pour dlmo.Graph[ ].MaxLifetime spécifie que dlmo.MaxLifetime doit être neutralisé et mis à la valeur spécifiée pour des DPDU Data suivant ce graphe particulier.
- Le fonctionnement du repli exponentiel qui est illustré dans le pseudocode suivant:

```
// Pour chaque voisin, indépendamment
BExp[Nei] = 0; // BackoffExponent[Neighbor] en texte
BCnt[Nei] = 0; // BackoffCounter[Neighbor] en texte
Pour chaque intervalle de temps (
Si (la liaison d'émission et la DPDU Data correspondent) (// Voir 9.1.8.5
   Si (liaison de repli non exponentielle) (
      // Liaison dédiée
      Tentative d'émission de DPDU Data utilisant une liaison;
      Si (l'émission a réussi) supprimer la DPDU Data de la file d'attente;
      )
   Autre (
      // liaison partagée
      Si (BCnt[Nei] > 0) BCnt[Nei]--
      Autre (
         Tentative d'émission de DPDU Data en liaison;
         Si (l'émission a réussi) (
            Supprimer la DPDU Data de la file d'attente;
            BExp[Nei]=0;
            BCnt[Nei]=0;
            )
         Autre (
            // L'émission a échoué; repli exponentiel
            Si (BExp[Nei] < MaxBackoffExp) BExp[Nei]++;
             BCnt[Nei] = Random (0, 2^(BExp[Nei]-1));
            )
         )
      )
   )
Delete all messages beyond MaxLifetime;
If (no queued Data DPDU for neighbor) (BCnt[Nei]=0; BExp[Nei]=0;)
```

NOTE Comme décrit en 9.1.8.5, il est possible qu'une liaison soit configurée comme liaison d'émission/réception (T/R), qui est une représentation comprimée d'une liaison d'émission et liaison de réception appariées. Logiquement, les liaisons T/R sont traitées comme étant deux liaisons indépendantes.

9.1.8.3 Utilisation de voie de supertrame

Des intervalles de temps dans une supertrame sont associés à un modèle de saut de voie lent ou discrétisé, ainsi qu'à un décalage dans le modèle en question.

De la perspective de chaque DLE utilisant une supertrame, il y a un décalage de modèle de saut de voie de ligne de base, qui peut varier d'une DLE à une autre DLE et qui peut être neutralisé avec un décalage alternatif appliqué à une liaison ou à un ensemble de liaisons au sein d'une supertrame.

Une transaction D en monodiffusion donnée se produit sur une seule voie, avec la DPDU Data et la/les DPDU ACK/NAK DPDU toutes émises sur la même voie.

Une supertrame n'est pas limitée à une seule voie à la fois; au contraire, une supertrame a une structure bidimensionnelle indiquant le temps et la voie, comme cela avait été précédemment montré à la Figure 62 (voir 9.1.7.2.5).

La Figure 62 montre une supertrame, avec le temps sur l'axe horizontal et la voie sur l'axe vertical. La supertrame recouvre toutes les voies sur la longueur (durée) de cette supertrame. Comme montré à la Figure 62, seize DLE peuvent utiliser seize décalages différents à partir

du modèle de saut de voie A; la supertrame englobe toutes les assignations de voie pour l'ensemble de tous les intervalles de temps de supertrame.

Le décalage de voie par défaut peut être différent pour l'émission vs. la réception et peut varier par liaison.

La période du modèle de saut de voie n'est pas nécessairement liée à la longueur de la supertrame. En se référant à la Figure 62, une supertrame pourrait être configurée comme ayant une longueur de 25 intervalles de temps, bien que le modèle de saut de voie A n'ait qu'une longueur de 16 sauts.

Pour la diversité de fréquence, la longueur de supertrame et la taille de modèle de saut de voie peuvent être configurées pour être des nombres premiers l'une par rapport à l'autre, c'est-à-dire, sans facteurs communs. Comme contre-exemple, considérer une configuration dans laquelle la longueur de supertrame est 25 intervalles de temps, avec un modèle de saut de voie se répétant sur un cycle de 15 voies, conduisant à un programme de supertrame où seules 3 des 15 voies disponibles sont utilisées. Un tel plan peut provoquer des problèmes de réglementation dans les situations où l'utilisation de toutes les voies est exigée par chaque appareil.

9.1.8.4 Organisation des supertrames

9.1.8.4.1 Généralités

Les deux types généraux de supertrame sont pris en charge:

- Saut de voie discrétisé, qui fait une utilisation optimale de la largeur de bande numérique disponible et prend en charge les routeurs alimentés par batteries.
- Saut de voie lent, destiné à des routeurs avec de l'énergie disponible pour faire fonctionner leurs récepteurs sans interruption pendant une période donnée. Le saut de voie lent permet à des DLE voisines de fonctionner avec exigences relatives à la synchronisation du temps moins contraignantes, en particulier au cours du processus de découverte de voisins.

Des configurations hybrides peuvent être arrangées en combinant les supertrames, par exemple, une discrétisée et une lente. Les sauts de voie discrétisé et lent seront débattus séparément, suivi d'un certain nombre d'exemples de configurations hybrides.

NOTE Sur le marché, le saut de voie lent est parfois appelé CSMA, et le saut de voie discrétisé AMRT. Ces termes ne sont pas utilisés dans la présente norme, excepté dans la mesure où le CSMA/CA est pris en charge par la norme dans un sens littéral. (voir 9.1.9.4.8.) Le saut de voie lent est construit sur la base de l'AMRT, le saut de voie discrétisé inclut des aspects du CSMA. Le concepteur de solution est libre de mélanger les approches.

9.1.8.4.2 Portée de supertrame

Les supertrames sont généralement débattues comme étant des abstractions qui enjambent plusieurs DLE. Néanmoins, alors que la supertrame peut être conceptualisée au niveau du sous-réseau D, la portée de la structure de données de supertrame est limitée à chaque DLE. Une supertrame est instanciée comme une structure de données sur une seule DLE qui commande indépendamment son diagramme d'états de DLE. Les définitions de supertrame d'une DLE ont besoin de se rapporter à celles de ses voisins afin que les DLE communiquent en même temps. Des définitions de supertrame au sein de chaque DLE sont numérotées, mais cette numérotation est nécessaire seulement au DMAP pour des opérations de lecture/écriture de table et à d'autres objets et attributs au sein de la DLE qui se réfèrent à la supertrame.

Une supertrame peut être contrastée avec une portée de graphe de routage. Un ID de graphe, à la différence d'un ID de supertrame, est transporté dans un en-tête DROUT d'une DPDU Data, et un ID de graphe doit être cohérent et unique dans toutes les DLE qui utilisent le graphe. Aucune contrainte de ce type ne s'applique à une supertrame.

9.1.8.4.3 Blocs de capacité à base de conflits

Les routeurs alimentés par secteur peuvent raisonnablement actionner leurs récepteurs en permanence. En tant que supertrame ayant la priorité la plus basse, un tel routeur peut prendre en charge une supertrame constituée, partiellement ou entièrement, de liaisons de réception. Les voisins du routeur peuvent maintenir les liaisons d'émission correspondantes partagées vers le routeur. Une telle configuration conduit à des blocs de largeur de bande numérique à base de conflits disponibles pour les voisins des routeurs. Le saut de voie lent ou le saut de voie discrétisé peut être utilisé dans une supertrame de ce type. Le décalage de saut de voie peut être sélectionné pour éviter des collisions entre les liaisons dédiées vs. un inventaire général des liaisons partagées.

9.1.8.4.4 Saut de voie discrétisé

Le saut de voie discrétisé utilise des intervalles de temps de supertrame de saut de voie d'égale durée. Chaque intervalle de temps de supertrame utilise une voie radio différente dans un modèle de saut. Dans le saut de voie discrétisé, chaque intervalle de temps de supertrame est prévu pour prendre en charge une seule transaction D, y compris une DPDU Data et sa/ses DPDU ACK/NAK.

La Figure 70 montre une supertrame de saut de voie discrétisé à partir de la perspective d'une DLE, qui peut être un routeur.

NOTE Les numéros de voie montrés sont ceux de l'IEEE 802.11 et de l'IEEE 802.15.4, au lieu de ceux de la présente norme.

Figure 70 – Exemple de supertrame pour saut de voie discrétisé

Dans cet exemple, la supertrame a une longueur de 1,5 s. Des intervalles de temps avec des assignations de liaison sont représentés avec des cercles (liaisons dédiées) et des losanges (liaisons partagées). Comme le montre la Figure 70, à partir de la perspective d'une seule DLE, de nombreux intervalles de temps de supertrame pourraient être laissés "idle". Les intervalles de temps avec assignations de liaison se répètent à un intervalle fixe défini par la longueur de supertrame.

9.1.8.4.5 Saut de voie lent

Dans le saut de voie lent, un ensemble d'intervalles de temps de supertrame contigus est groupé sur une seule voie radio. Chacun de tels ensembles d'intervalles de temps de supertrame est traité comme une seule période de saut de voie lent.

La Figure 71 montre le saut de voie lent.

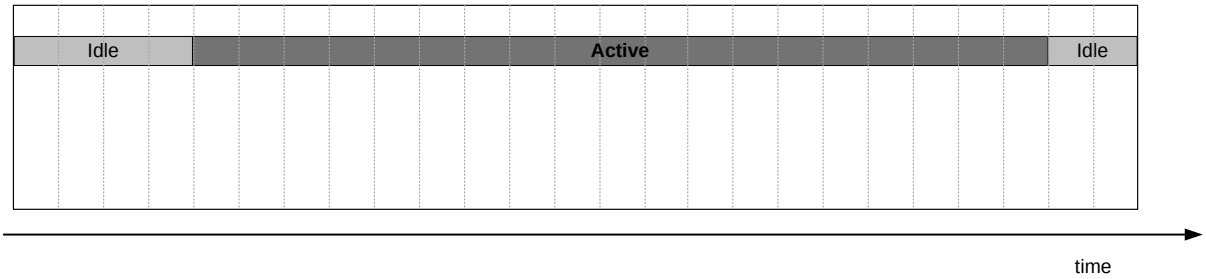
Figure 71 – Exemple de supertrame pour saut de voie lent

Les intervalles de temps dans une supertrame de saut de voie lent sont généralement partagés, fournissant une largeur de bande de voie à base de conflits instantanée, à la demande, aux voisins immédiats d'un routeur.

La Figure 72 montre les principales composantes d'une supertrame de saut de voie lent.



Légende

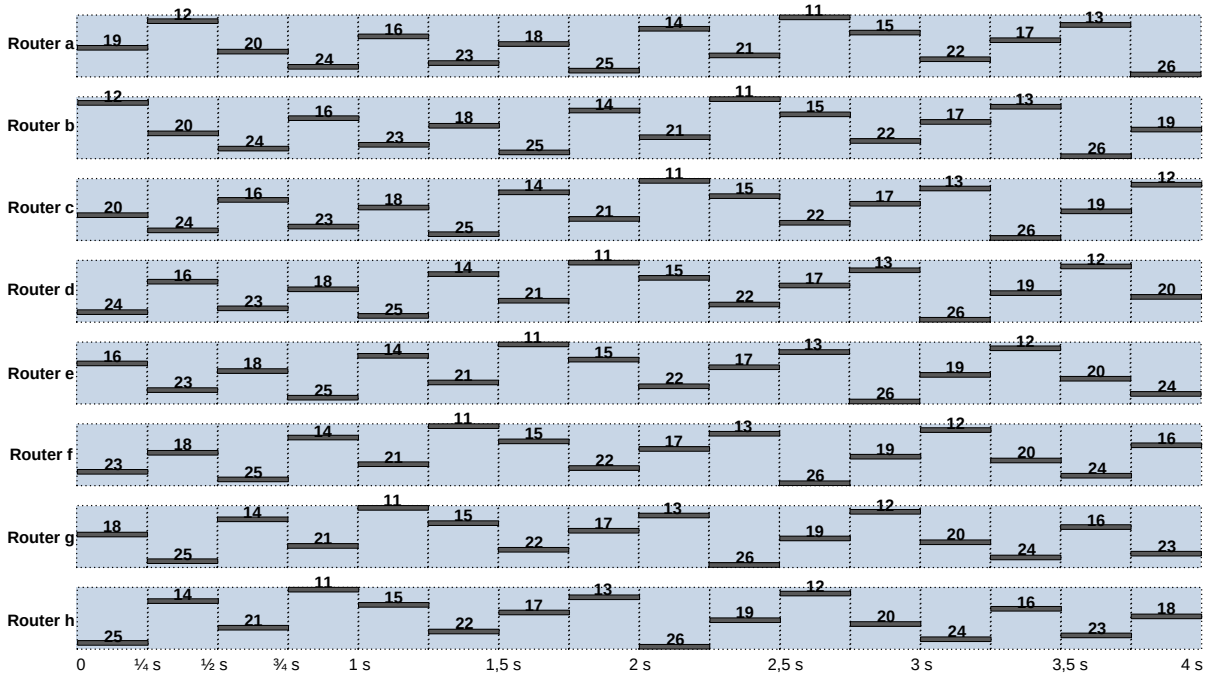
Anglais	Français
Idle	Inactive
Active	Active
Time	Temps

Figure 72 – Composantes d'une supertrame de saut de voie lent

Une période de saut de voie lent de ligne de base a une durée fixe, avec un nombre fixe d'intervalles de temps "idle" (qui peuvent être zéro) au début et à la fin du saut. L'exemple d'une période de saut de voie lent montré à la Figure 72 est composé de 25 intervalles de temps, y compris quatre intervalles de temps inactifs au début, dix-neuf intervalles de temps actifs au milieu, et deux intervalles de temps inactifs à la fin. Les intervalles de temps inactifs visent à prendre en charge des configurations hybrides où des supertrames de saut de voie lent sont appariées à des supertrames de saut de voie discrétisé, avec les intervalles de temps de saut de voie discrétisé programmés pour être utilisés pendant les périodes inactives de la supertrame de saut de voie lent.

NOTE 1 Les périodes inactives telles que décrites ici sont configurables en appariant les phases de supertrame et de saut de voie, et en définissant les liaisons qui concordent avec la plage active souhaitée.

Les sauts ne sont pas nécessairement effectués ensemble, par tous les routeurs d'une zone commune. La Figure 73 montre le nombre de routeurs disjoints les uns des autres auxquels il est possible d'assigner des modèles de sauts lents, évitant ainsi les collisions. Cela n'implique en aucune manière que tous les routeurs d'un système utilisent des voies de communication disjointes.



Légende

Anglais	Français
Router	Routeur

NOTE Les numéros de voie montrés sont ceux de l'IEEE 802.15.4, au lieu de ceux de la présente norme.

Figure 73 – Exemple de configuration pour éviter les collisions entre routeurs

Chaque routeur peut utiliser un décalage différent dans le modèle de saut de voie. Avec un modèle de saut de 16 voies, chacun d'un maximum de 16 routeurs peut être configuré avec un décalage différent dans le modèle et, donc, deux routeurs quelconques n'utilisent pas la même voie en même temps.

NOTE 2 Bien que la Figure 73 prétende montrer comment il est possible d'éviter les collisions par des assignations disjointes de modèles de sauts de voies, un système réel exige au moins un modèle de saut de voie partagé via lequel les routeurs peuvent communiquer entre eux.

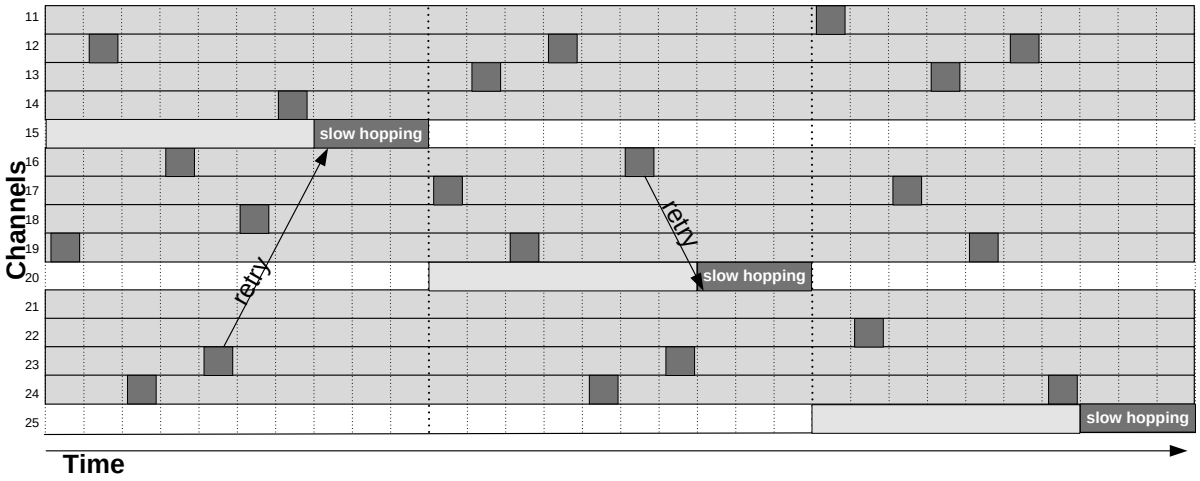
Voir 9.4.3.5.5 pour plus de détails relatifs au saut de voie lent.

9.1.8.4.6 Configurations hybrides de saut de voie

Les configurations hybrides peuvent utiliser des combinaisons de supertrames de saut de voie discrétisé et de saut de voie lent.

Des configurations hybrides sont habituellement arrangées de sorte que des liaisons de saut de voie discrétisé soient allouées pour la messagerie périodique programmée. Cela peut laisser des blocs de capacité de saut de voie lent légèrement utilisés, disponibles sur une base de conflits, pour des utilisations moins prévisibles telles que des alarmes et des répétitions de tentative.

L'exemple à la Figure 74 montre comment les supertrames de saut de voie discrétisé et de saut de voie lent peuvent être combinées.



Légende

NOTE Les numéros de voie montrés sont ceux de l'IEEE 802.15.4, au lieu de ceux de la présente norme.

Figure 74 – Configuration hybride

A la Figure 74, le saut de voie discrétisé a été couché sur un arrière-plan de saut de voie lent. Les périodes de saut lent remplissent le temps entre les ensembles périodiques d'intervalles de temps dédiés de supertrames.

Dans cette configuration, si une émission tentée dans un intervalle de temps dédié échoue, la période de saut de voie lent qui suit peut être utilisée pour répéter la tentative d'émission. A la Figure 74, deux des intervalles de temps de supertrame sont montrés avec des répétitions de tentative sur des voies différentes au cours de la période suivante de saut de voie lent.

9.1.8.4.7 Supertrames et gestion de spectre

Le terme gestion de spectre se réfère à la capacité du gestionnaire de système de configurer un sous-réseau D pour bloquer le fonctionnement de voies non désirées dans un sous-réseau D.

Chaque supertrame inclut une carte de voies, appelée Superframe[ ].ChMap, qui est un masque de bits des voies qui doivent être incluses et exclues dans la séquence de saut qui est référencée par la supertrame. Les voies exclues ont l'effet de raccourcir la séquence de saut.

Par exemple, une carte de voies de supertrame qui inclut les voies 11..25 et exclut la voie 26 a l'effet de raccourcir la séquence de saut en retirant la voie 26 de la séquence de saut. Plus généralement, le gestionnaire de système peut éliminer n'importe quel ensemble de voies des séquences de saut qui sont référencées par des supertrames dans un sous-réseau D, avec le résultat de retirer ces voies du fonctionnement.

Il y a également une carte de voies dans l'attribut DeviceCapability qui est rapporté au gestionnaire de système lorsque la DLE rejoint le sous-réseau D. La carte de voies de DeviceCapability ne raccourcit aucune séquence de saut de voie utilisée par la DLE, mais est plutôt un signal donné au gestionnaire de système lui indiquant que, pour des raisons de réglementation, toute liaison utilisant l'une des voies exclues sera traitée comme étant "idle".

Le gestionnaire de système peut également bloquer l'utilisation de certaines voies par l'intermédiaire de l'attribut dlmo.IdleChannels. A la différence de la carte de voies dans les supertrames, dlmo.IdleChannels ne provoque pas le raccourcissement des séquences de saut. A la place, il amène les liaisons sur les voies spécifiées à être traitées comme étant "idle".L'attribut dlmo.IdleChannels vise à fournir au gestionnaire de système un moyen rapide de désactiver certaines voies d'une manière qui n'exige pas la coordination à l'échelle du sous-réseau D des séquences révisées de saut.

Le diagnostic spécifique à une voie, tel que décrit en 9.4.2.27, fournit au gestionnaire de système les informations pour prendre en charge la gestion de spectre.

9.1.8.5 Fonctionnement de la file d'attente de messages de DLE

Les routeurs de DL conformes à la présente norme doivent prendre en charge une file d'attente de messages de DLE. Cette file d'attente de messages a un certain nombre d'attributs qui peuvent être configurés par le gestionnaire de système, affectant la façon dont la file d'attente fonctionne.

La norme ne spécifie pas généralement les mécanismes internes de la DLE. Cependant, à un degré limité, la file d'attente de messages de DLE est spécifiée par la norme. Le gestionnaire de système peut configurer la file d'attente de messages de DLE pour réaliser les objectifs particuliers de qualité de service, et un modèle limité du comportement de file d'attente de messages est implicite dans les variantes de configurations fournies au gestionnaire de système.

Lorsqu'une DLE reçoit une DPDU Data en monodiffusion issue du voisin, elle évalue d'abord s'il convient que la DSDU soit passée à la NL ou soit transmise à une autre DLE à travers la DL, comme décrit en 9.3.3.6.

Si la DPDU Data a besoin d'être transmise, la DLE évalue s'il convient que la DPDU Data soit acceptée ou acquittée négativement (NAK), en se basant en partie sur la capacité disponible de la file d'attente de messages de DLE. Les DPDU Data doivent être acquittées négativement (NAK) si la file d'attente de messages de DLE a épuisé la capacité pour les DPDU Data du type en question.

La DL rapporte sa capacité de file d'attente de transmission au gestionnaire de système lorsque la DLE rejoint le sous-réseau D, par le biais de l'attribut dlmo.DeviceCapability, champ QueueCapacity. Cette capacité de file d'attente rapportée à l'extérieur n'inclut pas les parties de la file d'attente qui sont réservées à l'usage interne de la DLE. Par exemple, la file d'attente de messages de DLE dans une DLE particulière pourrait rapporter qu'elle a une capacité de file d'attente pour cinq DPDU Data. Le gestionnaire de système est alors capable de configurer ces cinq positions dans la file d'attente. Cette capacité nominale se réfère seulement à une partie de la file d'attente de messages qui est exclusivement utilisée pour acheminer des DPDU Data par la DLE. Dans la pratique, la DLE réelle a un espace supplémentaire de capacité de file d'attente de messages qu'elle ne rapporte pas au gestionnaire de système, car la DLE a également besoin de traiter des DPDU Data pour son propre compte. La capacité non rapportée de tampon de messages, pour le propre usage de la DLE, est considérée comme étant une question interne de DLE et n'est pas allouée par le gestionnaire de système. Le gestionnaire de système suppose que la DLE a la capacité suffisante de file d'attente de messages pour son propre usage lorsque des contrats sont octroyés.

Considérons l'exemple d'un routeur de terrain avec une capacité rapportée de tampon de messages de DLE de huit DPDU Data. La capacité réelle de tampon peut être de douze DPDU Data, auquel cas la différence entre la capacité rapportée et la capacité réelle (quatre DPDU Data) est pour le propre usage de la DLE. Dans cet exemple, le gestionnaire de système pourrait raisonnablement configurer la capacité de tampon nominale de DLE comme suit:

- Pas plus de trois des huit tampons seront utilisés pour transmettre des DPDU Data avec la priorité ≤ 2.
- Pas plus de cinq des huit tampons peuvent utilisés pour transmettre des DPDU Data avec la priorité ≤ 5.

Voir 9.4.2.26 pour un débat plus poussé relatif à la capacité de tampon de file d'attente et aux niveaux de priorité.

En outre, pour un degré de commande plus fin, le gestionnaire de système peut spécifier un certain nombre de tampons exclusivement pour transmettre des DPDU Data qui sont en cours d'acheminement le long du graphe spécifique, comme décrit en 9.4.3.7.

La Figure 75 fournit une vue d'ensemble de la façon dont les liaisons interagissent avec une file d'attente implicite de messages de DLE au sein d'une DLE.

Figure 75 – Allocation d'intervalles et file d'attente de messages

Comme montré à la Figure 75, des Data DPDU sont maintenues dans une file d'attente de messages jusqu'à ce que des liaisons d'émission deviennent disponibles. Des DPDU Data sont placées dans la file d'attente dans l'ordre de leur réception. Généralement, la récupération des DPDU Data dans la file d'attente est premier entré, premier sorti (FIFO).

NOTE Cet exemple simplifié montre seulement une seule adresse de destination pour chaque DPDU Data. Dans la pratique, chaque DPDU Data sur la file d'attente de messages est réellement une candidate pour des liaisons vers plusieurs voisins.

Considérer l'exemple de la DPDU Data 3. La DPDU Data 3 a pour origine une application et pénètre dans la DL par le DLSAP (Figure 53). Lorsque la DPDU Data est traitée par la DLE, elle est placée dans la file d'attente de messages de la DLE. En fonction de la destination finale des DPDU Data, la DLE détermine que la DPDU Data a besoin d'une liaison vers la DLE B pour son prochain saut. Les DPDU Data 1 et 2 sont déjà dans la file d'attente et, donc, la DPDU Data 3 est placée dans la file d'attente derrière elles. Lorsqu'une liaison vers la DLE B devient disponible, la DPDU Data 2 sera envoyée avant la DPDU Data 3.

Chaque DPDU Data dans la file d'attente a une priorité assignée par la DLE émettrice. Ce tutoriel simplifié suppose que toutes les DPDU Data ont une égale priorité. Dans la pratique réelle, la priorité de liaison a la préséance sur la priorité de DPDU Data, en ce sens que des DPDU Data ne sont pas considérées pour l'émission qu'après la sélection d'une liaison d'émission. Une fois qu'une liaison d'émission a été sélectionnée, la DPDU Data dans la file d'attente est sélectionnée d'abord en fonction de la priorité et ensuite en fonction d'une base FIFO si plusieurs DPDU Data candidates ont la même priorité.

La DPDU Data 4 montre un exemple où une DPDU Data est reçue dans un intervalle de temps donné et est disponible pour être transmise dans le prochain intervalle de temps. En général, une DPDU Data reçue dans un intervalle de temps donné (intervalle de temps N) doit être disponible dans la file d'attente pour une transmission dans le prochain intervalle de temps (intervalle de temps N+1). Une exception est autorisée lorsque le modèle d'intervalle de temps par défaut 3 est utilisé (voir Figure 157). Dans ce cas, la transaction D pourrait être inachevée au début du prochain intervalle de temps. Une DPDU Data reçue en commençant dans un intervalle de temps donné (intervalle de temps N), en utilisant le modèle d'intervalle de temps par défaut 3, doit être disponible dans la file d'attente pour une transmission dans l'intervalle de temps suivant le prochain intervalle de temps (intervalle de temps N+2).

A la Figure 75, deux supertrames sont montrées, chacune étant associée à une série de liaisons. Par exemple, l'intervalle de temps 3 dans la supertrame 1 est associé à une liaison de réception (R), alors que l'intervalle de temps 3 dans la supertrame 2 est associé à une liaison d'émission vers la DLE B (T_B). Les intervalles de temps inactifs n'ont pas de liaisons définies.

Chaque liaison a une priorité. Les attributs dlmo.LinkPriorityXmit et dlmo.LinkPriorityRcv fournissent les priorités de liaison par défaut, qui peuvent être neutralisées pour n'importe quelle liaison particulière. L'exemple à la Figure 75 montre surtout les priorités par défaut 0 pour les liaisons de réception et 8 pour les liaisons d'émission.

Dans la plupart des cas, il convient que le gestionnaire de système assigne une plus faible priorité aux liaisons de réception (R) qu'aux liaisons d'émission (T), donnant ainsi la préséance pour desservir les DPDU Data sortantes dans sa file d'attente. Cependant, il ne s'agit pas d'une exigence stricte. Par exemple, si un flux entrant à la latence critique est programmé pour un intervalle de temps particulier, le gestionnaire de système peut configurer des liaisons de réception avec une priorité plus élevée dans le cas en question. Comme illustration à la Figure 75, la troisième liaison dans la supertrame 1 a une priorité assignée de 9, donnant à cette liaison de réception particulière une plus haute priorité qu'une liaison de transmission au même moment.

Les intervalles de temps d'émission/réception (T/R) utilisent un format compressé pour combiner une liaison d'émission et une liaison de réception. Logiquement, une liaison de T/R constitue deux liaisons, la partie réception de la liaison ayant une priorité de dlmo.LinkPriorityRcv qui prend une valeur par défaut de zéro. Par exemple, si un intervalle de temps a une liaison T_A/R de haute priorité et une liaison T_B de plus faible priorité, la liaison T_B a une plus haute priorité que la partie R de la liaison T_A/R. Le fonctionnement de ligne de base est qu'une DPDU Data placée en file d'attente pour une émission et une liaison sont appariées au début d'un intervalle de temps, et l'intervalle de temps est assigné à une transaction D qui sera exécutée jusqu'à son terme en fonction de la configuration de la liaison. Au cas où une transaction D serait prématurément arrêtée en raison de la détection CCA d'une activité de voies concurrentes, une mise en œuvre optimisée peut compléter l'intervalle de temps en utilisant une liaison de réception qui est valide pour le même intervalle de temps.

Une fois qu'une DPDU Data placée en file d'attente a été émise et acquittée, la transaction D est réputée avoir réussi et la DPDU Data est supprimée de la file d'attente. L'exemple suivant suppose que toutes les transactions ont réussi.

La boîte en bas à droite de la Figure 75 montre comment les liaisons sont utilisées dans l'exemple ci-après.

- Intervalle de temps 1: La première liaison dans les deux supertrames 1 et 2 est inactive; par conséquent, le premier intervalle de temps est inactif.
- Intervalle de temps 2: La deuxième liaison dans la supertrame 1 est inactive, mais il y a une liaison d'émission pour la DLE A (T_A) dans la supertrame 2. Il y a également une DPDU Data destinée à la DLE A dans la file d'attente; par conséquent, le deuxième intervalle de temps est assigné pour une émission vers la DLE A, et la DPDU Data 1 est envoyée.
- Intervalle de temps 3: La supertrame 1 a une liaison de réception et la supertrame 2 a une liaison d'émission. La liaison dans la supertrame 1 a la préséance en raison de sa priorité, si bien que l'intervalle de temps 3 est utilisé pour se mettre à l'écoute afin de déceler des DPDU Data entrantes. (Comme décrit ci-dessus, les liaisons de réception ont habituellement une priorité assignée inférieure à celle des liaisons d'émission. Cet exemple montre comment un gestionnaire de système peut donner la priorité à une liaison de réception, par exemple, pour desservir un flux entrant.)
- Intervalle de temps 4: La supertrame 1 a une liaison T_B/R, indiquant qu'il convient qu'elle émette s'il y a une DPDU Data destinée à la DLE B dans la file d'attente. La DPDU Data est envoyée.
- Intervalle de temps 5: Les deux supertrames sont inactives dans l'intervalle de temps 5, si bien que l'intervalle de temps est inactif.
- Intervalle de temps 6: La supertrame 1 désigne une ligne d'émission vers la DLE A, mais il n'y a plus de DPDU Data destinée à la DLE A dans la file d'attente. Sachant qu'il n'y a rien d'utile à faire pour la liaison d'émission dans cet intervalle de temps, la liaison dans la supertrame 2 est utilisée. La DLE reçoit des DPDU Data entrantes, détermine que son prochain saut est vers la DLE A, et place la DPDU Data dans la file d'attente.
- Intervalle de temps 7: Maintenant qu'il y a une DPDU Data pour la DLE A dans la file d'attente, la liaison d'émission dans la supertrame 1 obtient la priorité et la DPDU Data

4 est envoyée. Noter que la DPDU Data 3 a été sautée parce qu'aucune liaison T_B n'est encore devenue disponible.

- Intervalle de temps 8: Maintenant qu'une liaison T_B est disponible, la DPDU Data 3 est envoyée.
- Intervalle de temps 9: La liaison T_B/R conduit à un intervalle de temps de réception, car il n'y a pas de DPDU Data destinée à la DLE B dans la file d'attente.

Cet exemple a été simplifié en un certain nombre d'aspects essentiels.

– Comme noté ci-dessus, les priorités des DPDU Data ont été supposées être égales. Dans la pratique, si deux DPDU Data sur une file d'attente de messages concordent toutes les deux avec une liaison donnée, la DPDU Data avec la priorité la plus élevée est émise. La position dans la file d'attente FIFO n'est pertinente que pour des DPDU Data d'égale priorité.

– Si des DPDU Data en monodiffusion ne reçoivent pas un acquittement, elles restent dans la file d'attente et la stratégie de répétitions de tentative de la DL est appliquée. Voir 9.1.8.2.

– Une liaison peut être configurée pour être utilisée par un graphe particulier. Dans ce cas, les DPDU Data avec cet ID de graphe doivent avoir un accès hiérarchisé par ordre de priorité ou exclusif à cette liaison. Voir 9.4.3.7.

– Une DLE peut être conçue pour sauter des liaisons sur les voies radio avec des antécédents de connectivité inférieure à la normale. Une DLE peut également sauter des liaisons afin de répéter la tentative sur une liaison de remplacement. Voir 9.1.7.2.4.

Le fonctionnement du traitement de file d'attente est illustré dans le pseudocode suivant:

```
Pour chaque intervalle de temps (
   Ordonner les DPDU Data dans la file d'attente par priorité;
   // FIFO dans la priorité

   Ordonner les liaisons par priorité;
   // Traiter les liaisons T/R comme deux liaisons, avec un côté réception
   // de la liaison assignée priorité de liaison dlmo.LinkPriorityRcv;
   // Dans la priorité de liaison, ordonner par priorité de supertrame,
   // puis numéro de supertrame (dans l'ordre décroissant);

   Pour chaque liaison, dans l'ordre de priorité
      Si c'est une liaison reçue (
         Utiliser la liaison reçue;
         Effectué avec intervalle de temps;
         )
      Autre // c'est une liaison émise
         Pour chaque DPDU Data, dans l'ordre de priorité
            Si la liaison correspond à la DPDU Data (
                  Utiliser la liaison;
                  Effectué avec intervalle de temps;
                  )
)
```

9.1.9 Chronométrage de DL

9.1.9.1 Temporisation

9.1.9.1.1 Généralités

La DL propage et utilise le temps atomique international (TAI) pour son fonctionnement interne, et elle fournit également le temps TAI comme service (par le DMAP) aux appareils sans fil conformes à la présente norme.

Les DLE au sein d'un sous-réseau D peuvent être configurées pour suivre à la trace le sens partagé du temps à quelques millisecondes près l'une de l'autre, pour prendre en charge la séquence de comptes-rendus d'événements et autres opérations coordonnées de couche d'application dans la portée d'un sous-réseau D. Le temps synchronisé parmi les voisins immédiats est également essentiel au fonctionnement du protocole sans fil.

Le saut de voie discrétisé exige une synchronisation serrée du temps parmi les voisins immédiats. Cependant, l'horloge interne d'une DLE autre que de routage qui a été déconnectée du fonctionnement du sous-réseau D pendant plus de quelques minutes peut avoir dérivé de dizaines ou de centaines de millisecondes, ou plus, par rapport à l'horloge globale du sous-réseau D. Les configurations de saut de voie lent ou hybride prennent en charge le fonctionnement continu de ces DLE.

9.1.9.1.2 Temps atomique international

Dans la présente norme, le temps est basé sur le temps atomique international (TAI) comme référence temporelle. Voir 5.6.

9.1.9.1.3 Intervalles d'alignement

Dans la présente norme, les incréments TAI d'une seconde sont divisés en intervalles d'alignement de 250 ms (1/4 s), dans lesquels les cycles de 250 ms (2^{-2} s) doivent s'aligner à la seconde TAI nominale, conformément à la Figure 76.

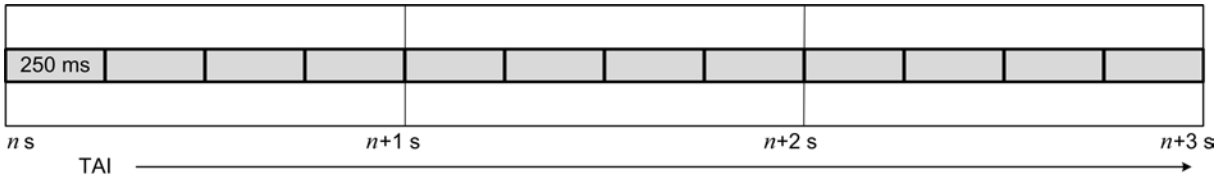

Figure 76 – Intervalles d'alignement de 250 ms

Les boucles de commande continues dans les industries de transformation, qui ont été un centre d'intérêt traditionnel du CE 65 de l'IEC, sont fréquemment basées sur le calcul à période fixe des sorties de commande. Ces boucles de transformation se répètent habituellement à des fréquences de 4 Hz (250 ms), de 1 Hz (1 s) ou de multiples de 4 s ou 5 s. La surveillance de processus est habituellement mappée à cette même structure de 4 Hz (et plus lente).

Les applications avec des fréquences de boucle légèrement plus élevées, comme les boucles de commande de pompage de compresseurs fonctionnant à 12 Hz, peuvent être prises en charge en programmant plusieurs occasions de communications par cycle de 250 ms.

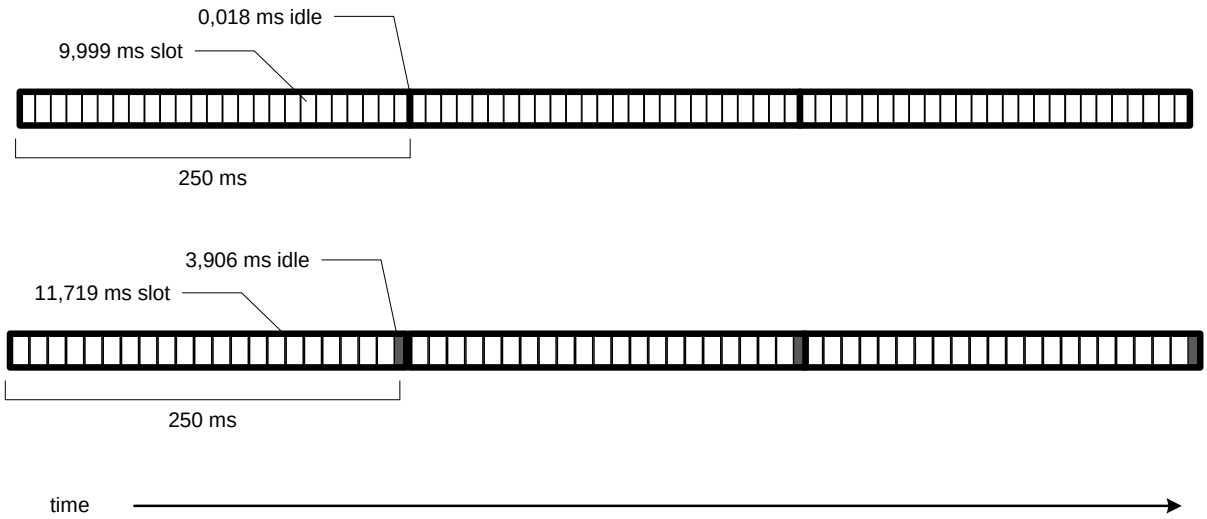
9.1.9.1.4 Durée d'intervalle de temps, alignement d'intervalle de temps et périodes inactives

Dans les intervalles d'alignement de 250 ms, le temps est divisé en intervalles de temps de durée configurable, mais égale. Un intervalle de temps est un intervalle de temps de durée prédéfinie utilisée pour envoyer ou recevoir une DPDU Data et toutes les éventuelles DPDU ACK/NAK correspondantes. Les intervalles de temps sont généralement partagés par au moins une paire de DLE qui communiquent pendant le temps alloué. La DL organise ces intervalles de temps en supertrames, qui sont des ensembles d'intervalles de temps avec une période commune et potentiellement d'autres attributs communs.

Les durées d'intervalle de temps sont configurées au cours de l'établissement du sous-réseau D. Normalement, pendant une période donnée de fonctionnement, tous les intervalles de temps au sein d'un sous-réseau D ont la même durée. La durée d'intervalle de temps est configurée en unités de 2^{-20} s (~0,95 µs).

NOTE 1 La DL lie la durée d'intervalle de temps à des supertrames, et rien dans la norme n'empêche plusieurs supertrames avec des durées différentes d'intervalle de temps d'être actives simultanément au sein d'un sous-réseau D. Cependant, la présente norme ne considère que des configurations dans lesquelles une seule durée d'intervalle de temps est utilisée au sein d'un sous-réseau D donné. Une DLE prenant en charge plusieurs durées d'intervalle de temps simultanément, telle qu'un routeur dorsal ou un pont entre deux sous-réseaux D, peut être modélisée comme contenant plusieurs DLE fonctionnant en parallèle.

Les intervalles de temps s'alignent avec des intervalles d'alignement de 250 ms, mais les durées d'intervalle de temps ne se divisent pas nécessairement de manière uniforme en 250 ms. Par conséquent, le système insère une courte période inactive toutes les 250 ms selon les besoins, réalignant ainsi les intervalles de temps à un cycle de 4 Hz. Cela est montré à la Figure 77 avec deux exemples illustratifs utilisant des durées différentes d'intervalles de temps respectives de 9,999 ms et de 11,719 ms.



Légende

Anglais	Français
0,018 ms idle	Inactif 0,018 ms
9,999 ms slot	Intervalle 9,999 ms
3,906 ms idle	Inactif 3,906 ms
11,719 ms slot	Intervalle 11,719 ms
Time	Temps

Figure 77 – Durées d'intervalle de temps et temporisation

NOTE 2 Calculs pour les temps inactifs à la Figure 77:

a) $10\,485 \times 25 \times 2^{-20}$ s = 249,982 ms. Soustraire à 250 ms pour obtenir 0,018 ms;

b) $12\,288 \times 21 \times 2^{-20}$ s = 246,094 ms. Soustraire à 250 ms pour obtenir 3,906 ms;

NOTE 3 L'intervalle de temps visant étroitement à approcher 10 ms a une durée de 10 485 unités, ou 9,999 275 ms.

La période inactive n'est pas utilisée par le système pour les opérations programmées; il s'agit simplement d'une courte période insérée pour s'assurer que les intervalles de temps s'alignent et se répètent à des intervalles de 250 ms. Cela permet au gestionnaire de système d'organiser facilement l'ensemble des intervalles de temps qui se répètent à des multiples exacts de 250 ms.

Les périodes de saut lent peuvent s'étendre sur un intervalle d'alignement. Dans de tels cas, les périodes de saut lent ne sont pas interrompues par des périodes inactives, c'est-à-dire, si une période de saut lent traverse la frontière d'un intervalle d'alignement, la radio du récepteur continue de fonctionner à travers la période inactive.

9.1.9.1.5 Temps d'intervalle de temps programmé

Chaque intervalle de temps de DL a un temps de début programmé en secondes fractionnaires, qui s'appelle le temps d'intervalle de temps programmé. Les protocoles tant de

DL que de couche supérieure utilisent ce sens coordonné de temps comme support de sécurité, assurant ainsi une protection contre le rejet. Voir 7.3.2.6.

Puisque les intervalles de 250 ms alignent avec des quarts de seconde de TAI, la temporisation d'intervalle de temps programmé peut être dérivée de la durée de l'intervalle de temps. Par exemple, si la durée d'intervalle de temps est 9,999 ms, les temps d'intervalle de temps programmé dans le deuxième quart de seconde du temps TAI t sont t + 0,250 000 s, t + 0,259 999 s, t + 0,269 998 s, etc.

NOTE Cette représentation à base multiple du temps facilite l'interconversion à des couches supérieures, où les PDU s'étendent souvent sur des sous-réseaux D avec des débits de données différents, des durées différentes d'intervalle de temps et/ou des protocoles de DL différents.

Le temps de début d'intervalle de temps programmé est en unités de 2^{-20} s (précision d'une microseconde). Les DL utilisent communément des horloges internes basées sur un cristal "de montre" très faible puissance et très précis de 2^{15} Hz (32 kiHz). Des mises en œuvre peuvent, et généralement le feront, arrondir le temps de début d'intervalle de temps programmé au top d'horloge de 32 kiHz le plus proche. Cet arrondi est autorisé sur une base d'intervalle de temps à intervalle de temps, sans réajuster le programme d'intervalle de temps sous-jacent basé sur des unités de 2^{-20} s Cependant, cet arrondissement à 32 kiHz n'est pas autorisé à s'accumuler au-dessus d'une période de 250 ms, conformément au Tableau 101. Cette considération est incluse au sein de la gigue de ±96 µs autorisée par la présente norme; voir 9.4.3.3.1.

Tableau 101 – Approximation de la temporisation nominale avec une horloge de 32 kHz

Décalage de l'intervalle de temps nominal (ms)	2^{-20} s (comptes d'horloge)	2^{-15} s (comptes d'horloge, arrondis)	Décalage de l'intervalle de temps réel (ms)
0	0	0	0
10	10 485 × 1	328	10,010
20	10 485 × 2	655	19,989
30	10 485 × 3	983	29,999
•••	•••	•••	•••
200	10 485 × 20	6 553	199,982
210	10 485 × 21	6 881	209,991
220	10 485 × 22	7 208	219,971
230	10 485 × 23	7 536	229,980
240	10 485 × 24	7 864	239,990

9.1.9.2 Propagation de temps DL

9.1.9.2.1 Généralités

La DLE utilise le temps TAI pour son fonctionnement interne, et fournit une notion de temps TAI comme service (par le DMAP) aux voisins sans fil conformes à la présente norme.

Dans un sous-réseau D, les DLE peuvent prendre trois fonctions dans le processus de propagation de temps:

- destinataire d'horloge de DL, un récepteur des mises à jour périodiques d'horloge par le biais de la DL; ou
- source d'horloge de DL, un fournisseur de mises à jour périodiques d'horloge aux voisins de DL; ou
- répéteur d'horloge de DL, un destinataire d'horloge de DL qui agit également comme source d'horloge de DL pour certains de ses voisins.

Des informations complémentaires relatives à la propagation de temps peuvent être trouvées en 6.3.10.

9.1.9.2.2 Stabilité d'horloge de DLE

La stabilité d'horloge de la DLE est la stabilité nominale d'horloge d'un appareil sans fil, en présence des corrections périodiques de temps issues du sous-réseau D.

La DLE, une fois configurée comme destinataire d'horloge, s'appuie sur le sous-réseau D pour fournir en mode sans fil les mises à jour périodiques de temps. Elle peut également utiliser ces mises à jour de temps dans l'étalonnage de son horloge interne pour rendre compte de conditions telles que la température, le vieillissement, et la tension électrique.

La référence temporelle pour un sous-réseau D provient d'un ou plusieurs maîtres d'horloge, qui fournissent le temps à croissance monotone à un taux qui suit étroitement le temps réel.

Lorsque la DLE rejoint le sous-réseau D, la DLE rapporte sa stabilité d'horloge au gestionnaire de système comme étant dlmo.DeviceCapability.ClockStability (appelée ClockStability ici), qui est dans les unités de parties par million (1×10^{-6}). ClockStability s'applique à n'importe quelle période arbitraire de 30 s au cours de la vie prévue de l'appareil, dans toutes les conditions qu'un utilisateur pourrait raisonnablement attendre de spécifications publiées de l'appareil.

Par exemple, si ClockStability rapporte qu'une DLE a une horloge d'une instabilité maximale de 10×10^{-6} s/s, alors l'horloge de la DLE doit être stable à $\pm$ 300 μ ms près au cours de n'importe quelle période de 30 s arbitrairement sélectionnée.

ClockStability est rapportée comme une enveloppe. Par exemple, si ClockStability rapporte qu'une DLE a une horloge d'une instabilité maximale de 10×10^{-6} s/s, alors l'horloge de la DLE doit être stable à $\pm$ 300 μ ms près à tout instant, au cours de n'importe quelle période de 30 s arbitrairement sélectionnée. L'intention en est de permettre la prise en charge d'appareils qui sont soumis à des chocs environnementaux occasionnels susceptibles de causer de petites discontinuités d'horloge. Les petites discontinuités sont acceptables, tant qu'elles ne s'accumulent pas pour dépasser $\pm$ClockStability $\times$ 30 μs à un moment quelconque sur une période de 30 s quelconque.

NOTE 1 ClockStability, spécifiée en unités de 1×10^{-6}s/s, est l'équivalent de 1 μs/s.

NOTE 2 Les DLE voisines peuvent avoir des horloges qui dérivent dans des sens opposés. Par conséquent, dans le cas le plus défavorable, ClockStability est additive entre des paires de DLE voisines. Dans la pratique, les répétiteurs d'horloge sont corrigés périodiquement, ce qui diminue cet effet.

La norme suppose que la dérive d'horloge est négligeable au sein d'un intervalle de temps.

ClockStability est rapporté au gestionnaire de système sans mises en garde. Si l'appareil est spécifié pour fonctionner sous contrainte environnementale, telle que des valeurs extrêmes de température ou de choc mécanique, alors ClockStability doit refléter les performances sous une telle contrainte.

L'attribut dlmo.ClockExpire, configuré par le gestionnaire de système, fournit le nombre maximal de secondes pendant lesquelles la DLE peut fonctionner en toute sécurité en l'absence d'une mise à jour d'horloge. Normalement, le gestionnaire de système s'arrange pour qu'une DLE maintienne la synchronisation d'horloge comme un sous-produit de la communication normale. Cependant, lorsque la DLE échoue à recevoir une mise à jour d'horloge pendant une période de temps prolongée, définie par ClockExpire, il convient que la DLE interroge activement une source d'horloge de DL pour une mise à jour du temps. Le manquement à le faire conduira finalement à la perte de la synchronisation du temps avec le sous-réseau D. ClockExpire prend par défaut une valeur qui est appropriée pour être utilisée au cours du processus de rattachement.

Il convient qu'un répétiteur d'horloge n'envoie pas de corrections d'horloge à ses voisins par des DPDU ACK/NAK s'il n'a pas lui-même reçu une correction d'horloge pendant une période qui excède l'attribut ClockExpire. Si l'horloge d'un répétiteur d'horloge a expiré et il est interrogé pour une mise à jour de temps, il convient qu'il réponde par un NAK1.

Il convient qu'une DLE avec une horloge expirée ne soit pas utilisée comme un répétiteur d'horloge, mais elle peut continuer à fonctionner dans le sous-réseau D, bien que ce soit avec un risque potentiel de perdre la synchronisation avec ses voisins. L'attribut dlmo.ClockTimeout fournit la quantité maximale de temps pendant laquelle une DLE peut raisonnablement continuer de fonctionner dans un sous-réseau D en l'absence d'une mise à jour d'horloge. Si la DLE n'a pas reçu une mise à jour d'horloge pendant une période de temps qui excède DLTimeout, la DLE peut raisonnablement se réinitialiser d'elle-même à l'état "provisioned "et initier une recherche d'un nouveau sous-réseau D.

NOTE 3 Une DLE fonctionnant dans une configuration de saut de voie lent est capable d'être configurée pour retenir une connexion de sous-réseau D pendant des périodes prolongées de temps, même avec une horloge qui a dérivé à travers les intervalles de temps.

9.1.9.2.3 Sources d'horloge préférentielles et secondaires

Le gestionnaire de système configure chaque destinataire d'horloge de DL pour traiter un ou plusieurs de ses voisins comme des sources d'horloge de DL. De telles sources d'horloge de DL peuvent être désignées comme étant préférentielles ou secondaires, selon l'attribut dlmo.Neighbor[ ].ClockSource. Plusieurs voisins peuvent être désignés comme étant des sources préférentielles d'horloge de DL. Il convient qu'un destinataire d'horloge de DL réajuste sa valeur d'horloge chaque fois qu'il a une interaction avec une source préférentielle d'horloge de DL.

L'attribut dlmo.ClockStale définit une période de temps qui doit s'écouler avant qu'une DLE ne commence à accepter des mises à jour d'horloge issues de sources secondaires d'horloge de DL. Si, après une période de ClockStale, aucune mise à jour d'horloge n'est reçue en provenance d'une quelconque source préférentielle, il convient que le destinataire d'horloge de DL accepte des mises à jour d'horloge dans ses interactions avec les voisins qui sont désignés comme étant des sources secondaires d'horloge de DL. Une fois qu'un destinataire d'horloge de DL accepte une mise à jour d'horloge issue d'une source secondaire d'horloge de DL, il convient qu'il continue d'utiliser cette source secondaire d'horloge de DL jusqu'à ce que soit (a) il reçoive une mise à jour d'horloge issue d'une source préférentielle d'horloge de DL, soit (b) la source secondaire d'horloge de DL temporise.

L'attribut dlmo.ClockStale détermine l'intervalle de temporisation. Par exemple, si ClockStale est mis à 45 s par le gestionnaire de système, il convient qu'une source d'horloge de DL n'accepte pas de mises à jour d'horloge issues d'une source secondaire d'horloge de DL jusqu'à ce qu'elle n'ait pas reçu une mise à jour d'horloge issue d'une quelconque source préférentielle d'horloge de DL pendant au moins 45 s.

Chaque destinataire d'horloge de DL peut être configuré pour conserver et rapporter périodiquement des statistiques (voir 9.4.3.9) pour n'importe laquelle de ses sources préférentielles d'horloge de DL, y compris:

- Un compte des événements de temporisation d'horloge.
- Une moyenne glissante des corrections d'horloge, un nombre entier signé en unités de 2^{-20} s, indiquant un biais si différent de zéro.
- L'écart-type des corrections d'horloge, estimé en unités de 2^{-20} s, par exemple, une valeur qui rend grossièrement compte de 68 % approximativement des corrections d'horloge.
- Un compte des corrections d'horloge au-dessus de trois fois de tels écarts-types.

9.1.9.2.4 Sens partagé de temps pendant le fonctionnement du sous-réseau D

Les transactions de sous-réseau D se produisent nominalement dans un intervalle de temps de DL, sur un programme connu à la fois de l'expéditeur et du récepteur. Ce sens partagé de temps est utilisé comme support de sécurité, tant pour la compression d'en-tête que pour la protection contre le rejet.

Des sources d'horloge de DL peuvent être configurées pour émettre périodiquement des annonces de DL intégrées dans un sous-en-tête DAUX d'une DPDU Data. Chaque annonce de ce type fournit une référence de temps TAI pour le sous-réseau D. Toutes les DLE compatibles avec la norme qui reçoivent une annonce sont supposées être capables de participer à une communication synchronisée en temps avec la DLE d'annonce. Les destinataires d'horloge de DL avec des horloges relativement imprécises peuvent avoir une capacité limitée de ne communiquer qu'avec les routeurs qui utilisent le saut de voie lent.

L'authentification de couche MAC exige des clés de sécurité partagées, le sens partagé du temps, et la connaissance de l'adresse EUI64Address d'un voisin. Ces informations sont acquises par étapes au cours du processus de rattachement, avec des clés de sécurité fournies à la fin. La DL utilise le chiffrement normalisé par blocs (habituellement AES-128), ainsi qu'une clé de sécurité bien connue, au cours du processus de rattachement afin de fournir une vérification d'intégrité améliorée (mais pas la sécurité). Cela est décrit en plus de détails en 7.4.

Dans le saut de voie discrétisé, les initiateurs de transaction et les destinataires de transaction partagent un sens intrinsèque de l'intervalle de temps qui est utilisé; autrement, les DLE ne seraient pas capables de communiquer. Chaque intervalle de temps a un temps de début programmé qui est connu par toutes les DLE participantes.

Dans le saut de voie lent, une DLE avec un sens inexact du temps de DL émettra nominalement dans un intervalle de temps particulier, en fonction de son propre sens du temps. Cependant, une telle DLE est autorisée à manquer sa cible, et peut réellement émettre dans n'importe quel intervalle de temps dans les limites de la période de saut de voie lent. Par conséquent, les DPDU Data en monodiffusion qui sont émises en utilisant une supertrame de saut de voie lent doivent inclure un octet supplémentaire dans l'en-tête de la DPDU Data pour indiquer quel intervalle de temps au sein de la période de saut de voie lent était prévu. Cela permet à la DLE réceptrice d'accorder son sens d'intervalle de temps avec celui de la DLE émettrice, appliquant la correction de temps à travers les intervalles de temps pour valider l'exactitude de l'horloge de l'initiateur de la transaction, et d'utiliser le temps de début programmé de l'intervalle de temps comme support de sécurité.

Pour les besoins de la sécurité, un temps de début programmé (qui n'est pas le temps de début d'une DPDU Data obtenue) d'un intervalle de temps est transmis au DSC pour être utilisé dans des opérations de sécurité relatives à la DL. Voir 9.1.11. Dans la plupart des cas, l'intervalle de temps des DPDU Data et l'intervalle de temps de n'importe quelle DPDU ACK/NAK répondeuse sont les mêmes. Il y a une exception, qui se produit pour le saut de voie lent lorsque l'horloge d'une des DLE a dérivé pour entrer dans un intervalle de temps différent. Dans ce cas, le décalage de saut de voie de la DLE d'acquittement doit être inclus dans le DMXHR de la DPDU ACK/NAK (Tableau 117) pour identifier sans ambiguïté le temps exact qui doit être utilisé pour des opérations de sécurité, même si la DLE d'acquittement n'agit pas comme source d'horloge de DL pour le destinataire de la DPDU ACK/NAK DPDU. L'absence (à savoir la non-inclusion) champ décalage de saut de voie dans la DPDU ACK/NAK implique que la DLE qui est la source de la DPDU Data et la DLE qui est la source de la DPDU ACK/NAK utilisent le même intervalle de temps.

9.1.9.3 Synchronisation du temps par paires

9.1.9.3.1 Généralités

Des mises à jour d'horloge sont propagées à travers le sous-réseau D au cours des communications normales dans les limites d'un intervalle de temps ou d'une période de saut

de voie lent. Ces blocs modules de base sont soumis à un effet de levier par le gestionnaire de système pour arranger la propagation du temps de sous-réseau D.

Les sources d'horloge de DL utilisent trois mécanismes généraux pour propager des mises à jour d'horloge vers leurs voisins.

- Une source d'horloge de DL initie une DPDU Data qui inclut une annonce. Le temps est acheminé en fonction de l'instant où la DPDU Data est émise.
- Une source d'horloge de DL acquitte une DPDU Data reçue dans un intervalle de temps. Le temps est acheminé en mesurant l'instant où la source d'horloge de DL détecte le début de la DPDU Data et en faisant écho au résultat de cette mesure dans la/les DPDU ACK/NAK.
- Une source d'horloge de DL acquitte une DPDU Data dans les limites d'une période de saut de voie lent. Le processus est similaire à l'acquittement au sein d'un intervalle de temps, avec l'addition d'un octet pour identifier de façon univoque l'intervalle de temps si besoin est.

La norme s'appuie sur des horloges stables, en particulier dans des routeurs de terrain, pour le fonctionnement fiable du sous-réseau D. Pour des exigences relatives à la stabilité d'horloge de DL, voir le Tableau B.8.

Un destinataire d'horloge de DL maintient une liste de sources valides d'horloge de DL voisines. S'il reçoit une mise à jour d'horloge issue d'une source désignée d'horloge de DL, il utilise les données pour mettre à jour son horloge.

Lorsqu'une DLE découvre un sous-réseau D, elle acquiert le temps du sous-réseau D et utilise cette référence pour la communication ultérieure. La DLE doit alors resynchroniser périodiquement son horloge interne à l'horloge de sous-réseau D. Ces opérations de resynchronisation sont incrémentielles, en fonction des décalages dans un intervalle de temps avec une référence temporelle programmée connue à la fois de la source d'horloge de DL et du destinataire d'horloge de DL.

Chaque fois qu'une DLE interagit avec l'une de ses sources désignées d'horloge de DL, elle reçoit des informations mises à jour relatives aux horloges. Des réajustements d'horloge sont inclus dans les DPDU ACK/NAK, acheminant ainsi les informations relatives au temps vers le destinataire. Des mises à jour d'horloge sont également incluses dans le sous-en-tête DAUX des DPDU Data d'annonce provenant de la source d'horloge de DL.

Ainsi, une DLE peut recevoir des mises à jour d'horloge comme un sous-produit des données de routage par l'intermédiaire d'une source d'horloge de DL. En variante, si une DLE a besoin de plus fréquentes mises à jour d'horloge, elle peut être configurée pour recevoir des mises à jour d'horloge en permettant à son récepteur de fonctionner à des temps coïncidant avec des DPDU Data programmées périodiques provenant de sources d'horloge de DL qui incluent le sous-en-tête DAUX avec une annonce.

Une DLE peut acquérir une mise à jour d'horloge en envoyant une DPDU Data avec une DSDU de longueur zéro vers une source d'horloge de DL. Une source d'horloge de DL doit acquitter une telle DPDU Data et ensuite la rejeter.

9.1.9.3.2 La source d'horloge acquitte la réception d'une DPDU Data au sein d'un intervalle de temps

Lorsqu'une DLE émet une DPDU Data en monodiffusion (voir Figure 81) vers une source d'horloge de DL, elle peut recevoir une mise à jour d'horloge dans la DPDU ACK/NAK, comme montré à la Figure 78.

Figure 78 – La source d'horloge acquitte la réception d'une DPDU Data

La DPDU ACK/NAK issue de la source de données de DL inclut le temps de début de l'émission d'origine rapporté comme étant un décalage de temps (avec une précision de microseconde, en unités de 2^{-20} s) du temps de début de la DPDU Data (à savoir le temps de début de la PhSDU) par rapport au temps de début d'intervalle de temps programmé tel que mesuré par la source d'horloge de DL.

Une transaction D en monodiffusion donnée se produit sur une seule voie, avec la DPDU Data et la/les DPDU ACK/NAK DPDU toutes émises sur la même voie.

Ces informations de synchronisation d'horloge sont ciblées à la DLE qui est à l'origine de la DPDU Data. Alors que d'autres DLE peuvent entendre par hasard et mettre à jour leurs horloges en fonction des mêmes informations, la conception n'est pas optimisée pour cette utilisation.

Alors que les détails internes d'une DLE relatifs à la synchronisation d'horloge ne sont pas spécifiés par la présente norme, la transaction est destinée à prendre en charge un processus de synchronisation d'horloge qui fonctionne généralement comme suit:

a) Le destinataire d'horloge de DL envoie une DPDU Data à la source d'horloge de DL et enregistre qu'elle a envoyé la DPDU Data à un décalage de temps Y.

b) La source d'horloge de DL reçoit la DPDU Data virtuellement au même instant et enregistre qu'elle a reçu la DPDU Data à un décalage de temps X.

c) Le diagramme montre le cas où l'horloge du destinataire d'horloge de DL tourne plus vite que la source d'horloge de DL. Dans ce cas, $X > Y$. Si la source d'horloge de DL tourne plus vite, $X < Y$. Le temps de la source d'horloge de DL est supposé être correct.

d) Dans la DPDU ACK/NAK, la source d'horloge de DL rapporte qu'elle a reçu la DPDU Data à un décalage de temps X.

e) Le destinataire d'horloge de DL applique une correction de temps qui est calculée comme étant $(Y - X)$.

Le résultat montré dans la Figure 78 est que les intervalles de temps commencent à des temps différents, mais finissent au même temps. Une mise en œuvre réelle peut retarder l'application des corrections de temps, par exemple en réajustant progressivement l'horloge. Voir 9.1.9.2.2.

9.1.9.3.3 Une source d'horloge initie une DPDU Data qui inclut une annonce

Une source d'horloge de DL est souvent la source d'une DPDU Data. Tel est généralement le cas lorsqu'une source d'horloge de DL émet une annonce prévue qui inclut le temps TAI. La charge utile de la DPDU Data peut être sans rapport avec la synchronisation; les informations relatives au temps TAI sont contenues dans le sous-en-tête DAUX et elles peuvent donc être entendues par hasard par n'importe lequel des voisins de la source d'horloge de DL.

Plusieurs DLE peuvent être configurées pour activer leurs destinataires simultanément par anticipation d'une DPDU Data programmée acheminant une annonce.

La présente norme exige qu'une source d'horloge de DL soit capable de commander précisément le moment où des DPDU Data d'annonce sont émises, avec une précision des $\pm$ 96 μs (3 octets), en étant référencées à l'horloge interne de la DLE. Voir 9.4.3.3.1.

9.1.9.3.4 Une source d'horloge acquitte une DPDU Data dans les limites d'une période de saut de voie lent

Comme noté précédemment, les sources d'horloge de DL utilisent des DPDU ACK/NAK pour rapporter le temps avec une résolution de microseconde (2^{-20} s), comme étant un décalage par rapport au temps de début nominal programmé d'un intervalle de temps. L'identification de l'intervalle de temps est supposée être non ambiguë, connue à la fois de l'expéditeur et des destinataires. Ainsi, seul le décalage est communiqué dans les mises à jour d'horloge.

Cependant, au cours des périodes de saut de voie lent, l'horloge interne d'un destinataire d'horloge de DL peut avoir dérivé des dizaines ou des centaines de millisecondes, ou plus, par rapport à l'horloge de l'expéditeur, si bien que la présomption de l'identification de l'intervalle de temps pourrait être incorrecte. Par conséquent, un octet supplémentaire, identifiant un intervalle de temps spécifique, est ajouté aux en-têtes de DPDU dans les limites des périodes de saut de voie lent, tel que spécifié dans le DHDR de la DPDU. L'intervalle de temps initial au sein d'une période de saut de voie lent est défini comme ayant un décalage de zéro.

Au sein des périodes de saut de voie lent, il convient que les DLE avec un sens exact du temps fonctionnent à l'intérieur des frontières d'intervalle de temps. Cependant, les DLE sans sens exact du temps pourraient ne pas être capables de respecter les frontières d'intervalle de temps, et pourraient même ne pas savoir quel intervalle de temps elles utilisent

réellement. Un décalage d'intervalle de temps dans chaque en-tête de DPDU permet au récepteur de reconstruire le sens du temps de l'expéditeur et vice-versa (voir 9.3.3.3).

9.1.9.3.5 Audit de la qualité d'une horloge de voisin

Lorsqu'une DLE rejoint le sous-réseau D, elle rapporte ses caractéristiques de stabilité d'horloge à la fonction de gestion du système. Dans leurs interactions normales avec ces DLE, les sources d'horloge de DL et les destinataires d'horloge de DL peuvent être configurés par le système pour recueillir le diagnostic, sur une base voisin par voisin, pour auditer ces spécifications nominales (voir 9.4.3.9).

9.1.9.3.6 Réajustements d'horloges discontinus

Sous certaines conditions, il peut être nécessaire pour le gestionnaire de système de réajuster l'ensemble de toutes ses horloges de DLE par dizaines ou centaines de millisecondes, ou plus, par exemple lorsque deux sous-réseaux D sont rejoints. Le gestionnaire de système peut programmer un réajustement d'horloge discontinu qui se produit à un temps TAI particulier, en positionnant l'attribut dlmo.TaiAdjust sur chacune de ses DLE. Au temps désigné, toutes les DLE doivent réajuster leurs horloges en les avançant ou retardant d'une quantité de temps spécifiée.

Le réajustement d'horloge a un certain nombre d'impacts sur le système qu'il convient de prendre en compte chaque fois que cette caractéristique est utilisée.

- Le modèle de sécurité dans la présente norme n'autorise pas que le temps recule. Le temps est utilisé dans le nonce de sécurité, qui ne peut jamais être répété dans une quelconque couche de communication normalisée. En conséquence, il doit y avoir une interruption de service, égale à l'amplitude du réajustement plus au moins un intervalle de temps, si le temps est réajusté à un temps antérieur.
- Les rapports échelonnés décaleront leur temps de la quantité du réajustement d'horloge, à moins que des contrats correspondants ne soient révisés en tandem avec le réajustement d'horloge.
- Les DLE qui ne reçoivent pas la correction de temps avant l'heure de basculement peuvent perdre la synchronisation avec le fonctionnement du sous-réseau D, et peuvent avoir besoin de redécouvrir leurs voisins.

9.1.9.4 Transactions au sein des modèles d'intervalle de temps

9.1.9.4.1 Généralités

NOTE Les transactions sont également décrites en 4.6.11.

La temporisation de transaction au sein d'un intervalle de temps de DL est spécifiée par des modèles d'intervalle de temps. La norme définit les modèles d'intervalle de temps par défaut qui sont nécessaires à la DLE pour ses interactions avec une DLE de configuration sans fil. Des modèles complémentaires d'intervalle de temps peuvent être ajoutés par le gestionnaire de système pendant ou après le processus de rattachement. (Voir 9.4.3.3 pour plus d'informations relatives aux modèles d'intervalle de temps.)

La Figure 79 montre certains aspects traités par les modèles d'intervalle de temps de DL.

Figure 79 – Attributs de temporisation de transaction

Comme montré à la Figure 79, les modèles d'intervalle de temps définissent la temporisation pour les opérations telle que le temps d'attente de réception des DPDU Data, et le temps d'inversion (traitement de réception de DPDU Data et transition radio) entre la réception d'une DPDU Data et l'émission d'une ACK/NAK DPDU.

Généralement, il y a deux types de modèles de transaction: émission et réception. Un modèle d'initiateur de transaction spécifie une plage de temps pour commencer l'émission d'une DPDU Data, pour vérifier l'activité avant émission, et le placement relatif de toutes les éventuelles DPDU ACK/NAK DPDU dans l'intervalle de temps. Un modèle de récepteur de transaction spécifie l'intervalle pendant lequel une DPDU Data reçue peut commencer à arriver et, ainsi, quand temporiser si aucun début de DPDU Data n'est détecté. Il spécifie également la temporisation de toutes les éventuelles DPDU ACK/NAK envoyées par des répondeurs de transaction.

Les modèles d'intervalle de temps par défaut couvrent les transactions de ligne de base nécessaires pour interagir avec une DLE de configuration, qui sont utilisables au cours du processus de rattachement. Des modèles par défaut peuvent également être utilisés par des DLE rattachées pour des transactions générales. Des modèles complémentaires peuvent être configurés dans la DLE pour prendre en charge des caractéristiques telles que:

- périodes d'accès multiple avec détection de porteuse avec évitement de collision (CSMA/CA) au début d'un intervalle de temps (voir 9.1.9.4.8); et
- temporisation prolongée de DPDU ACK/NAK par rapport à la fin de la DPDU Data ou par rapport à la fin de l'intervalle de temps (voir 9.1.9.4.6).

Par convention dans la présente norme, la temporisation de modèle d'intervalle de temps est spécifiée en fonction des temps de début et de fin de DPDU Data et ACK/NAK et de la fin de l'intervalle de temps. La temporisation de PhPDU, dépendante des détails de la couche

physique qui achemine chaque DPDU, peut être inférée à partir des ces temps de début et de fin de DPDU (voir 9.4.3.3).

9.1.9.4.2 Vue d'ensemble d'une transaction D

Comme montré à la Figure 80, la DL prend en charge les transactions en modes tant monodiffusion que diffusion.

Figure 80 – Intervalles de temps de transaction dédiés et partagés

Les transactions en monodiffusion, indiquées dans la moitié gauche de la Figure 80, peuvent utiliser des intervalles de temps dédiés, par exemple, lorsqu'une DLE rend répétitivement compte d'un programme. La duodiffusion est une variante de la monodiffusion, dans laquelle

un second destinataire est programmé pour entendre par hasard la Data DPDU et fournit une seconde DPDU ACK/NAK. La duodiffusion est montrée graphiquement à la Figure 84.

La réception d'une DPDU ACK (acquittement positif) par l'initiateur de la transaction indique que le destinataire de la transaction a reçu avec succès la DPDU Data et qu'il convient que l'initiateur de la transaction marque la transaction comme étant achevée. Les transactions en monodiffusion et duodiffusion exigent l'émission de DPDU ACK/NAK en réponse à une telle réception.

Les transactions en diffusion, indiquées dans la moitié droite de la Figure 80, peuvent également utiliser des intervalles de temps dédiés, comme pour les annonces programmées. Les transactions en diffusion ne peuvent pas utiliser un acquittement immédiat de DL (à savoir par l'intermédiaire d'une DPDU ACK/NAK).

Comme montré dans le quadrant inférieur gauche de la Figure 80, les transactions en monodiffusion et en duodiffusion peuvent utiliser des intervalles de temps partagés, comme au sein de périodes de saut lent. Les intervalles de temps partagés sont communément utilisés pour les répétitions de tentative, les demandes de rattachement, les rapports relatifs à des exceptions et le trafic en salves.

Comme montré dans le quadrant inférieur droit de la Figure 80, les transactions en diffusion telles que des sollicitations peuvent également utiliser des intervalles de temps partagés.

Le terme sans conflits à la Figure 80 n'est pertinent qu'au sein de l'allocation d'intervalles de temps de sous-réseau D. Si deux sous-réseaux D, ou des DLE au sein du même sous-réseau D, allouent des intervalles de temps d'une manière non coordonnée, l'accès n'est pas sans conflits. De même, d'autres utilisateurs du spectre de 2,4 GHz, tels que WiFi, Bluetooth®[9], ZigBee, IEC 62591 et IEC 62601, peuvent potentiellement interférer aussi. La coexistence améliorée avec ces systèmes non coordonnés est réalisée en utilisant la CCA (voir 9.1.9.4.3) pour vérifier la voie avant émission.

L'utilisation de la diffusion dans la présente norme est limitée à ces opérations de DL: annonces et sollicitations. Les annonces et les sollicitations, utilisées pour la découverte de sous-réseau D, sont décrites en 9.1.13.

NOTE La diffusion telle que décrite ici n'utilise pas les MPDU en diffusion définies dans l'IEEE 802.15.4. Voir 9.1.5. La diffusion et la multidiffusion, comme services d'AL, ne sont pas prises en charge dans la présente version de la norme.

9.1.9.4.3 Transaction en monodiffusion

La Figure 81 montre une transaction en monodiffusion.

Figure 81 – Transaction en monodiffusion

Avant qu'une DLE n'émette une DPDU Data dans un intervalle de temps, elle prépare la DPDU Data pour l'émission, généralement avec la sécurité de DL. Avant l'émission, la DLE est normalement configurée pour accomplir une évaluation de voie libre (CCA) de l'espace radio.

La CCA doit être mise en œuvre conformément à la description de l'IEEE 802.15.4. La présente norme spécifie une période de détection de 8 symboles. La CCA doit être accomplie telle que configurée dans le champ de modèle d'intervalle de temps dlmo.TsTemplate[ ].CCAmode (voir Tableau 163), où les choix, énumérés par leur codage, sont:

- CCA Mode 4 (Aloha);
- CCA Mode 1 (énergie au-dessus du seuil);
- CCA Mode 2 (détection de porteuse seulement);
- CCA Mode 3 (détection de porteuse et/ou énergie au-dessus du seuil).

La conformité à l'IEEE 802.15.4 exige qu'au moins un des modes de CCA soit pris en charge. La conformité à l'ETSI EN 300 328 exige que le Mode 1 CCA soit pris en charge. Si une valeur différente de zéro pour dlmo.TsTemplate[ ].CCAmode est sélectionnée et le mode sélectionné n'est pas pris en charge par la DLE, la DLE peut choisir un mode CCA différent

pris en charge par la DLE et autorisé par le régime de réglementation applicable. Les modes CCA pris en charge par la DLE sont spécifiés dans dlmo.DeviceCapability.SupportedCCAmodes; voir 9.4.2.23.

L'IEEE 802.15.4 permet au Mode 3 CCA d'être mis en œuvre soit comme AND (c'est-à-dire ET), soit comme OR (c'est-à-dire OU), du Mode 1 CCA et du Mode 2 CCA. Lorsque le Mode 3 CCA est mis en œuvre comme AND du Mode 1 CCA et du Mode 2 CCA, il peut être utilisé en lieu et place du Mode 1 CCA dans les régimes de réglementation qui exigent le Mode 1 CCA. Lorsque le Mode 3 CCA est mis en œuvre comme OR du Mode 1 CCA et du Mode 2 CCA, il ne peut pas être utilisé en lieu et place du Mode 1 CCA dans les régimes de réglementation qui exigent le Mode 1 CCA.

Si un mode CCA spécifique est exigé par la réglementation, mais n'est pas pris en charge par la mise en œuvre, la DLE ne doit pas initier de transactions.

Si la CCA rapporte un support occupé, la transaction d'émission doit être abandonnée.

L'utilisation de la CCA telle que définie par l'IEEE n'est pas censée exclure des vérifications CCA complémentaires qui pourraient être prises en charge par des appareils évolués. Par exemple, si un routeur dorsal est capable de détecter la modulation IEEE 802.11:2012, la DLE peut raisonnablement exercer un effet de levier sur cette capacité pour détecter et rapporter un support occupé.

Il convient que la CCA soit parachevée 192 μs avant le début de l'en-tête de couche physique.

Si la transaction D exige une DPDU ACK/NAK, la DLE émettrice active son récepteur après l'achèvement de l'émission, à un temps spécifié dans TsTemplate. Si une DPDU ACK est reçue, la DPDU Data émise est supprimée de la file d'attente d'émission de DEL.

Lorsqu'une DLE est programmée pour recevoir une DPDU Data, elle active son récepteur de PhLE au temps spécifié dans le TsTemplate et attend la PhPDU prévue. Si elle détecte un SHR et un PHR IEEE 802.15.4 valides, elle continue de tenter de recevoir la PhPDU complète. Elle traite ensuite les DPDU Data (y compris l'authentification de DMIC) contenues et détermine si la DPDU Data requiert un acquittement. Pour envoyer une DPDU ACK/NAK en acquittement, une DLE qui est une répondeuse de transaction active son émetteur de PhLE et envoie la DPDU ACK/NAK dans le même intervalle de temps de telle sorte que la DPDU ACK/NAK est transmise lors du temps spécifié par le modèle d'intervalle de temps pour la répondeuse principale (ou secondaire, etc.) de l'intervalle de temps en question, selon le rôle de la DLE comme répondeuse primaire (ou secondaire, etc.).

La fenêtre de temps pour chaque DPDU ACK/NAK attendue est définie par le modèle d'intervalle de temps. S'il y a un retard substantiel entre la fin de la DPDU Data et le début programmé de la DPDU ACK/NAK attendue, une mise en œuvre peut raisonnablement mettre hors tension son récepteur pendant le retard.

9.1.9.4.4 Acquittements négatifs

Un destinataire de transaction doit répondre à la réception des DPDU Data en monodiffusion par une DPDU NAK lorsqu'il ne peut pas accepter la DPDU Data à cet instant, mais l'a reçue avec succès sans autres erreurs. Les informations relatives à la synchronisation du temps peuvent être incluses dans des DPDU NAK. De même, une DPDU NAK assure que les statistiques RF journalisent correctement une émission propre. Une DPDU NAK peut être utilisée pour exercer une contre-pression comme un simple mécanisme de contrôle de flux (régulation de débit).

La DL prend en charge deux types de DPDU NAK: NAK0 et NAK1. Une DPDU NAK0 vise à indiquer des limitations de ressources dans le routeur, alors qu'une DPDU NAK1 vise à signaler des problèmes de connectivité aval dans le sous-réseau D.

La DLE doit répondre à une DPDU Data en monodiffusion par une DPDU NAK0 lorsqu'elle reçoit correctement la DPDU Data, mais ne peut pas l'accepter en raison du manque de capacité dans sa file d'attente de messages. Voir 9.1.8.5 pour un débat relatif à la file d'attente de messages de DLE. Une DLE peut également répondre par une NAK0 lorsqu'elle est configurée au-dessus de sa capacité de transmission (ForwardRate), telle que décrite en 9.4.2.23.

La DLE peut répondre à une DPDU Data en monodiffusion par une DPDU NAK1 pour appliquer une contre-pression en cas de perte de connectivité aval. Par exemple, lorsque la DLE perd la connectivité aval à tous ses prochains voisins dans un graphe spécifique et reçoit alors une DPDU Data suivant le même graphe, la DLE peut raisonnablement générer une réponse immédiate DPDU NAK1 afin d'indiquer qu'elle n'est pas capable de transmettre des DPDU Data dirigées vers le même graphe.

Lorsqu'une DLE reçoit une PDU NAK0 ou NAK1 issue d'un voisin, elle doit se replier en n'émettant pas plus de DPDU Data vers le voisin en question pendant une période dlmo.NackBackoffDur. Ce retard de repli n'inclut pas le retard des DPDU Data sans charge utile, ce qui permet à la DLE d'interroger un voisin qui est une source d'horloge de DL pour une mise à jour de temps bien que le voisin n'accepte pas des DPDU Data à l'instant en question.

Comme décrit en 9.1.9.2.2, si l'horloge d'un répétiteur d'horloge de DL a expiré et il est interrogé pour une mise à jour de temps, il convient qu'il réponde par un NAK1.

9.1.9.4.5 Notification d'encombrement explicite

La présente norme prend en charge la notification d'encombrement explicite (ECN) telle que décrite dans l'IETF RFC 3168. L'ECN fournit un mécanisme pour un routeur pour affecter le contrôle de flux de l'AL.

Comme décrit en 12.12.4.2.3, il y a un nombre limité de demandes de source de données qui peuvent attendre simultanément la réponse issue d'un puits de données. Le contrôle de flux à la source de données fonctionne en augmentant par incréments la limite sur les demandes en attente, en fonction de la réception d'acquittements en temps utile du puits de données.

L'ECN fournit un mécanisme par lequel le contrôle de flux peut être efficace sans conduire le sous-réseau D au point de défaillance. Tout routeur le long du chemin allant de la source de données au puits de données peut établir l'ECN pour indiquer que le routeur approche de sa capacité. Lorsque le puits de données reçoit l'ECN, il en fait l'écho à la source de données, qui rend alors compte de l'ECN dans sa logique de contrôle de flux.

Un indicateur d'ECN dans l'en-tête de la DPDU Data peut être positionné par tout routeur de terrain qui est confronté à un encombrement, suivant les lignes directrices dans l'IETF RFC 3168, comme signal indiquant à une source de données qu'il convient qu'elle applique le contrôle de flux pour réduire son utilisation des ressources du réseau D. Cet indicateur d'ECN est propagé vers le puits de données, tel qu'une passerelle, et retourne finalement à la source de donnée par un acquittement de TL.

En outre, la DL fournit un type spécial d'acquittement appelé ACK/ECN. Une DLE recevant un ACK/ECN le traite comme un acquittement de DL normal. En outre, la DLE peut traiter l'ACK/ECN comme étant une indication précoce que l'acquittement du puits de données inclura une ECN.

Il convient de limiter l'utilisation de l'ACK/ECN aux DPDU Data ayant une priorité de sept (7) ou inférieure, correspondant à des flux séquentiels de meilleur effort, placés en file d'attente et temps réel.

9.1.9.4.6 Temps d'attente de DPDU Data

Les temps d'horloge des DLE émettrices et réceptrices sont rarement en parfaite synchronisation. Une DLE émettrice est donc peu susceptible d'émettre une PDU (unité de données de protocole) au temps exact où une DLE réceptrice l'attend. Si une PDU est émise trop tôt, le récepteur pourrait ne pas avoir été encore activé. Si une PDU est émise trop tard, la DLE réceptrice peut avoir désactivé sa radio pour économiser de l'énergie. Le temps d'attente de PDU (PWT) est la période de temps où le récepteur est censé écouter pour détecter des PDU entrantes. Un degré particulier d'exactitude de temporisation entre les DLE est implicite dans la sélection du PWT par le gestionnaire de système.

Les DLE conformes avec la présente norme prennent en charge des PWT configurables et des durées d'intervalle de temps configurables. Le PWT n'est pas directement spécifié dans la norme, mais peut être inféré dans des modèles d'intervalle de temps à partir des temps au plus tôt et au plus tard auxquels la réception de PDU commence. Voir Tableau 161.

NOTE 1 Le présent tutoriel ne fait pas de distinction entre les temporisations de PhPDU et de DPDU. Comme spécifié en 9.4.3.3, la DL suit une convention consistant à spécifier la temporisation d'intervalle de temps en référence à la DPDU (PhSDU), pas à la PhPDU. Dans les mises en œuvre basées sur l'IEEE 802.15.4 (2,4 GHz), la détection d'en-tête de PhPDU implique la réception d'un préambule, d'un délimiteur de début de trame (SFD), et d'une longueur de trame, pour un en-tête total de PhPDU de 192 μs (6 octets) avant que la DPDU ne commence. De même, l'émission radio d'une PhPDU commence 192 μs avant le temps de début nominal de DPDU.

Des temps d'attente de PDU dans une PDU en monodiffusion sont montrés à la Figure 82. Les mêmes principes s'appliquent à d'autres types de PDU.

Figure 82 – Temps d'attente de PDU (PWT)

La durée PWT est configurée par le gestionnaire de système rendant compte de la stabilité intrinsèque des horloges des DLE émettrices et réceptrices, et du temps maximal garanti entre les mises à jour d'horloge.

Par exemple, si les DLE émettrices sont exactes à ±1 ms près par rapport au récepteur dans la période d'expiration d'horloge (dlmo.ClockExpire), il convient que le PWT du récepteur ait une longueur de 2 ms. Une DLE émettrice moins exacte exigera un plus long PWT de récepteur ou une plus courte période d'expiration d'horloge. (Dans cet exemple, il convient que le temps d'écoute de la radio soit légèrement plus long que le PWT de 2 ms, pour rendre compte des durées de SHR et de PHR de la PhPDU.)

Si, à la fin de son PWT, le récepteur ne commence pas à recevoir la PDU attendue, le récepteur est autorisé à désactiver sa radio pendant la durée de l'intervalle de temps.

Des durées d'intervalle de temps de 10 ms ont un budget de temporisation qui peut allouer environ 2 ms au PWT. Pour un PWT plus long, soit les autres allocations doivent être réajustées, soit la durée d'intervalle de temps doit être augmentée. Par exemple, si le sous-réseau D prend en charge des DLE qui dorment pendant une durée pouvant atteindre deux minutes au maximum, des erreurs de temporisation d'environ ±2 ms peuvent s'accumuler entre les comptes-rendus. Cela peut être pris en charge en augmentant le PWT de (par exemple) 2 ms à 4 ms, avec une augmentation correspondante de la durée d'intervalle de temps et de la consommation d'énergie de récepteur.

NOTE 2 Les DLE avec des intervalles entre rapports peu fréquents sont capables d'être configurées pour vérifier périodiquement le sous-réseau D afin de détecter des DPDU Data recevables. Ces DLE sont capables de recevoir des corrections d'horloge par le sous-en-tête DAUX comme partie intégrante du même processus.

9.1.9.4.7 Transactions en duodiffusion/N-diffusion

Duodiffusion/N-diffusion est une variante de la monodiffusion, dans laquelle un ou plusieurs récepteurs supplémentaires sont programmés pour entendre par hasard les DPDU Data et fournir des acquittements supplémentaires. Duodiffusion/N-diffusion fournit la prise en charge d'accès contrôlée par la latence à une dorsale avec une probabilité accrue de succès au premier essai. Les transactions duodiffusion/N-diffusion sont principalement destinées pour des DLE avec des liaisons à deux ou plus de deux DLE d'infrastructure, en particulier à des routeurs dorsaux (voir la Figure 83).

Figure 83 – Prise en charge de duodiffusion dans la norme

Les DLE recevant des acquittements duodiffusion/N-diffusion, cerclées à la Figure 83, ont besoin d'être configurées avec des modèles d'intervalle de temps avec une fenêtre d'écoute étendue pour l'(les) acquittement(s) complémentaire(s). Les DLE envoyant les acquittements duodiffusion/N-diffusion secondaires (l'une des DLE grises cerclées à la Figure 83, par

exemple) ont besoin d'être configurées individuellement avec des modèles d'intervalle de temps avec les fenêtres d'acquittements correctement différées/harmonisées pour leurs acquittements individuels, et avec l'adresse du destinataire primaire prévu pour leur permettre de répondre seulement à la DPDU Data attendue. La prise en charge de la duodiffusion/N-diffusion implique habituellement une plus longue durée d'intervalle de temps d'environ 1 ms à 2 ms par destinataire secondaire, telle que configurée par le gestionnaire de système.

NOTE 1 La coordination de la réponse de duodiffusion/N-diffusion peut impliquer la coordination arrière-voie entre les DLE d'infrastructure répondeuses (car de tels répondeurs sont habituellement des routeurs dorsaux qui sont également connectés à une dorsale de débit plus élevé), mais la coordination par l'intermédiaire de la messagerie de configuration normalisée est également possible, selon la conception des DLE d'infrastructure.

NOTE 2 Si la probabilité de succès d'une seule transaction en monodiffusion acquittée est de p, la probabilité d'échec pour une telle transaction en monodiffusion est de $(1 – p)$. Pour la transaction en duodiffusion correspondante, elle est typiquement de $(1 – p)^2$, alors que dans le cas général pour une transaction en N-diffusion, elle est de $(1 – p)^N$. Ainsi lorsque p = 95 %, la probabilité d'échec est de 5 % pour une transaction en monodiffusion, de 0,25 % pour une duodiffusion, de 0,0125 % pour une transaction en tridiffusion, etc. Ainsi, dans la plupart des environnements relativement planaires, la duodiffusion suffit, mêmes si dans les environnements tridimensionnels fortement métalliques et obstrués tels que les plateformes pétrolières aux larges des côtes (offshore), la tridiffusion peut mériter une prise en considération.

NOTE 3 Dans plusieurs cas, la duodiffusion concerne des contrats avec une taille maximale d'APDU réduite, de telle sorte que les DPDU Data qui initient une transaction ainsi que les sous-baies DPDU et ACK/NAK n'exigent pas une durée supérieure à une transaction en monodiffusion de charge utile maximale avec un acquittement DPDU Data unique et ses acquittements uniques ultérieurs de DPDU ACK/NAK. Dans ce cas, une durée d'intervalle de temps unique est utilisable par les transactions en monodiffusion et les transactions en duodiffusion restreintes, avec toutefois des modèles de transactions différents.

Des intervalles de temps de duodiffusion/N-diffusion peuvent être programmés conjointement avec la largeur de bande numérique disponible pour une répétition de tentative rapide sur une voie alternative (voir Figure 66).

La Figure 84 montre une transaction impliquant l'émission et la réception en duodiffusion.

Figure 84 – Transaction en duodiffusion

Dans l'exemple de la Figure 84, la DPDU Data est adressée au récepteur 1, le destinataire primaire, et est entendue par hasard par le récepteur 2, un destinataire secondaire. Pour des transactions en duodiffusion/N-diffusion, l'adresse de destination de la DPDU Data est mise à celle du destinataire primaire (récepteur 1 à la Figure 84), et un acquittement est attendu en provenance d'au moins un destinataire au cours du même intervalle de temps. Comme illustré à la Figure 84, le destinataire primaire émet une DPDU ACK/NAK à la réception de la DPDU Data. Les destinataires secondaires émettent également une DPDU ACK/NAK, mais après un retard dépendant du destinataire afin d'accorder du temps pour permettre à toutes les DPDU ACK/NAK antérieurs de s'achever.

Si une DPDU ACK est reçue d'un quelconque destinataire donnant acquittement, la transaction est achevée et la DPDU Data est supprimée de la file d'attente de messages de la DLE à l'origine de la transaction.

Si une DPDU ACK est reçue d'un destinataire, la DLE à l'origine de la transaction n'est pas tenue de dépenser l'énergie à recevoir et traiter toute DPDU ACK/NAK subséquente. Cependant, il convient que la DLE à l'origine de la transaction vérifie périodiquement qu'elle est capable de recevoir une DPDU ACK/NAK issue de chaque destinataire censé donner acquittement, pour confirmer la disponibilité ininterrompue des récepteurs secondaires.

Comme noté en 9.1.5 et décrit en 9.3.4, un acquittement en duodiffusion/N-diffusion issu d'un destinataire secondaire inclut le champ adresse propre de la DLE donnant acquittement dans le champ adresse de source du MHR. Cela permet à l'initiateur de transaction d'identifier la source de l'acquittement et de rapporter épisodiquement celle-ci au gestionnaire de système/sécurité pour faciliter la détection des cyberattaques.

9.1.9.4.8 Intervalles de temps partagés avec CSMA/CA

Les transactions en monodiffusion peuvent se produire dans les intervalles de temps qui sont dédiés à une liaison spécifique. En variante, des intervalles de temps partagés peuvent être désignés pour fournir la largeur de bande à la demande à un ensemble de DLE. Des intervalles de temps partagés sont habituellement configurés pour émettre seulement près du début de l'intervalle de temps.

Les modèles d'intervalle de temps spécifient le temps d'émission sous la forme d'une plage conformément à 9.4.3.3. A tout le moins, le temps d'émission doit être configuré à une plage d'au moins 192 μs, permettant ainsi la prise en charge de ± 96 μs (± 6 périodes symboles PHY) de gigue qui est admissible dans un initiateur de transaction. Si la plage de temps d'émission est configurée pour être supérieure à 200 μs, la DLE doit sélectionner un temps randomisé au sein de la plage pour commencer son émission, faisant de la place raisonnable pour les caractéristiques réelles de gigue d'émission de la DLE.

La Figure 85 montre l'utilisation d'un intervalle de temps partagé avec CSMA/CA.

Figure 85 – Intervalles de temps partagés avec CSMA/CA active

Dans l'exemple de la Figure 85, deux DLE se disputent l'utilisation de la voie dans un intervalle de temps partagé. Cette approche est utilisée pour tous les intervalles partagés, configurables pour être utilisés de diverses façons.

Les priorités au sein d'un intervalle de temps partagé peuvent être gérées en configurant les DLE avec différents modèles d'intervalle de temps. Une DLE avec une DPDU Data de haute priorité, telle qu'une répétition de tentative pour une transaction en duodiffusion ayant échoué, peut être configurée pour émettre sa DPDU Data le plus tôt possible au sein de l'intervalle de temps. Une DLE avec des exigences moins critiques peut être configurée pour retarder son émission à un instant légèrement plus tardif dans l'intervalle de temps, tel que 2 ms plus tard. Si une autre DLE a déjà revendiqué l'intervalle de temps, comme montré à la Figure 85, la CCA de la DLE retardée pourrait (ou pourrait ne pas) détecter que la voie est utilisée et, en conséquence, différer son émission à un autre intervalle de temps.

L'utilisation de CSMA/CA active dans des intervalles de temps partagés peut impliquer des configurations avec de plus longs intervalles de temps et de plus longs temps d'attente de DPDU Data, et l'utilisation de plus d'énergie de récepteur.

9.1.9.4.9 Transactions au cours des périodes de saut de voie lent

Certaines DLE n'ont pas une base de temps suffisamment stable pour communiquer à leur débit de messagerie normal au sein de courts intervalles de temps. Ces DLE peuvent avoir besoin d'utiliser des périodes de saut lent pour leur communication. Les périodes de saut de voie lent sont simplement un jeu d'intervalles de temps concaténés sur la même voie, dans lequel le récepteur fait marcher sa radio sans interruption et l'initiateur de transaction n'est pas tenu de respecter les frontières d'intervalle de temps au sein de la période de saut lent.

Comme montré à la Figure 86, une transaction au cours d'une période de saut de voie lent est très similaire à une transaction en monodiffusion dans un intervalle de temps partagé, excepté que l'émission de DPDU Data peut se produire n'importe où dans la période de saut de voie lent. Les DLE émettrices visent le début d'un intervalle de temps spécifique au sein d'une période de saut de voie lent, selon le propre sens du temps de l'initiateur, qui n'est pas tenu d'être très bien synchronisé avec celui du/des récepteur(s) prévu(s). Les DLE émettrices utilisent la CCA pour vérifier la voie avant émission. En l'absence d'opérations prioritaires de plus haute priorité (telles que la transmission des DPDU Data), un récepteur hébergeant la période de saut de voie lent fait marcher son récepteur radio sans interruption, sauf pour répondre aux DPDU Data qu'il reçoit.

Figure 86 – Transaction au cours des périodes de saut de voie lent

Les DLE peuvent cibler n'importe quel intervalle de temps au sein d'une période de saut de voie lent, avec une mise en garde majeure: le temps programmé d'intervalle de temps de DPDU Data doit augmenter avec chaque transaction.

Il convient que les DLE respectent les frontières d'intervalle de temps au sein des périodes de saut de voie lent du mieux qu'elles peuvent. Si toutes les DLE au sein des périodes de saut de voie lent sont bien dressées, avec des horloges bien synchronisées, les performances résultant sont approximativement comparables à celles du protocole ALOHA discrétisé.

Une DLE dont le sens de temps diffère de celui de ses récepteurs prévus émettra nominalement près du début d'un intervalle de temps particulier, selon son propre sens de temps. Cependant, une telle DLE peut réellement initier l'émission dans n'importe quelle phase de n'importe quel intervalle de temps au sein de la période de saut de voie lent.

Par exemple, une DLE qui a une source d'horloge avec une stabilité de $\pm 50 \times 10^{-6}$ sur un intervalle de quelques minutes, en raison de fluctuations environnementales non compensées, peut dormir plus de 3 min entre les transactions, ce qui correspond à une dérive d'horloge de ±9 ms environ. Une DLE de ce type pourrait attendre une annonce programmée pour se faire resynchroniser avant l'émission. En variante, elle pourrait émettre au cours d'une période de saut de voie lent (si disponible) et recevoir la synchronisation de temps dans l'acquittement. En continuant cet exemple, une DLE avec une exactitude de ±9 ms sélectionnerait un des intervalles de temps au sein de la période de saut de voie lent, et émettrait en utilisant le modèle approprié de liaison. La DLE émettrait nominalement dans un intervalle de temps particulier, selon le propre sens du temps de la DLE, mais peut réellement émettre dans un intervalle de temps différent.

Dans cet exemple, il convient que la DLE ne tente pas d'émettre dans le premier ou le dernier intervalle de temps dans la période de saut de voie lent, car elle peut réellement émettre à l'extérieur de la plage de temps disponible. Il est de la responsabilité de la DLE d'éviter de sélectionner des intervalles de temps incompatibles avec les capacités de chronométrage de la DLE, rendant compte de la propre dérive d'horloge non étalonnée de la DLE en combinaison avec la dérive d'horloge de 10×10^{-6} autorisée pour un routeur voisin ou la dérive d'horloge de 100×10^{-6} autorisée pour un appareil de terrain voisin autre que de routage.

Toutes les DPDU Data dans des périodes de saut de voie lent doivent inclure un octet supplémentaire dans l'en-tête de DPDU Data pour indiquer quel décalage d'intervalle de temps au sein de la période de saut de voie lent était prévu. Cela permet à la DLE réceptrice de reconstruire les informations relatives aux intervalles de temps issues de la DLE émettrice, d'appliquer la correction de temps à travers les intervalles de temps, de valider l'exactitude de l'horloge de l'initiateur de transaction, et d'utiliser le temps de début programmé de l'intervalle

de temps comme support de sécurité pour l'authentification de message. (Cela est spécifié dans les sous-en-têtes Media Access Control de DPDU Data, DMXHR; voir 9.3.3.4.)

S'il y a lieu, un décalage corrigé d'intervalle de temps est fourni dans l'acquittement (voir 9.3.4). L'identification non ambiguë d'intervalle de temps partagé est nécessaire tant à l'initiateur de transaction qu'aux récepteurs de transaction pour authentifier la DPDU Data et resynchroniser le temps. Même si la DLE émettrice a un sens de temps hautement exact, les DLE réceptrices pourraient ne pas en avoir. Par conséquent, l'octet de décalage de saut de voie est exigé pour toutes les DPDU Data utilisant une supertrame de saut de voie lent.

L'intervalle de temps initial au sein d'une période de saut de voie lent est défini comme ayant un décalage de zéro.

9.1.10 Adressage de sous-réseau D

9.1.10.1 Types d'adresse

Les adresses DL16Addresses doivent toujours être utilisées au sein d'un sous-réseau D, excepté que les adresses EUI64Addresses sont utilisées d'une manière limitée au cours de la phase initiale du processus de rattachement pour communiquer avec l'appareil se rattachant.

Chaque DLE dans un sous-réseau D est identifiée de trois façons:

- Chaque DLE de sous-réseau D a un identificateur d'adresse EUI64Address qui est présumé être unique.
- Chaque DLE conforme à la présente norme doit avoir au moins une adresse IPv6Address assignée lorsqu'elle rejoint le sous-réseau D. Cependant, au sein de la DL, seul le pseudonyme (alias) DL16Address pour cette adresse IPv6Address (décrite ci-après) doit être utilisé.
- Chaque DLE ou appareil étranger qui est accessible à travers un sous-réseau D a une adresse DL16Address unique dans un sous-réseau D, qui est un pseudonyme pour son adresse IPv6Address. La portée de toute adresse DL16Address doit être limitée à un sous-réseau D particulier.

L'adresse EUI64Address doit être utilisée comme une nouvelle adresse de DLE pour l'adressage de voisin immédiat avant et pendant le processus de rattachement. Une fois qu'une DLE a rejoint le sous-réseau D et reçu son adresse IPv6Address, elle doit être adressée soit par son adresse IPv6Address, soit par son pseudonyme DL16Address local à un sous-réseau D pour l'adresse IPv6Address en question.

L'adresse EUI64Address est également utilisée dans chaque nonce de sécurité de la DPDU. Chaque fois qu'une adresse DL16Address est utilisée dans une DPDU Data ou une DPDU ACK/NAK, le(s) destinataire(s) de la DPDU a(ont) besoin d'une connaissance a priori de l'adresse EUI64Address correspondante. Ces informations relatives aux voisins sont fournies par le gestionnaire de système comme partie intégrante du processus d'établissement de liaison. Une exception est faite pour une nouvelle DLE qui communique avec un voisin qui a annoncé son adresseDL16Address. Dans ce cas, la DLE de la DLE se joignant doit acquérir l'adresse EUI64Address de la DLE annonciatrice en initiant une transaction avec ce voisin, lui envoyant une DPDU Data avec une charge utile vide tout en demandant l'adresse EUI64Address dans la DPDU ACK/NAK de réponse, comme décrit en 9.3.3.3. Pour cette transaction d'amorçage, la clé D applicable est K_global, utilisée avec un DMIC-32, qui est la même que pour d'autres DPDU Data impliquant une adresse EUI64Address. (Voir 9.1.11 pour un débat relatif à la sécurité de DL.)

Lorsqu'une adresse DL16Address se réfère à une DLE au sein d'un sous-réseau D, l'adresse DL16Address est toujours l'adresse MAC 16 bits de la DLE. Lorsqu'une DPDU Data contient une adresse DL16Address qui se réfère à un appareil hors de la portée du sous-réseau D, la DPDU Data est acheminée vers une DLE qui est en service comme routeur dorsal, qui effectue un mapping de l'adresse DL16Address à sa contrepartie d'adresse IPv6Address.

La plupart des DPDU Data incluent deux adresses DL16Addresses de source et deux adresses DL16Addresses de destination. Une paire d'adresses DL16Address source/destination est pour l'adressage de prochain saut à la sous-couche MAC. Une deuxième paire d'adresses DL16Address source/destination (des pseudonymes D, en fait) est au sein du sous-en-tête DADDR de la DPDU Data, où elles spécifient les NLE source et destination finales locales à un sous-réseau D via leurs pseudonymes D.

Le routage est habituellement spécifié par des graphes, pas par des adresses D. Cependant, lorsque le routage par source est utilisé au sein d'un sous-réseau D, des adresses DL16Address sont normalement utilisées. Encore une fois, la seule exception est que les adresses EUI64Address sont utilisées pendant le processus de rattachement pour la communication avec un voisin immédiat au sein du sous-réseau D.

9.1.10.2 Identificateur de sous-réseau et unicité des adresses DL16Address

La portée d'une adresse DL16Address est un sous-réseau D. Un sous-réseau D voisin peut utiliser la même adresse DL16Address pour référencer une DLE différente. Des sous-réseaux D différents peuvent utiliser des adresses DL16Address différentes pour se référer au même appareil de dorsale.

Chaque sous-réseau D a un identificateur de sous-réseau D de 16 bits (dlmo.SubnetID; voir 9.4.2.1), qui a la même valeur que le PAN ID situé dans l'en-tête de MPDU de l'IEEE 802.15.4. Dans la portée d'un réseau, chaque sous-réseau D doit avoir un dlmo.SubnetID unique. Au sein de la portée d'un réseau, chaque sous-réseau D doit avoir une dlmo.SubnetID unique. Cependant, des réseaux différents ne sont pas nécessairement coordonnés et, donc, il n'est pas garanti que les dlmo.SubnetID à travers les réseaux conformes à la norme contigus sont uniques. Ainsi, il est possible, bien que peu probable, qu'une DPDU issue d'un différent sous-réseau D conforme à la norme soit reçue avec ce qui semble être une adresse DL16Address valide et un PAN ID valide. La DLE se fonde sur le DSC pour rejeter de telles DPDU à la réception en raison d'une discordance de DMIC ou d'une non-authentification de DMIC, discordance due à des clés symétriques de sécurité D non identiques.

SubnetID=0x0000 et SubnetID=0xFFFF ne doivent pas être utilisés comme ID de sous-réseau D dans la présente norme. SubnetID=0x0001 est réservé pour les sous-réseaux D de configuration (voir 13.1) et ne doit pas être autrement utilisé.

9.1.11 Service gestion de DL

9.1.11.1 Généralités

Des messages de gestion vers une DLE sont entièrement sécurisés à l'AL, en utilisant la relation de bout en bout entre le gestionnaire de système/sécurité et le DMAP de la DLE.

La MAC de DL basée sur l'IEEE 802.15.4 n'est pas accessible directement par le DMAP, elle est à la place configurée indirectement à travers la DMSAP. Cela isole le reste de la présente norme par rapport aux changements évolutifs apportés aux spécifications de l'IEEE, facilite la future adoption de spécifications de couche physique de remplacement (par exemple, radios), qui peuvent avoir des MAC associées alternatives ou améliorées, et permet que certains aspects opérationnels de MAC et de PHY (tels que CCA) soient utilisés ou pas, sur une base d'intervalle de temps par intervalle de temps.

Comme montré à la Figure 87, la gestion de DL commande généralement le flux à travers la pleine pile de protocoles de communication définie par la présente norme.

Figure 87 – Flux de SAP de gestion de DL à travers une suite normalisée de protocoles

Une DLE est configurée par l'intermédiaire de son DMAP par le biais de DMSAP. La plupart des SAP de gestion sont génériques, lisant et établissant simplement des structures de données au sein de la couche. Ces structures de données définissent généralement comment une DLE exploite son diagramme d'états. Le DMAP communique avec le gestionnaire de système par la sous-couche d'application, en utilisant la sécurité de bout en bout.

Pour des informations relatives au traitement général des objets de gestion normalisés, voir 6.2.5 et 6.2.6.

9.1.11.2 Attributs de gestion et attributs indexés

Les DMSAP impliquent la manipulation de l'objet de gestion de DL (DLMO). Le DLMO inclut une diversité d'attributs qui sont utilisés pour configurer la DLE et/ou rapporter son statut.

Certains attributs de DLMO s'appliquent à des valeurs spécifiques. Par exemple, l'attribut dlmo.SubnetID fournit l'ID de sous-réseau pour le sous-réseau D que la DLE a rejoint.

Certains attributs de DLMO peuvent être visualisés sous forme de tableaux avec un ensemble de rangées à indices. Chaque attribut de ce type est spécifié comme un OctetString indexé. Par exemple, la DLE inclut l'attribut dlmo.Neighbor, qui est un attribut OctetString indexé contenant un ensemble de DLE voisines. Chaque entrée de l'attribut dlmo.Neighbor inclut un jeu de champs pour le voisin en question, tel qu'un indicateur signalant si ce voisin est une source d'horloge de DL ou non. Chaque entrée de la table dlmo.Neighbor est identifiée de façon univoque par l'adresse DL16Address du voisin. Les attributs OctetString indexés dans le DLMO comprennent:

- dlmo.Ch: modèles de saut de voie;
- dlmo.TsTemplate: modèles d'intervalle de temps;
- dlmo.Neighbor: voisins de DLE;
- dlmo.NeighborDiag: diagnostics pour voisins de DLE;
- dlmo.Graph: graphes pour routage;
- dlmo.Superframe: supertrames spécifiant des attributs communs pour clés associées;
- dlmo.Link: liaisons, dont chacune est associée à une supertrame;
- dlmo.Route: chemins utilisables dans des sous-en-têtes DROUT.

Les relations entre ces attributs sont décrites en 9.4.3.1.

Les attributs de DLMO doivent être maintenus à travers le DMAP en utilisant les méthodes qui sont décrites à l'Article 9 et à l'Article 12. Les services Read et Write de l'ASLE décrits dans le Tableau 271 fournissent un cadre général pour lire et écrire des attributs de DLMO. Les méthodes pour écrire des attributs qui doivent devenir actifs au temps TAI de basculement, ainsi que les méthodes pour lire et écrire des attributs OctetString indexés, sont décrites en 9.5.

Le format des attributs de DLMO est défini dans la spécification de la DLE. Lorsque ces objets sont intégrés au sein de messages par liaison radio, les formats spécifiés doivent être utilisés. La présente norme ne contraint pas (et ne peut pas contraindre) la façon dont les données sont stockées au sein d'une DLE, ou définir comment les informations correspondantes sont relayées en internes à une DLE.

9.1.11.3 Messages de gestion issus de voisins immédiats

Toute DPDU Data peut inclure un sous-en-tête DAUX, par exemple transportant des informations d'annonce issues d'un voisin immédiat. Les informations de sous-en-tête DAUX ne sont pas propagées à des couches supérieures de la suite de protocoles de communication. Dans la plupart des cas, le contenu du sous-en-tête DAUX est destiné au processus de gestion des DLE de destinataires, qui à son tour peut utiliser ces informations pour configurer le diagramme d'états de la DLE. Par exemple, le sous-en-tête DAUX peut inclure des définitions de supertrame qui sont prévues être utilisées par la DLE comme point de départ dans le processus de rattachement et/ou pour la découverte de voisins.

Le sous-en-tête DAUX est modélisé comme étant instantanément visible au DMAP et immédiatement soumis à une action s'il y a lieu.

NOTE Sachant que les normes s'appliquent seulement aux aspects visibles extérieurement, l'interface DMSAP interne n'est pas soumise à normalisation.

9.1.11.4 Plusieurs sous-réseaux D

Les objets de gestion de DL prennent en charge un seul sous-réseau D actif à la fois. Toutes les adresses DL16Addresses doivent être uniques dans la portée du seul sous-réseau D en

question. Cette contrainte n'empêche pas un appareil de participer simultanément à plusieurs sous-réseaux D. Plusieurs sous-réseaux D pourraient être modélisés comme plusieurs instances d'une DLE, mais une telle opération n'est pas spécifiée par la présente norme.

Si dlmo.SubnetID=0, la DLE ne participe pas encore au sous-réseau D.

9.1.11.5 Plusieurs PhLE (radios)

Chaque DSAP d'une DLE est supposé être associé à une seule PhLE (radio). Cela n'empêche pas des mises en œuvre avec plusieurs radios, qui pourraient être modélisées comme plusieurs instances d'une DLE. Une telle opération n'est pas spécifiée par la présente norme.

9.1.12 Relation entre DLE et DSC

La relation entre la DLE et le DSC est décrite en 7.3.2. Une revue soignée de 7.3.2 est essentiel pour quiconque qui souhaite comprendre complètement le fonctionnement de la DLE.

Généralement, la DLE s'appuie sur le DSC pour l'authentification, l'intégrité et la confidentialité conditionnelle. Toutes les DPDU incluent un DMIC qui valide sans ambiguïté qu'une MPDU a comme source une DLE qui a partagé la même clé de sous-réseau D, vs. celles qui mettent en œuvre un autre protocole utilisant une modulation, un codage et des voies similaires. Le DMIC utilise une clé de sécurité non secrète pendant le processus de rattachement; mais il est habituellement configuré pour utiliser une clé secrète partagée une fois que la DLE s'est rattachée.

Les DPDU Data ACK/NAK sont étendues par la DLE, en insérant le DMIC de la DPDU dans l'en-tête DPDU ACK/NAK, comme un champ virtuel avant d'être traitées par le DSC. Ce champ virtuel, qui n'est pas émis, est inclus dans le calcul du DMIC de la DPDU ACK/NAK. Ainsi, le DMIC de la DPDU Data est essentiellement repris en écho dans la DPDU ACK/NAK sans émettre réellement le champ. De cette manière, la DPDU ACK/NAK est liée sans ambiguïté aux DPDU Data correspondantes de la transaction D.

9.1.13 Découverte de voisins de DLE

9.1.13.1 Généralités

Les sous-réseaux D sans fil conformes à la présente norme sont détectés par la DLE. Une nouvelle DLE peut entendre les annonces issues de DLE voisines qui ont déjà rejoint un sous-réseau D d'intérêt. Cela s'appelle la découverte de voisins. A la suite de la découverte de voisins, la DLE peut rejoindre le sous-réseau D comme décrit en 7.4.

Les processus d'annonce de DL et de découverte de voisins de DL sont les blocs modules de base qui permettent à une DLE d'apprendre les adresses DL16Address et EUI64Address d'un routeur voisin, et le jeu de liaisons programmées qui ont été allouées pour être utilisées lors du rattachement. Ces informations sont ensuite utilisées par la DLE et la DME pour rejoindre le sous-réseau D.

Les DLE découvrent les sous-réseaux D par l'intermédiaire des DPDU Data d'annonce reçues en provenance d'une ou plusieurs DLE d'annonce qui annoncent périodiquement leur présence. Une DLE d'annonce est capable d'agir comme un proxy dans le processus de configuration ou de rattachement. Une annonce contient des informations qui permettent à une nouvelle DLE d'envoyer une demande de rattachement à la DLE d'annonce, pour la relayer à un gestionnaire de système, et de recevoir un certain temps plus tard une réponse de rattachement.

Après avoir rejoint un sous-réseau D, la DLE reçoit des DPDU Data d'annonce issues de DLE voisines dans le sous-réseau D et dresse une liste locale de voisins candidats avec lesquels elle peut avoir des communications de qualité raisonnable. Cette liste de candidats est

rapportée à un gestionnaire de système par l'intermédiaire de l'attribut dlmo.Candidates. Le gestionnaire de système utilise ces informations pour déterminer comment les DLE s'adaptent dans la topologie de sous-réseau D. A leur tour, ces informations sont utilisées pour établir des relations de communication entre la nouvelle DLE et ses voisins.

Les DLE d'annonce peuvent être découvertes en utilisant le balayage passif, le balayage actif, ou une combinaison de balayage passif et actif.

Dans le balayage passif, la DLE se met périodiquement à l'écoute pour détecter des annonces sur une série de voies. En général, une DLE de balayage passif alimentée par batterie se mettra fréquemment à l'écoute lorsqu'elle est mise sous tension pour la première fois. Si un sous-réseau D n'est pas découvert rapidement, la DLE peut prolonger la durée de vie de sa batterie en balayant moins fréquemment et/ou en allouant des intervalles de temps plus courts pour chaque balayage. De telles réductions peuvent conduire à des retards substantiels dans le rattachement au sous-réseau D et/ou de formation de sous-réseau D, et ne sont donc utilisées que si la stratégie de rattachement rapide a échoué.

Le balayage actif surmonte certains inconvénients du balayage passif. Les DLE qui sont configurées pour le balayage actif recherchent un sous-réseau D en émettant périodiquement des DPDU de sollicitations, qui déclenchent en réponse les DPDU Data de sollicitations issues de routeurs voisins. La DLE émettant la DPDU Data de sollicitation est appelée un interrogateur de balayage actif, alors que la DLE répondeuse est appelée un hôte de balayage actif. Les hôtes de balayage actif dépensent de l'énergie à faire fonctionner leurs récepteurs radio pendant l'écoute pour détecter des DPDU Data de sollicitation. Certains hôtes de balayage actif ont de l'énergie disponible pour le fonctionnement continu de récepteur. Des hôtes de balayage actifs avec des sources d'énergie plus limitées peuvent être configurés pour écouter sans interruption pendant certaines périodes de temps, comme pendant la formation de sous-réseau D.

Des programmes de liaison utilisés pour le rattachement ne sont pas nécessairement liés à des programmes de supertrame utilisés pour le fonctionnement normal du sous-réseau D. Ainsi, peu d'informations relatives au fonctionnement du sous-réseau D ont besoin d'être acheminées dans les annonces.

9.1.13.2 Sous-en-tête auxiliaire et annonces

Les annonces et les sollicitations de DL sont acheminées dans un sous-en-tête auxiliaire de DPDU Data (DAUX) au sein de l'en-tête de DPDU (DHR). Voir 9.3.1 pour une vue d'ensemble du DHR. Une DPDU Data qui achemine une sollicitation est appelée une DPDU de sollicitation. De même, une DPDU Data qui achemine une annonce est appelée une DPDU d'annonce.

Le sous-en-tête DAUX est habituellement absent d'un DHR, mais doit être inclus dans tout DHR s'il est configuré ainsi pour liaison particulière. Une DPDU Data contenant un sous-en-tête DAUX peut également transporter une charge utile de couche supérieure qui est sans rapport avec la fonction de découverte de voisins.

L'émission d'une annonce est déclenchée par un fanion d'annonce tel que configuré au sein d'une définition de liaison. Le fanion d'annonce indique qu'une annonce doit être émise dans un intervalle de temps de supertrame, en l'absence d'une liaison de priorité plus haute.

La même définition de liaison peut également inclure un fanion d'émission, auquel cas la DLE doit vérifier la file d'attente de messages pour déceler des DPDU Data sortantes concordantes. Ainsi, la DPDU Data peut transporter simultanément:

- une annonce; et
- une charge utile de DSDU qui est complètement sans rapport avec l'annonce.

La capacité de charge utile de la DPDU Data est réduite lorsqu'une annonce est intégrée au sein du DHR. Certaines DPDU Data dans la file d'attente de messages, en particulier les messages qui ont été fragmentés à la NL, peuvent être trop longues pour être combinées avec une annonce. De tels messages ne sont pas des candidats pour les liaisons qui sont partagées avec une annonce, donnant effectivement à l'annonce l'accès prioritaire à ces intervalles de temps.

NOTE Lorsque des messages sont fragmentés par la NL, la taille du fragment est établie par la NL avant d'être passée à la DLE, la taille de fragment étant configurée par le gestionnaire de système. Dans les configurations où des annonces sont rarement combinées à des liaison d'émission, la taille maximale du fragment est souvent limitée par la capacité de charge utile de la DPDU Data sans considérer l'annonce combinée.

En général, les DPDU Data contenant une annonce utilisent un DMIC basé sur la clé de sécurité du sous-réseau D, fournissant ainsi une annonce à laquelle les DLE peuvent faire confiance après qu'elles ont rejoint le sous-réseau D. Ce DMIC ne peut pas être validé avant le rattachement, car une DLE non rattachée n'a pas encore la clé de sécurité de sous-réseau D. Par conséquent, une DLE non rattachée qui balaye pour trouver un sous-réseau D est autorisée à traiter une annonce dans un sous-en-tête DAUX, même si elle est incapable d'authentifier la DPDU Data contenant le DAUX.

Sans la garantie d'un DMIC, une DLE non rattachée recevant une annonce peut toujours utiliser la FCS de l'IEEE 802.15.4 comme contrôle d'intégrité. Cependant, la FCS de l'IEEE 802.15.4 seule ne filtre pas les MPDU issues d'autres systèmes qui utilisent l'EEE 802.15.4. Par conséquent la présente norme fournit un contrôle d'intégrité supplémentaire, n'impliquant pas de clé de sécurité, couvrant spécifiquement le sous-en-tête d'annonce, telle que spécifiée en 9.3.5.2.4.3.

9.1.13.3 Sollicitation de balayage actif et réponse

Dans le balayage actif, une nouvelle DLE, agissant comme un interrogateur de balayage actif, sollicite périodiquement des annonces issues d'hôtes qui se trouvent être dans la plage radio. Une DLE recevant la sollicitation peut être configurée pour répondre avec une annonce.

Le balayage actif est destiné pour les configurations dans lesquelles une DLE d'annonce, en sa qualité d'hôte de balayage actif, est capable faire fonctionner son récepteur de façon plus ou moins continue dans une configuration de saut de voie lent. Des hôtes de balayage actif peuvent être alimentés en puissance sans interruption. En variante, ils peuvent être des DLE à énergie contrainte qui font marcher leurs récepteurs dans une configuration de saut de voie lent pendant des périodes limitées, comme pendant la formation de sous-réseau D.

La demande de sollicitation est codée dans le sous-en-tête DAUX de la DPDU Data de sollicitation. Une DPDU Data de sollicitation ne doit pas contenir une charge utile de NL.

Une DPDU Data de sollicitation, lorsqu'elle est reçue par une DLE hôtesse de balayage actif, amène cette DLE à une DPDU Data d'annonce dans le prochain intervalle de temps si la DLE est ainsi configurée. Un routeur recevant une DPDU Data de sollicitation doit répondre en émettant une DPDU Data d'annonce dans le prochain plein intervalle de temps si, et seulement si:

- la liaison de réception par défaut pour le balayage (Tableau 165) s'applique dans le prochain intervalle de temps et se produit sur la même voie radio que la sollicitation; et
- l'attribut dlmo.ActScanHostFract de la DLE est configuré pour la réponse à des DPDU Data de sollicitation. L'attribut dlmo.ActScanHostFract indique que la fraction du temps dans laquelle il convient que la DLE réponde lorsqu'elle a reçu un sollicitation de balayage actif, où
  - une valeur de 0 indique que la DLE n'est pas configurée comme un hôte de balayage actif et elle ne répondra pas à des sollicitations,
  - une valeur de 255 indique qu'il convient que la DLE réponde toujours aux sollicitations, et

  - une valeur dans la plage 1..254 indique que la DLE fait une sélection uniformément aléatoire dans la plage 1..255 chaque fois qu'elle reçoit une sollicitation, et ne répond pas avec une sollicitation si le résultat est supérieur à dlmo.ActScanHostFract, produisant ainsi une réponse de sollicitation de DPDU Data avec la probabilité dlmo.ActScanHostFract/255; et

- la DLE est configurée pour répondre à l'identificateur de sous-réseau D inclus dans la DPDU Data d'annonce, comme décrit en 9.4.2.20. Une DPDU Data de sollicitation peut être configurée pour inclure un identificateur de sous-réseau D pour limiter les répondants à un jeu désiré de sous-réseaux D.

Le prochain plein intervalle de temps, dans ce contexte, doit être défini comme le prochain intervalle de temps qui commence à la suite de la fin de PhPDU de la sollicitation plus 1 ms. Dans le prochain intervalle de temps en question, la DPDU Data d'annonce doit être émise en utilisant la temporisation telle que définie dans le modèle d'initiateur de transaction par défaut dans le Tableau 166, même si le modèle par défaut en question est neutralisé pendant la configuration de la DLE.

Il convient qu'un interrogateur de balayage actif, qui n'est pas présumé synchronisé avec la temporisation de sous-réseau D, permette à sa radio de recevoir une DPDU Data d'annonce dès 3 212 μs après la fin de la DPDU Data de sollicitation, qui est 1 ms plus les 2 212 μs du Tableau 166. Suivant cet instant, il convient que l'interrogateur de balayage actif maintienne son récepteur activé assez longtemps pour recevoir une DPDU Data d'annonce commençant à n'importe quel instant pendant une pleine durée d'intervalle de temps. Il convient que l'interrogateur de balayage actif utilise sa propre durée d'intervalle de temps comme la durée d'intervalle de temps supposée de l'hôte de balayage actif. Par conséquent, lorsque des DPDU Data de sollicitations sont utilisées, il convient que l'interrogateur de balayage actif soit configuré avec une durée d'intervalle de temps qui concorde ou dépasse la durée d'intervalle de temps du sous-réseau D cible.

Une DPDU Data de sollicitation est exigée pour une liaison qui est configurée comme une liaison de sollicitation.

Pour prendre en charge le balayage passif par de nouvelles DLE, des hôtes de balayage actif peuvent également être configurés pour émettre périodiquement des DPDU Data d'annonce.

Il peut être nécessaire de supprimer des sollicitations, pour rendre compte de situations où il est dangereux ou illégitime qu'une DLE fasse fonctionner son émetteur radio sans autorisation. Pour traiter de telles situations, l'attribut dlmo.RadioSilence de DLMO fournit un mécanisme pour désactiver les sollicitations avec toutes les autres émissions de DLE.

Les sollicitations sont désactivées par défaut. Les sollicitations ne sont pas utilisées dans la configuration par défaut, et dlmo.ActScanHostFract a zéro comme valeur par défaut.

9.1.13.4 Balayage continu

Il convient que la découverte de voisins soit un processus continu, même après qu'une DLE a rejoint le sous-réseau D. Les balayages continus peuvent, au fil du temps, aider à former un sous-réseau D plus optimal. Les routeurs alimentés électriquement par le secteur qui dépensent une partie substantielle de leur temps à écouter peuvent, au fil du temps, recevoir de nombreuses annonces issues de routeurs voisins. Les appareils alimentés par batterie à piles ne peuvent pas dépenser un pourcentage élevé de leur temps à écouter, mais même s'ils échantillonnent juste la voie périodiquement, ils peuvent, sur des périodes de temps prolongées, construire une image des routeurs voisins. Si le sous-réseau D est configuré avec un programme coordonné d'annonces, un tel balayage peut être accompli plus efficacement.

Une fonction de gestion de système peut établir un programme global de sous-réseau D pour des annonces, et une DLE rattachée peut être configurée avec un programme de liaisons de réception pour s'assurer que de telles annonces sont entendues au fil du temps. Lorsqu'elle

est utilisée, cette approche permet à des DLE sur le sous-réseau D de trouver efficacement des voisins. En plus, une DLE de faible facteur d'utilisation peut être configurée pour utiliser ces annonces programmées pour rester synchronisée en temps avec le sous-réseau D.

Les annonces sont authentifiées avec un DMIC, pour permettre à des DLE qui ont rejoint le sous-réseau D de s'appuyer de façon fiable sur des annonces programmées comme une source digne de confiance d'informations relatives à la temporisation et à la connectivité.

9.1.14 Découverte de voisins et rattachement – considérations de DL

9.1.14.1 Généralités

La DL fournit un mécanisme configurable pour découvrir des DLE voisines.

Pendant la configuration, une DLE est configurée pour rechercher par balayage des voisins qui peuvent agir comme des proxys dans le processus de rattachement. Lorsqu'une annonce est reçue en provenance d'un voisin candidat, la DLE utilise les informations contenues dans l'annonce pour créer des liaisons de communication à destination et en provenance du voisin en question et fournit ensuite au DMAP les informations d'adressage du voisin. Pour le reste du processus de rattachement, la DLE fournit la prise en charge des communications aux couches supérieures en passant les DPDU Data à destination et en provenance du voisin.

Après avoir rejoint le sous-réseau D, la DLE est chargée, implicitement ou explicitement, par le gestionnaire de système de rechercher par balayage de nouveaux voisins pendant une période de temps désignée, en utilisant des supertrames et des liaisons fournies par le gestionnaire de système. Le résultat de ce balayage est rapporté comme informations relatives aux voisins au gestionnaire de système qui utilise les informations pour pourvoir à la DLE une configuration optimale au sein de la maille de DLE. La DLE continue alors d'accumuler des informations relatives aux nouveaux voisins candidats dans tout son cycle de vie, et ces informations sont périodiquement rapportées au gestionnaire de système pour faciliter la configuration de configurations de maillage améliorées et adaptatives.

Le processus de rattachement au sous-réseau D, du point de vue de la DLE, peut être récapitulé à titre informatif comme suit:

– La DLE, possiblement dans son état d'usine, recherche une annonce auprès de la DLE de configuration. Cette recherche est intégrée dans la DLE telle que définie par la norme.
– La DLE reçoit une annonce issue de la DLE de configuration. Cette annonce, avec l'ID de sous-réseau D = 1, fournit une configuration comprimée, mais pleinement fonctionnelle, pour le diagramme d'états de la DLE. La DLE utilise cette configuration pour communiquer avec la DLE de configuration. Pendant le processus de configuration, une configuration de DLE différente, qui est ultérieurement utilisée pour rechercher un sous-réseau D cible, est inscrite dans l'objet de configuration d'appareil (DPO).
– A la fin du processus de configuration, la DLE de configuration met Join_Command=1, indiquant l'achèvement réussi du processus de configuration et amenant la DLE à se réinitialiser à l'état configuré. La DLE définit cette réinitialisation comme consistant à réinitialiser d'abord la DLE à son état d'usine, ensuite à effacer le support de l'annonce de la DLE de configuration et ensuite à initialiser la DLE avec les valeurs de réglage stockées dans le DPO.
– La DLE commence alors le fonctionnement de son diagramme d'états, en utilisant la configuration telle qu'initialisée par le DPO. Il convient que cette configuration issue de la DLE de configuration soit appariée au sous-réseau D cible pour faciliter la découverte efficace de sous-réseau D. Par exemple, si le sous-réseau D cible est configuré pour émettre des annonces sur trois voies, le DPO pourrait raisonnablement configurer la DLE pour balayer ces mêmes trois voies.

Le processus de découverte est réussi lorsque la DLE reçoit une annonce issue du sous-réseau D cible. Cette annonce contient une configuration de DLE comprimée, mais

pleinement fonctionnelle, qui peut être utilisée pour la communication avec le gestionnaire de système par l'intermédiaire du routeur qui a émis l'annonce.

Si le processus de rattachement temporise, la DLE est réinitialisée à l'état configuré. La configuration dérivée de l'annonce est effacée, la configuration de DPO est rétablie, et la DLE reprend sa recherche d'un sous-réseau D cible.

Si le processus de rattachement est réussi, la configuration de rattachement de la DLE persiste jusqu'à ce qu'elle soit explicitement mise à jour par le gestionnaire de système. Ainsi, à la fin du processus de rattachement, la DLE maintient habituellement une connexion provisoire avec le gestionnaire de système par l'intermédiaire du routeur d'annonce.

Après un rattachement réussi, la DLE recherche un jeu de routeurs candidats qui peuvent être utilisés pour la communication. Après une période de temps configurable, prenant la valeur par défaut de 60 secondes, la DLE rapporte cette liste de candidats au gestionnaire de système. Ces informations sont utilisées par le système pour remplacer la connexion provisoire par une configuration plus permanente et plus résiliente de la DLE.

Si le taux de rapports prévu de DLE est si bas que le temps de synchronisation exigé pour le saut de voie discrétisé ne peut pas être maintenu et si le sous-réseau D local fournit des intervalles de saut de voie lent, alors le DLE peut changer pour utiliser le saut de voie lent pour la plupart des communications rares.

NOTE Le processus de rattachement, prévu pour une utilisation rare et acyclique de toute DLE donnée, utilise le saut de voie discrétisé; le saut de voie lent n'est pas pris en charge pendant le processus de rattachement.

9.1.14.2 Etats de DLE

Lorsqu'un appareil est manufacturé, la DLE est dans son état par défaut. Les attributs dans l'état par défaut sont définis par la présente norme.

Dans l'état par défaut, la DLE doit rechercher périodiquement par balayage un sous-réseau D de configuration, en utilisant une procédure de recherche définie par la norme. Lorsque la DLE reçoit une ou plusieurs annonces issues d'une DLE de configuration dans un sous-réseau D de configuration, la DLE doit utiliser les informations contenues dans l'une des annonces pour établir une supertrame avec les liaisons qui peuvent être utilisées pour communiquer la DLE de configuration sélectionnée. La DLE informe alors le DPO (objet de configuration d'appareil) qu'une association D a été établie, et commute la DLE vers son état de configuration.

Dans l'état de configuration, la DLE met fin à la procédure de recherche définie par la norme. Plutôt, la DLE actionne son diagramme d'états selon une supertrame avec des liaisons qui ont été fournies par l'annonce de la DLE de configuration. Pendant le processus de configuration, la DLE fournit des services de communication aux couches supérieures en actionnant son diagramme d'états selon la supertrame et les liaisons annoncées, si bien que les APDU de configuration peuvent être passées entre le DPO et la DLE de configuration par l'intermédiaire de la DLE qui est en train d'être configurée.

Si le processus de configuration temporise, la DLE retourne à son état par défaut et reprend sa procédure de recherche par défaut d'un sous-réseau D de configuration.

Si le processus de configuration est réussi, le DPO fournit à la DLE un jeu d'attributs, y compris les informations relatives au sous-réseau D, les supertrames, et les liaisons, que la DLE peut utiliser pour rechercher le(s) sous-réseau(x) D cible(s). La DLE commute alors de l'état "provisioning" vers l'état "provisioned", et actionne son diagramme d'états tel que configuré dans les supertrames et les liaisons qui avaient été fournies par le DPO.

La commutation de l'état "provisioning" vers l'état "provisioned" est déclenchée lorsque la DLE de configuration met Join_Command=1 (Tableau 10). Lorsque cela se produit, la DLE est

réinitialisée à son état "provisioned" et actionne alors son diagramme d'états tel que configuré afin de rechercher un sous-réseau D cible.

En général, une réinitialisation de DLE vers l'état "provisioned" est accomplie en deux étapes. D'abord, la DLE est réinitialisée à son état par défaut. Puis, l'information issue de l'attribut Target_DL_Config du DPO est appliquée à la DLE. Cela fournit un jeu d'attributs, y compris l'information relative au sous-réseau D, les supertrames, et les liaisons, que la DLE utilise pour rechercher le réseau de cible et les sous-réseaux D correspondants D. Voir 13.8.

Si la DLE est configurée par un mécanisme hors bande, l'état "provisioning" peut être contourné et dans ce cas, la DLE passe directement de l'état "unprovisioned"(non configuré) à l'état "provisioned".

Le DPO retient une copie des informations qui avaient été utilisées pour configurer la DLE, fournissant des moyens de réinitialiser la DLE à son état "provisioned" en mettant la DLE dans son état par défaut et en ajoutant ensuite les attributs configurés issus du DPO.

Une DLE dans l'état "provisioned' actionne son diagramme d'états tel que configuré dans ses supertrames et liaisons configurées. Il convient que les supertrames et liaisons configurées soient mises en concordance avec les caractéristiques de fonctionnement du(des) sous-réseau(x) D cible(s), de sorte qu'un réseau-cible soit efficacement découvert lorsque la DLE et un sous-réseau D cible sont placés à proximité l'un de l'autre. Le résultat est que la DLE reçoit au moins une annonce issue d'au moins une DLE proxy qui participe à l'un de ces sous-réseaux D cibles. La DLE utilise les informations acheminées par l'une des annonces reçues pour établir une supertrame avec les liaisons qui peuvent être utilisées pour communiquer avec la DLE proxy émettrice. La DLE qui tente de rejoindre le sous-réseau D informe alors le DMAP qu'une association D a été établie vers un proxy voisin, et que la DLE commute alors de l'état "provisioned" vers l'état "joining" (rattachement).

Lorsque la DLE entre dans l'état "joining", elle maintient sa configuration provenant de l'état "provisioned" (voir 13.8), et ajoute le supertrame, les liaisons et d'autres attributs définis ou sous-entendus par l'annonce. La DLE fournit alors des services de communication aux couches supérieures au cours du processus de rattachement, en actionnant son diagramme d'états selon la supertrame et les liaisons annoncées avec le résultat que les APDU de rattachement sont passées entre le DMAP et la DLE proxy par l'intermédiaire de la DLE qui est en train d'être configurée.

Si le processus de rattachement du DMAP temporise, la DLE se réinitialise à son état "provisioned" et recommence à rechercher par balayage un sous-réseau D en utilisant des supertrames et liaisons configurées.

Si le processus de rattachement du DMAP est réussi, les supertrames et les liaisons annoncés continuent d'être utilisées temporairement pour la communication avec le gestionnaire de système. Le DPO conserve les informations nécessaires pour réinitialiser la DLE vers l'état "provisioned" en cas de réinitialisation de DLE.

Lorsque la DLE est d'abord placée dans son état rattaché, elle a une seule connexion au sous-réseau D par l'intermédiaire de la DLE proxy voisine, utilisant la supertrame et les liaisons définies dans l'annonce. Cette connexion unique, sélectionnée implicitement lorsque la DLE a sélectionné la DLE proxy, manque de diversité de chemin, et peut être suboptimale pour un nombre quelconque de raisons. Par conséquent, le gestionnaire de système doit fournir des instructions pour que la DLE recherche plusieurs voisins et rapporte le résultat lorsque la recherche est achevée. Des instructions simples peuvent être fournies par l'intermédiaire de la même annonce qui avait établi la connexion initiale à la DLE proxy, ou des instructions de recherche plus élaborées peuvent être fournies par le gestionnaire de système immédiatement après que la DLE a rejoint le sous-réseau D. Dans un cas comme dans l'autre, la DLE fournit au gestionnaire de système une liste de voisins candidats peu après qu'elle a rejoint le sous-réseau D, 60 s étant le temps de rapport par défaut tel que commandé par l'attribut dlmo.DiscoveryAlert. Le gestionnaire de système analyse cette liste

de voisins candidats, fournit alors à la DLE une configuration mise à jour qui inclut la diversité de chemin (maille) et fournit généralement une connexion de sous-réseau D plus optimale.

Pour prendre en charge le traitement de sécurité, le DMAP a besoin de l'adresse EUI64Address de la DLE d'annonce pendant le processus tant de configuration que de rattachement. Sachant que la DPDU Data d'annonce fournit seulement l'adresse DL16Address du routeur d'annonce, la DLE doit acquérir l'adresse EUI64Address du voisin lorsque la communication commence. L'adresse EUI64Address du voisin doit être acquise en utilisant une liaison d'émission pour interroger le voisin à l'aide d'une DPDU Data avec une charge utile vide, en mettant à 1 le bit d'adresse EUI64Address de la demande de DHDR (bit 5, Tableau 118), faisant retourner l'adresse EUI64Address du voisin dans la DPDU ACK/NAK.

9.1.14.3 Informations consolidées de configuration de DL

Le DPO maintient l'attribut Target_DL_Config qui inclut les valeurs de réglage pour les divers attributs dans la DLE. Cet OctetString est fourni à la DLE à la fin du processus de configuration, et est conservé par le DPO au cas où il aurait besoin de réinitialiser la DLE à son état "provisioned".

Le DL_Config_Info OctetString contient un ensemble d'attributs que le DPO fournit à la DLE afin d'établir l'état "provisioned". Chaque attribut est exprimé comme un tuple comprenant le numéro d'attribut, suivi d'un OctetString qui contient la nouvelle valeur d'attribut. La structure de DL_Config_Info est montrée dans le Tableau 102.

Tableau 102 – Structure de DL_Config_Info

Octets	Bits							
	7	6	5	4	3	2	1	0
1 octet	N (nombre d'attributs)							
1 octet	$AttributeNumber_1$ (Unsigned8)							
–	$NewAttribute_1$ (OctetString)							
...	...							
1 octet	$AttributeNumber_N$ (Unsigned8)							
–	$NewAttribute_N$ (OctetString)							

Plusieurs des attributs dans DL_Config_Info sont des OctetString indexés. Dans ces cas, $NewAttribute_X$ est une nouvelle entrée de rangée. Par convention de DL, chaque entrée de rangée dans un attribut OctetString indexé inclut l'indice de rangée comme étant son premier champ.

DL_Config_Info peut être utilisé pour configurer n'importe quel attribut de lecture/écriture dans la DLE. A tout le moins, DL_Config_Info doit configurer:

- AdvFilter, qui fournit un filtre de sorte que la DLE puisse sélectionner les supertrames qui sont d'intérêt.
- Au moins une supertrame, et au moins une liaison, qui peuvent être utilisées par la DLE pour rechercher des annonces.

Des modèles d'intervalle de temps utilisés pour rechercher le sous-réseau D, s'ils sont différents des modèles d'intervalle de temps par défaut, seront fournis au DLE au cours du processus de configuration.

DL_Config_Info ne doit pas être utilisé excepté par l'intermédiaire du DPO.

Les attributs configurés de la DLE doivent être conservés par le DPO afin que la DLE puisse être réinitialisé à son état "provisioned".

Le fonctionnement de supertrame peut être retardé ou désactivé en positionnant le champ IdleTimer dans la supertrame. Par exemple, deux supertrames peuvent être configurées dans une DLE, la supertrame numéro1 recherchant agressivement le sous-réseau D alors que la supertrame numéro2 effectue une recherche sur un facteur d'utilisation faible. L'IdleTimer de la supertrame numéro1 pourrait conduire cette supertrame à temporiser quelques minutes après que la DLE a été configurée. En variante, une supertrame pourrait être configurée avec un IdleTimer afin qu'elle soit inactive jusqu'à un certain temps dans le futur. Si la DLE est réinitialisée à l'état "provisioned", les temporisateurs d'inactivité de la supertrame doivent également être réinitialisés à l'état initialement configuré.

Une DLE dans l'état "provisioned" doit actionner son horloge de DL et incrémenter le temps TAI. Cela permet à la DLE d'actionner ses supertrames telles que configurées pour découvrir des sous-réseaux D candidats. Pendant le processus de rattachement, un temps TAI révisé sera reçu dans des annonces et l'horloge de DL sera réinitialisée en conséquence.

La DLE pourrait perdre complètement son sens du temps pendant qu'elle est dans l'état configuré, par exemple en raison du retrait d'une batterie. La perte complète du sens de temps dans une DLE configurée doit déclencher une réinitialisation de la DLE à son état configuré.

9.1.14.4 Recherche de voisins par balayage dans l'état "unprovisioned"

Une DLE non configurée commence dans l'état par défaut du système. Sa configuration de DLE inclut les cinq modèles de saut de voie par défaut et les trois modèles d'intervalle de temps par défaut. Ses supertrames, liaisons, graphes et chemins sont blancs.

Avant d'essayer de rejoindre le réseau d'installation, la DLE non configurée a besoin d'établir le contact avec une DLE de configuration et être passée à l'état configuré. Cela peut se produire par l'intermédiaire d'un mécanisme hors bande, tel qu'un modem câblé ou une liaison infrarouge.

La norme définit une procédure de recherche de DLE non configurée pour une annonce de sous-réseau D de configuration. La procédure de recherche est en silence radio, n'impliquant pas de sollicitations ou toute autre émission jusqu'à ce qu'une annonce soit reçue en provenance d'un sous-réseau D de configuration.

Une DLE non configurée doit rechercher par balayage des annonces d'un sous-réseau de configuration D sur les voies 4 et 14, correspondant aux voies 15 et 25 de l'IEEE 802.15.4, si le règlement des radiocommunications le permet (voir Figure 59). Dans chacune de ces voies, la DLE non configurée doit rechercher par balayage une annonce à un intervalle fixe d'exactement 0,25 s, 0,5 s, 1 s, 2 s, 4 s, 8 s, 16 s, ou 32 s. Lorsque la DLE est mise sous tension ou physiquement réinitialisée, elle doit réaliser le balayage au plus court intervalle de 0,25 s pendant au moins 10 s, et ensuite elle peut augmenter progressivement l'intervalle selon les besoins pour préserver son alimentation en énergie.

SubnetID=1 est réservé au sous-réseau D de configuration. Par conséquent, seules les annonces avec SubnetID=1 doivent être considérées par une DLE dans l'état non configuré.

9.1.14.5 Recherche par balayage de voisins dans l'état "provisioned"

Une fois qu'une DLE est dans l'état configuré, elle doit utiliser ses supertrames et liaisons configurées pour rechercher par balayage un sous-réseau D d'intérêt. La DLE peut découvrir plusieurs routeurs d'annonce et ensuite en sélectionner un devant être utilisé comme proxy dans le processus de rattachement.

9.1.14.6 Recherche de voisins par balayage après rattachement au sous-réseau D

Une DLE rejoint le sous-réseau D par l'intermédiaire d'un seul voisin qui envoie des annonces. Les contrats initiaux sont établis en fonction d'un chemin qui n'est pas

nécessairement optimal, par l'intermédiaire de la DLE proxy se rattachant. Ayant établi une seule connexion par le processus de rattachement, la DLE doit être configurée par le gestionnaire de système pour rechercher immédiatement des voisins supplémentaires et alternatifs afin de prendre en charge une configuration de maille plus optimisée.

Une DLE dans l'état rattaché peut être configurée par le gestionnaire de système pour rechercher, par balayage passif, des annonces en configurant la DLE avec les liaisons et les supertrames qui activent le récepteur radio de la DLE à des temps programmés. La DLE peut être configurée pour rechercher, par balayage actif, des annonces utilisant des sollicitations.

L'alerte NeighborDiscovery (voir 9.6.2 et 9.4.2.24) fournit un mécanisme pour que la DLE transfère ces informations vers le gestionnaire de système. L'alerte est prévue pour les scénarios suivants:

- Dans la limite de 15 s de son entrée dans l'état rattaché, la DLE doit être configurée avec les supertrames et les liaisons qui recherchent des annonces issues de routeurs qui sont dans la portée, et sélectionner les candidats les plus prometteurs. La configuration peut être accomplie par l'intermédiaire de l'annonce elle-même, avant le rattachement, comme décrit en 9.3.5.2.4.2. En variante, la configuration peut être fournie en configurant des attributs de DLMO après le rattachement. Après une quantité de temps écoulée configurable, telle que définie par l'attribut dlmo.DiscoveryAlert, la DLE doit utiliser l'alerte de découverte de voisins pour envoyer la liste de candidats vers le gestionnaire de système. Une supertrame dédiée à cette recherche initiale peut être configurée pour temporiser automatiquement par l'intermédiaire de son champ IdleTimer.
- Il convient que la DLE soit configurée par le gestionnaire de système pour rechercher continuellement, par balayage continu passif et/ou actif, des annonces sur une base continue. Au fil du temps, cela permet à la DLE d'établir une liste de voisins candidats. Le HRCO peut être configuré pour émettre périodiquement cette table de voisins candidats, avec le diagnostic de voisin, à destination du gestionnaire de système. Le gestionnaire de système peut en variante lire la table de voisins candidats, dlmo.Candidates, sur son propre programme.
- Une DLE doit aussi utiliser l'alerte de découverte de voisins chaque fois qu'un problème de connectivité est rapporté par l'intermédiaire de l'alerte de DL_Connectivity (voir 9.6.1). Cela fournit une image mise à jour de la connectivité de voisinage, permettant au gestionnaire de système de considérer immédiatement des solutions de remplacement au problème rapporté de connectivité de DLE.

9.1.15 Commande de liaison radio et mesure de qualité

9.1.15.1 Généralités

Les informations relatives à la qualité de signal sont accumulées dans la DLE et rapportées par l'intermédiaire du DMAP. A l'appui de ces fonctions de plus haut niveau, la DLE fournit des primitives qui rapportent les informations relatives à la qualité de signal. La DLE fournit aussi les attributs qui permettent au gestionnaire de système de commander les émissions radio.

9.1.15.2 Métrique de performances

De nombreuses métriques de performances peuvent être accumulées par la DLE sur une base voisin par voisin, configurées par le gestionnaire de système et rapportées par l'intermédiaire du DMAP (voir 9.4.3.9).

La DLE peut être configurée par le gestionnaire de système pour accumuler les types suivants de données de performances sur une base voisin par voisin:

- Indicateur d'intensité de signal reçu (RSSI) et indicateur de qualité de signal reçu (RSQI).

NOTE La présente norme définit des pratiques pour rendre compte de RSSI et RSQI pour faciliter la cohérence, de sorte que les caractéristiques de signal soient quelque peu comparables entre des appareils de construction différentes.

- Pour les émissions: comptes des émissions réussies, replis de CCA, erreurs en monodiffusion, et NAK.
- Compte des DPDU Data reçues.
- Diagnostics de corrections d'horloge.

Les diagnostics par voie sont également recueillis et consolidés pour tous les voisins.

RSSI doit être rapporté sous la forme d'un nombre entier signé de 8 bits, reflétant une estimation de l'intensité de signal reçu en dBm. Les rapports de RSSI doivent être biaisés de +64 dBm pour donner une étendue de mesure de -192 dBm à +63 dBm. Par exemple, une valeur rapportée de RSSI de -16 correspond à une intensité de signal reçu de -80 dBm.

La force de signal réelle reçue pour un appareil dépend du bruit de fond du receveur, qui dépend de la construction de l'appareil et des températures d'exploitation, ainsi que de la sensibilité minimale du receveur. Ceux-ci peuvent être pris en compte dans l'appareil de réception, car ils sont assez reproductibles pour la conception d'appareil donnée et la température d'exploitation de l'appareil. Néanmoins, il convient que les concepteurs d'appareil établissent un mapping approximatif des indications disponibles sur la force de signal reçue et la température de l'appareil (lorsqu'elle est connue) à une estimation raisonnable de RSSI afin que les gestionnaires de système aient une base cohérente pour prendre des décisions de routage parmi les DLE.

RSQI doit être rapporté comme étant une évaluation qualitative de la qualité de signal, un nombre plus élevé indiquant un meilleur signal. Une valeur de 1..63 indique un signal médiocre, 64..127 un signal passable, 128..191 un bon signal, et 192..255 un excellent signal. Une valeur égale à zéro indique que le jeu de puces ne prend en charge aucun diagnostic de qualité de signal autre que RSSI.

RSSI est une mesure quantitative, mappée sur des unités physiques. RSQI est une mesure qualitative. Les appareils RF de fabricants différents, ou avec des numéros de pièces différents, ou avec un schéma de principe amélioré ou une rétractation photolithographique, peuvent générer des valeurs de RSQI brutes différentes. Etant donné que la PHY de l'IEEE 802.15.4 ne spécifie aucune mesure commune et méthodologie de rapports pour le matériel sous-jacent, aucune sous-couche logicielle supérieure ne peut la créer; l'information n'est simplement pas présente parmi les différents appareils.

Les métriques de RSQI sont destinées à être particulièrement utiles pour comparer différentes entrées dans dlmo.Candidates, où l'évaluation réside dans la signalisation des origines différentes reçues par un même appareil. Une DLE peut utiliser des techniques innovantes pour rapporter des comparaisons de la qualité de liaison probable de différents voisins candidats. Puisque les variances entre appareils sur l'appareil receveur sont supprimées, les entrées de RSQI dans dlmo.Candidates rapportées à partir d'une DLE donnée peuvent être raisonnablement comparées entre elles, et des distinctions fines peuvent être considérées comme étant sensées. Par exemple, des différences au sein de la gamme de bons signaux peuvent être raisonnablement prises en compte si les métrique de RSQI sont issues de la DLE.

RSQI peut également être comparé à travers des DLE différentes, mais les distinctions fines sont peu susceptibles d'être aussi sensées. Par exemple, la distinction entre une liaison passable et une liaison excellente est susceptible d'être sensée même si elle est rapportée à partir d'appareils dissemblables, mais les distinctions entre différents niveaux de bonnes liaisons n'ont aucune signification normalisée si elles sont rapportées à partir d'appareils différents.

Etant donné que toute valeur RSQI rapportée est une mesure qualitative, la comparaison de telles valeurs doit nécessairement prendre en compte la nature spécifique de la puce RF des

mesures en question. Etant donné l'interprétation spécifique des valeurs rapportées, deux valeurs RSQI différentes de zéro rapportés par des DLE différentes variant d'une quantité de 32 ou plus peuvent être classées "meilleure" ou "pire", la fiabilité du classement augmentant à mesure que les valeurs numériques augmentent.

De façon similaire, des valeurs RSSI rapportées par le même appareil à des temps différents ou pour des correspondances à distance différentes peuvent être de façon fiable comparées, tout comme les valeurs RSSI parmi des appareils qui sont connus (par le fournisseur ou tout autre identification de modèle spécifique à l'appareil) pour fournir des estimation RSSI calibrées. Dans d'autres cas, de telles comparaisons sont au mieux approximatives, quelque peu similaires aux RSQI bien que présumées plus proches de l'approximation de la force réelle du signal reçu par l'appareil rapporteur. En particulier, les ordres de grandeur de magnitude parmi les rapports du même appareil rapporteur sont toujours fiables en termes d'ordre de grandeur et de magnitude de différence approximative.

9.1.15.3 Accumulation et comptes-rendus d'informations de diagnostic

Le gestionnaire de système établit une relation de communication de DL entre une DLE et son voisin en ajoutant une entrée à l'attribut dlmo.Neighbor de la DLE. Chaque entrée indique un niveau du diagnostic devant être collecté, par l'intermédiaire du champ dlmo.Neighbor[ ].DiagLevel. Pour chaque voisin, le diagnostic peut être recueilli à un niveau de ligne de base, ou à un niveau détaillé incluant le diagnostic d'horloge.

Les diagnostics par voie sont accumulés et consolidés pour tous les voisins, dans l'attribut dlmo.ChannelDiag.

Lorsque le champ dlmo.Neighbor[ ].DiagLevel est mis pour un voisin particulier, la DLE doit créer les entrées correspondantes dans l'attribut en lecture seule dlmo.NeighborDiag. Les valeurs de NeighborDiag sont accumulées à partir du temps où l'entrée de dlmo.NeighborDiag est créée.

Trois mécanismes sont fournis pour rapporter les informations de diagnostic contenues dans dlmo.NeighborDiag et dlmo.ChannelDiag:

- L'objet concentrateur de rapports de santé (HRCO), décrit en 6.2.7.7, peut être configuré pour rapporter tout attribut dans la DLE sur une base périodique. Les entrées de dlmo.NeighborDiag et de dlmo.ChannelDiag peuvent être rapportées par l'intermédiaire du mécanisme en question.
- Les informations de diagnostic peuvent être récupérées à tout moment par le gestionnaire de système, en lisant les attributs applicables.
- Les informations de diagnostic peuvent être rapportées par la DLE sur une base d'exception, par l'intermédiaire de l'alerte de DL_Connectivity.

Les diagnostics incluent une combinaison de niveaux, tels que RSSI, et des compteurs, tels qu'un compte d'acquittements.

Des niveaux sont accumulés sous forme de moyennes mobiles exponentielles (EMA). Le niveau est initialisé avec la première valeur de données, après laquelle chaque nouvelle valeur de données est accumulée dans le niveau d'EMA comme suit, où:

$$EmaLevel_{NEW} = EmaLevel_{OLD} + (\alpha / 100) \times (NewData - EmaLevel_{OLD})$$

Le facteur de lissage α est exprimé sous la forme d'un nombre entier dans la plage 0..100, représentant un pourcentage; il est configuré par le gestionnaire de système par l'intermédiaire de l'attribut dlmo.SmoothFactors (voir 9.4.2.25).

Les compteurs dans dlmo.NeighborDiag sont accumulés comme des nombres entiers non signés ExtDLUint, qui sont intérieurement des entiers de 15 bits. Lorsqu'un compteur atteint sa valeur maximale, de 32 767 (0x7FFF), il doit "se bloquer" et continuer de rapporter cette

valeur maximale. Les compteurs doivent être réinitialisés à zéro chaque fois que la rangée est rapportée par l'intermédiaire du HRCO ou récupérée par l'intermédiaire d'une opération "read" (lecture). Le fait de rapporter la valeur par l'intermédiaire de l'alerte de DL_Connectivity ne doit réinitialiser aucun compteur.

9.1.15.4 Silence radio

La DLE peut être configurée pour émettre seulement lorsqu'elle participe activement à un sous-réseau D. Ce comportement est configuré par l'attribut dlmo.RadioSilence, qui désigne une période de temporisation pour la participation à un sous-réseau D, en secondes. Par exemple, si l'attribut dlmo.RadioSilence est mis à la valeur par défaut de 600 s (10 min), la DLE met en silence son émetteur radio 10 min après avoir perdu la communication avec le sous-réseau D. Lorsque toutes les DLE sur un sous-réseau D sont configurées pour le silence radio, il est possible de désactiver entièrement le sous-réseau D, même si certaines DLE ne reçoivent pas une commande explicite de désactiver des communications.

Lorsqu'une mise à jour de temps valide est acceptée par la DLE à partir d'une annonce ou d'un acquittement, la DLE enregistre intérieurement le temps courant comme référence de temps de silence radio. Si la DLE n'accepte pas une autre mise à jour de temps dans la période de temps suivante désignée par dlmo.RadioSilence, la DLE doit devenir silencieuse en ignorant l'ensemble de toutes ses liaisons d'émission configurées, y compris les sollicitations. Dans l'état de silence radio, la DLE continue d'actionner son récepteur radio selon ses liaisons de réception programmées, mais sans émettre d'acquittements en l'absence d'une mise à jour d'horloge.

Par exemple, supposons que la DLE reçoive une mise à jour de temps 01h:02m:03s et que dlmo.RadioSilence est mis à 600 s (10 min). Si la DLE ne reçoit pas d'autre mise à jour de temps au plus tard à 01h:12m:03s, soit 10 min plus tard, elle mettra alors sa radio en silence.

Si dlmo.RadioSilence est configuré comme étant zéro, l'appareil est désactivé.

Le silence radio est la valeur par défaut. La procédure de découverte de sous-réseau D par défaut n'utilise pas de sollicitations, et dlmo.RadioSilence prend la valeur par défaut de 600 s.

La prise en charge de l'attribut dlmo.RadioSilence est exigée pour toutes les DLE.

Le profil de silence radio limite la plage autorisée de l'attribut dlmo.RadioSilence. Le profil de silence radio est rapporté au gestionnaire de système lors du rattachement par l'intermédiaire de dlmo.DeviceCapability. Une DLE avec le profil de silence radio doit rejeter les mises à jour de dlmo.RadioSilence qui sont à l'extérieur de la plage 1 s à 600 s, assurant ainsi qu'une telle DLE n'émettra jamais une DPDU une fois qu'elle a perdu le contact avec le sous-réseau D pendant 600 s.

Le silence radio temporaire peut être accompli avec un autre attribut dlmo.RadioSleep. Lorsque dlmo.RadioSleep est mis à une valeur positive, la DLE traite toutes les liaisons, y compris les liaisons de réception, comme étant inactives pendant le nombre désigné de secondes. Le silence radio temporaire peut être accompli avec un autre attribut dlmo.RadioSleep. Lorsque dlmo.RadioSleep est mis à une valeur positive, la DLE traite toutes les liaisons, y compris les liaisons de réception, comme étant inactives pendant le nombre désigné de secondes. L'activation de dlmo.RadioSleep doit être légèrement retardée pour permettre la prise en charge de l'émission d'un acquittement AL pour la APDU du DMAP qui a fait positionner l'attribut. Lorsque la période de sommeil est terminée, dlmo.RadioSleep est automatiquement réinitialisé à zéro, indiquant que la caractéristique est désactivée.

9.1.15.5 Puissance d'émission radio

La norme fournit au gestionnaire de système un degré de commande sur la puissance d'émission radio, par l'intermédiaire de l'attribut dlmo.RadioTransmitPower.

L'attribut dlmo.RadioTransmitPower est utilisé pour commander le niveau de puissance d'émission radio de la DLE, en dBm EIRP. Il prend comme valeur par défaut le niveau de puissance maximale prise en charge et il est toujours contraint par dlmo.CountryCode (9.1.15.6) aux contraintes de réglementations du lieu d'utilisation. Cette valeur par défaut contrainte est également rapportée au gestionnaire de système au cours du processus de rattachement par l'intermédiaire de dlmo.DeviceCapability.

Lorsque dlmo.RadioTransmitPower est changé par le gestionnaire de système, la DLE ne doit pas émettre à un niveau de puissance de sortie au-dessus de dlmo.RadioTransmitPower.

En outre, une DLE peut de façon autonome étalonner son niveau de puissance de sortie par rapport au niveau minimal exigé pour maintenir une connectivité fiable. Pour permettre cela, la DLE prend en charge le renvoi en écho des informations relatives à la qualité de signal dans les acquittements, de sorte qu'une mise en œuvre peut étalonner la qualité de signal reçu à divers niveaux de puissance. Voir 9.3.5.5.

NOTE Un calcul exact du niveau de sortie réel des DLE depuis les rapports correspondants des RSSI reçues dépend des informations de conception de la DLE correspondante reportant, qui n'est pas connue par la DLE auto-étalonnée. Ces facteurs incluent le bruit de fond et la sensibilité reçue minimale des DLE correspondantes. Ainsi, tout auto-ajustement des niveaux de transmission basés sur les RSSI reçues est au mieux approximatif, en particulier lorsque les sous-systèmes RF des DLE correspondantes ne partagent pas une conception commune (lorsqu'ils proviennent de constructeurs différents, par exemple).

Il est possible pour les DLE de fournir des corrections locales des valeurs RSSI qu'elles rapportent pour rendre compte de l'influence du bruit de fond et de la sensibilité reçue minimale sur leur propre receveur. De telles corrections, non adressées par la norme IEEE 802.15.4, peuvent habituellement être réalisées de façon linéaire et par partie. Les valeurs rapportées résultant sont considérés comme satisfaisant aux exigences RSSI de la présente norme et de l'IEEE 802.15.4, même si elles sont légèrement ajustées à partir des mesures des sous-sections RF des DLE de mise en œuvre (puisque ces mesures réelles ne prennent pas en compte les autres caractéristiques pertinentes du sous-système RF). Voir également 9.1.15.2.

9.1.15.6 Code de pays

La DLE de configuration et/ou le gestionnaire de système peu ou peuvent informer la DLE configurée des considérations de réglementations par l'intermédiaire de son attribut dlmo.CountryCode, Tableau 103, qui est une structure condensée de 16 bits composée d'un code de pays de 10 bits et de six booléens:

- Les bits 0..9 fournissent un code de pays de 10 bits sous la forme d'un nombre entier Unsigned10, utilisant les codes de pays numériques à trois chiffres selon l'ISO 3166-1.
- Les bits 10..15 spécifient une formation à six éléments booléens:
  - Le bit 10 (Index 0) indique si les règles de la FCC s'appliquent. Une DLE doit opérer en conformité avec les règles FCC lorsque l'Index0 (Bit10) se vérifie.
  - Bit 11 (Index 1), ETSI indique si les règles EU (de la norme ETSI) s'appliquent. Une DLE doit opérer en conformité avec les règles EU lorsque l'Index1 (Bit11) se vérifie.
  - Bit 12 (Index 2), LP, indique si une limite de 10 dBm EIRP s'applique. Une DLE doit limiter ses émissions à ≤ 10 dBm lorsque l'Index2 (Bit12) se vérifie.
  - Bit 13 (Index3), LBT, indique si la DLE doit opérer sous des règles d'adaptabilité, en utilisant LBT, pour détecter la voie lors de l'initiation d'une transaction et cesser l'utilisation du connecteur si l'activité est détectée: ne se vérifie pas=non adaptatif, se vérifie= adaptatif.
  - Bit 14 (Index14), FHSS, indique si la DLE doit opérer sous des règles d'étalement de spectre à saut de fréquence: ne se vérifie pas=règles-non-FHSS, se vérifie= règles-FHSS.
  - Le bit 15 (Index15), Locked, indique si la valeur de cet attribut est fixe lorsque la DLE est opérationnelle. Une fois que ce bit "collant" est mis, toute tentative

ultérieure de modifier l'attribut dlmo.CountryCode doit être rejetée, sauf lorsqu'elle la DLE est réinitialisée à ses valeurs de réglage d'usine par défaut au cours de la (re)configuration.

Tableau 103 – CountryCode

Numéro d'octet	Bits							
	7	6	5	4	3	2	1	0
1	Mode						ISO 3166-1 CountryCode bits 9..8	
	Locked	FHSS	LBT	PCLF	ETSI	FCC		
2	ISO 3166-1 CountryCode bits 7..0							

Lorsque les Bit11 et Bit13 (ETSI et LBT) se vérifient tous les deux, chaque transaction D doit commencer avec un intervalle d'observation LBT d'au moins 20 us, en utilisant le mode 1 de CCA, prenant ainsi en charge les modes décrits en Annexe V, 3) et Annexe V, 6).

NOTE 1 Le mode 3 de CCA est également acceptable sous ETSI EN 300 328 v1.8.1 lorsqu'il est mis en œuvre en tant que AND du mode 1 de CCA et du mode 2 de CCA mais n'est pas acceptable lorsqu'il est mis en œuvre en tant que OR du mode 1 de CCA et du mode 2 de CCA. Voir 9.1.9.4.3.

Lorsque les Bit11, Bit13 et Bit14 (ETSI, LBT et FHSS) se vérifient tous, l'exploitation change momentanément vers les règles non adaptatives de l'ETSI EN 300 328 v1.8.1 pendant l'envoi d'une DPDU ACK/NAK (en tant que SCS (Short Control Signaling)) au sein d'une transaction et pour le Tx-gap-time d'une non-émission mandatée-EN immédiat suivant, prenant ainsi en charge le mode décrit en Annexe V, 6).

Le Bit15 (Locked) prend en charge l'exploitation d'appareil (lorsqu'il se vérifie) dans des régimes de réglementation qui interdisent l'aptitude à reconfigurer un appareil de telle manière qu'il viole les contraintes de réglementation, tout en prenant encore en charge les appareils (lorsqu'il ne se vérifie pas) sur des plateformes mobiles telles que les navires et les trains qui peuvent franchir des frontières juridictionnelles de réglementation et tout en permettant toujours (via l'exception de reconfiguration) la réparation ou la remise à neuf d'appareils avec une revente ou une réutilisation ultérieure dans des marchés où d'autres réglementations s'appliquent.

Lorsque aucun pays spécifique d'utilisation prévue n'a été identifié, la valeur par défaut pour dlmo.CountryCode doit être 0x3C00, indiquant qu'il convient qu'un appareil dans l'état par défaut se conforme aux règles de l'US FCC, aux règles de l'UE, à la limite < 10 dBm p.i.r.e, et soit classé comme appareil adaptatif non-FHSS. Voir 5.2.5 et Annexe V.

NOTE 2 Cette valeur par défaut assure que l'équipement, avant d'être configuré, satisfait aux exigences de réglementation de la plupart des régions dans lesquelles il pourrait être déployé, et en particulier comme de telles règles s'appliqueraient à la configuration par défaut à trois voies utilisée pour la configuration par liaison radio dès le déballage. Une telle contrainte permet à l'appareil de participer à la configuration de courte portée sur un support sans fil de Type A, point auquel l'attribut dlmo.CountryCode serait changé pour refléter le régime de réglementation prévu qui s'applique au lieu initial (et habituellement unique) de déploiement de l'appareil.

9.1.16 Rôles et options de DLE

La DL spécifiée par la présente norme est conçue dans le but général de contraindre la gamme des options de construction pour un appareil conforme, tout en permettant des solutions de système flexibles et innovantes.

Le cadre de DL n'exige pas que toutes les DLE soient équivalentes. Par exemple, certains routeurs, conçus comme des appareils d'infrastructure dédiés, pourraient avoir une source continue d'énergie, des processeurs puissants, et une capacité mémoire essentiellement illimitée. Par contraste, certains instruments de terrain peuvent avoir des batteries de faible capacité et peuvent manquer de capacité de routage.

Ces distinctions parmi les DLE sont couvertes de trois façons générales dans la présente norme:

- capacité mémoire;
- capacités de DLE; et
- rôles de DLE.

Chaque DLE a une quantité limitée de mémoire qui est disponible pour des opérations de DL, et le gestionnaire de système a besoin de la connaissance de ces limitations afin de configurer la DLE et équilibrer le fonctionnement du sous-réseau D. La mémoire DL de la DLE n'est pas rapportée sous forme d'un seul bloc, mais plutôt comme des capacités de mémoire spécifiques pour des besoins spécifiques. Par exemple, chaque attribut OctetString indexé prend en charge un nombre limité d'entrées, avec la capacité disponible au gestionnaire de système comme métadonnées. De même, la capacité de tampon pour la transmission de DPDU Data est rapportée par la DLE au démarrage.

Certaines capacités de DLE sont également rapportées au démarrage. Par exemple, la DLE rapporte la stabilité de sa propre horloge, ainsi qu'une liste de voies radio qu'elle peut prendre légalement en charge. Les capacités de DLE rapportées avec la demande de rattachement sont énumérées en 9.4.2.23.

Les rôles de DLE décrivent les capacités générales d'une configuration donnée de DLE. Par exemple, une DLE peut être capable de routage ou pas. Les distinctions de ce type ont diverses implications dans toute la DLE, en termes de capacité mémoire minimale, de capacités de DLE, et de prise en charge de diverses caractéristiques. La DLE rapporte simplement quels rôles elle prend en charge, et le gestionnaire de système est alors responsable d'en faire un mapping dans un portefeuille de capacités de DLE. Des mappings normalisés entre les rôles et les capacités minimales sont fournis en Annexe B.

9.1.17 Considérations relatives à l'énergie des DLE

Les appareils ont différents niveaux d'énergie disponible. Un appareil peut avoir une source d'énergie continue. Un autre appareil peut avoir une grande batterie, mais a besoin de la majeure partie de cette capacité d'énergie pour faire fonctionner un capteur. Un autre appareil encore peut utiliser la récupération d'énergie comme sa source d'énergie primaire. Les compositions chimiques différentes des batteries ont des caractéristiques différentes, une chimie donnée de batterie peut fournir des performances différentes selon le fournisseur, et une capacité de batterie peut varier selon des facteurs environnementaux. Les nouvelles technologies de batterie sont susceptibles d'émerger avec des caractéristiques de performance actuellement inconnues. Une application pourrait avoir besoin d'une durée de vie de batterie de 20 ans, alors qu'une application différente pourrait tolérer une durée de vie de six mois.

La DLE peut être configurée par le gestionnaire de système pour consommer différentes quantités d'énergie. La DLE consomme de l'énergie de deux manières générales:

- La DLE consomme de l'énergie en fournissant le service sans fil à ses propres applications. Lorsqu'une DLE établit un contrat pour émettre des données toutes les 5 s, la DLE consomme une quantité correspondante d'énergie.
- La DLE consomme de l'énergie en agissant comme un routeur pour le compte de DLE voisines. Une DLE peut être configurée pour émettre des annonces toutes les 10 s. Une DLE peut être configurée pour actionner son récepteur presque sans interruption, se mettant à l'écoute pour déceler des sollicitations. Le sous-réseau D peut être configuré de sorte qu'une DLE transmette jusqu'à 100 DSDU par minute. Tous ces scénarios consomment de l'énergie.

La DLE rapporte un sens général de sa capacité de prendre en charge des opérations de routage de DL dans certains champs des attributs dlmo.EnergyDesign. Cet attribut est rapporté par l'intermédiaire de l'attribut dlmo.DeviceCapability.

L'attribut dlmo.EnergyDesign indique la capacité désignée en énergie de l'appareil pour traiter les opérations de DL. Cet attribut est constant au cours de la vie de l'appareil et reflète la conception de l'appareil, pas son état courant. Il convient qu'un gestionnaire de système configure une DLE dans ces limitations énoncées relatives à l'énergie:

– EnergyLife indique la vie de l'énergie de l'appareil par conception. Une valeur positive fournit la vie d'énergie en jours; une valeur négative fournit la grandeur de la vie d'énergie en heures. Une valeur de 0x7FFF indique une source d'énergie continue et l'absence de limitations contraignantes relatives à l'énergie d'appareil. D'autres champs EnergyDesign décrivant la capacité en énergie de la DLE sont basés sur cette vie d'énergie ciblée. La configuration de la DLE au-delà de ces capacités en énergie énoncées est susceptible de réduire la vie d'énergie de l'appareil.
– ListenRate indique la capacité en énergie de la DLE en moyenne, en secondes par heure, pour actionner son récepteur radio. ListenRate inclut le temps pour recevoir des DPDU Data pour les propres contrats d'application de la DLE, plus des DPDU Data transmises par la DLE pour le compte d'autres DLE.
– TransmitRate indique la capacité en énergie de la DLE, en DPDU Data par minute, d'émettre des DPDU Data pour son propre compte et de transmettre des DPDU Data pour le compte de ses voisins.
– AdvRate indique la capacité en énergie de la DLE, en DPDU Data par minute, d'émettre des DPDU Data d'annonce (ou de sollicitation) dédiées.

La constante EnergyDesign ne reflète pas l'état changeant de la source d'énergie d'un appareil. L'attribut dynamique en lecture seule dlmo.EnergyLeft peut être utilisé pour rapporter la capacité d'énergie restante de l'appareil. Une valeur positive indique la vie restante en jours et une valeur négative indique la vie restante en heures. Une valeur de 0x7FFF indique que la caractéristique n'est pas prise en charge. L'attribut dlmo.EnergyLeft est rapporté à la suite du démarrage par l'intermédiaire de dlmo.DeviceCapability, et peut également être rapporté périodiquement par l'intermédiaire du HRCO.

9.2 DDSAP

9.2.1 Généralités

Le DDSAP prend en charge l'acheminent par sauts multiples d'une DSDU (par exemple, et d'une NPDU) entre des DLE dans un sous-réseau D.

DD-DATA.request prend une DSDU issue de la NLE, ajoute un en-tête de DPDU Data comme préfixe, et l'ajoute à la file d'attente de messages. DD-DATA.confirm rapporte ultérieurement si la DSDU a été acheminée avec succès vers une DLE voisine dans le sous-réseau D.

DD-DATA.indication indique la réception d'une DPDU Data qui a atteint sa destination finale au sein du sous-réseau D, et passe sa DSDU à la NLE.

Toutes les interfaces entre la DLE et les entités de couche ou entités de gestion adjacentes sont des interfaces internes au sein de l'appareil, et sont donc inobservables. Par conséquent, elles sont strictement virtuelles et ne sont pas soumises à une normalisation.

9.2.2 DD-Data.request

DD-DATA.request est une primitive qui accepte une DSDU provenant de la NL, sélectionne le chemin à travers le sous-réseau D, et place une DPDU Data correspondante dans la file d'attente de messages de la DLE.

La sémantique de la primitive DD-DATA.request est comme suit:

DD-DATA.request (
SrcAddr,
DestAddr,
Priority,
DE,
ECN,
LH,
ContractID,
DSDUSize,
DSDU,
DSDUHandle)

Le Tableau 104 décrit les paramètres pour DD-DATA.request.

Tableau 104 – Paramètres DD-Data.request

Nom du paramètre	Type du paramètre
SrcAddr (DL source address)	Type: Adresse DL16Address ou adresse EUI64Address
DestAddr (adresse de destination DL)	Type: Adresse DL16Address ou adresse EUI64Address
Priorité (priorité de la charge utile)	Type: Unsigned4
Discard Eligible (éligible au rejet)	Type: Unsigned1
ECN (notification d'encombrement explicite)	Type: Unsigned2
LH (dernier saut, NL)	Type: Unsigned1
ContractID (ContractID de la charge utile)	Type: Unsigned16 ou null
DSDUSize (taille de la charge utile)	Type: Unsigned8
DSDU (nombre d'octets par DSDUSize)	Type: Octets
DSDUHandle (identifie de manière unique chaque invocation de cette primitive)	Type: Extrait

Les paramètres de DD-DATA.request comprennent:

- SrcAddr est l'adresse source de la NSDU. Il s'agit normalement du pseudonyme de l'adresse DL16Address de l'adresse IPv6Address source de la NSDU, excepté lorsqu'il s'agit de l'adresse EUI64Address d'une DLE non rattachée. Le paramètre Subnet ID est implicite, basé sur dlmo.SubnetID.
- DestAddr est l'adresse de destination de la NSDU. Il s'agit normalement du pseudonyme de l'adresse DL16Address de l'adresse IPv6Address de destination de la NSDU, excepté lorsqu'il s'agit de l'adresse EUI64Address d'une DLE non rattachée. Le paramètre Subnet ID est implicite, basé sur dlmo.SubnetID.
- Le paramètre Priority est copié dans le sous-en-tête DROUT et indique la priorité de la DPDU Data dans des files d'attente de messages de DLE.
- Le paramètre DE est copié dans le sous-en-tête DADDR. DE=1 indique que la DSDU est éligible à être rejetée d'une file d'attente de messages en faveur d'une DPDU Data entrante avec DE=0, et de priorité égale ou plus haute.

NOTE L'expression "est éligible" ne signifie pas "est obligatoire". Un tel rejet est une option de mise en œuvre.

- Le paramètre ECN est copié dans le sous-en-tête DADDR. Voir 9.1.9.4.5 pour un débat relatif à l'ECN.
- Le paramètre LH est copié dans le sous-en-tête DADDR. Une valeur de 1 indique que la DSDU est entrée dans le sous-réseau D par un routeur dorsal, et donc elle ne doit pas sortir de la DL par un routeur dorsal pour éviter les chemins circulaires à la NL. Cela permet à la NL d'élider le champ limite de saut de l'IPv6. Logiquement, le paramètre LH est transporté par la DL pour le compte de la NL, et LH ne doit pas être changé par la DL.

- ContractID peut être utilisé par la DLE dans la sélection de chemin (voir le débat en 9.1.6.5).
- DSDUSize indique le nombre d'octets contenus dans la charge utile de DPDU Data.
- Le paramètre DSDU est le jeu d'octets formant la charge utile. Il peut être mis en œuvre comme pointeur vers la mémoire qui est partagée parmi les couches.
- Le paramètre DSDUHandle est une abstraction qui connecte chaque invocation de DD-DATA.request avec le rappel ultérieur par DD-DATA.confirm.

9.2.3 DD-Data.confirm

DD-DATA.confirm est une primitive qui rapporte les résultats d'une demande d'émettre une DSDU qui a été précédemment placée dans la file d'attente de messages de la DLE par DD-DATA.request.

Le Tableau 105 décrit les paramètres pour DD-DATA.confirm.

Tableau 105 – Paramètres DD-Data.confirm

Nom du paramètre	Type du paramètre
DSDUHandle (identificateur pour la charge utile)	Type: Extrait
Status (voir le Tableau 106)	Type: Unsigned

Le Tableau 106 spécifie la valeur pour le paramètre "status".

Tableau 106 – Jeu de valeurs pour le paramètre "status"

Valeur	Description
SUCCESS	L'opération a réussi
FAILURE	L'opération a échoué, l'opération a expiré

NOTE Le traitement des erreurs entre la DLE et la NLE contiguë est une question d'appareil interne, qui n'est visible à travers aucune interface observable et n'est donc pas normalisé.

9.2.4 DD-Data.indication

DD-DATA.indication est une primitive virtuelle qui indique la réception d'une DSDU. Une DPDU Data ne déclenche pas d'indication de données tant qu'elle n'a pas atteint sa destination dans le sous-réseau D.

La sémantique de la primitive DD-DATA.indication est comme suit:

```
DD-DATA.indication(
                SrcAddr,
                DestAddr,
                Priority,
                DE,
                ECN,
                LH,
                DSDUSize,
                DSDU)
```

Le Tableau 107 décrit les paramètres pour DD-DATA.indication.

Tableau 107 – Paramètres DD-Data.indication

Nom du paramètre	Type du paramètre
SrcAddr	Type: Adresse DL16Address ou adresse EUI64Address
DestAddr	Type: Adresse DL16Address ou adresse EUI64Address
Priorité (priorité de la charge utile)	Type: Unsigned4
Discard Eligible (éligible au rejet)	Type: Unsigned1
ECN (notification d'encombrement explicite)	Type: Unsigned2
LH (dernier saut, NL)	Type: Unsigned1
DSDUSize (taille de la charge utile)	Type: Unsigned8
DSDU (nombre d'octets par DSDUSize)	Type: Octets

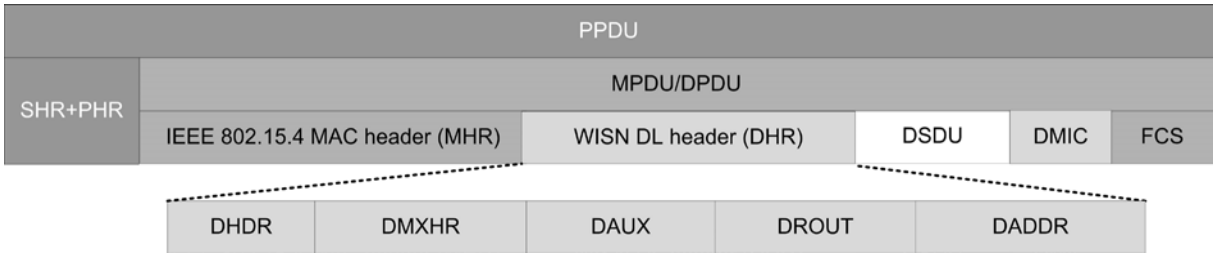
Les paramètres de DD-DATA.indication comprennent:

- SrcAddr est l'adresse source de la NSDU. Il s'agit normalement du pseudonyme de l'adresse DL16Address de l'adresse IPv6Address source de la NSDU, excepté lorsqu'il s'agit de l'adresse EUI64Address d'une DLE non rattachée. Le paramètre D-subnet ID est implicite, basé sur dlmo.SubnetID.
- DestAddr est l'adresse de destination de la NSDU. Il s'agit normalement du pseudonyme de l'adresse DL16Address de l'adresse IPv6Address de destination de la NSDU, excepté lorsqu'il s'agit de l'adresse EUI64Address d'une DLE non rattachée. Le paramètre D-subnet ID est implicite, basé sur dlmo.SubnetID.
- Le paramètre Priority est inclus dans le sous-en-tête DROUT et peut être utilisé par la NL pour routage ultérieur. ContractID, si exigé par la NL, n'est pas transporté dans l'en-tête de la DPDU Data.
- Le paramètre DE fournit la valeur du bit DE copiée à partir du sous-en-tête DADDR entrant.
- Le paramètre ECN fournit la valeur du bit ECN copiée à partir du sous-en-tête DADDR entrant et il correspond au bit ECN décrit dans l'IETF RFC 3168. Voir 9.1.9.4.5 pour un débat relatif à l'ECN.
- Le paramètre LH fournit la valeur du bit LH copiée à partir du sous-en-tête DADDR entrant.
- DSDUSize indique le nombre d'octets contenus dans la charge utile de DPDU Data.
- Le paramètre DSDU est le jeu d'octets formant la charge utile. Il peut être mis en œuvre comme pointeur vers la mémoire qui est partagée parmi les couches.

9.3 Data DPDU et DPDU ACK/NAK

9.3.1 Généralités

La structure des DPDU utilisées par la présente norme est montrée à la Figure 88.



Légende

Anglais	Français
IEE 802.15.4 MAC header (MHR)	En-tête (MHR) MAC IEE 802.15.4
WISN DL header (DHR)	En-tête WISN DL (DHR)

Figure 88 – Structure de PhPDU et de DPDU

La DPDU reflète la structure multi-couche de la PDU décrite en 9.1.4, y compris:

- En-tête MAC (MAC header (MHR)): Le MHR est une structure de données modelée sur celle de l'IEEE 802.15.4, telle que spécifiée en 9.1.4 et 9.1.5, qui inclut des informations relatives aux formats de trames et des informations d'adressage des sous-réseaux D. La FCS à la fin de la DPDU est logiquement associé au MHR.
- En-tête de DPDU (DPDU header (DHR): Les informations d'en-tête de DL suivent le MHR. Les sous-en-têtes au sein du DHR comprennent:
  - En-tête de DHR (DHR header (DHDR)): DHDR inclut les valeurs de réglage pour diverses sélections de DLE et un numéro de version.
  - Sous-en-tête d'extension de DHR MAC (DMXHR): Des champs complémentaires, non indiqués par l'IEEE 802.15.4, qui sont nécessaires pour envoyer une DPDU Data vers un voisin immédiat et pour recevoir une DPDU ACK/NAK immédiate. Le DMXHR comprend des informations relatives à l'intégrité cryptographique et aux mesures de confidentialité qui s'appliquent à la DPDU. Le DMIC suivant la DSDU est logiquement associé au DMXHR.
  - Sous-en-tête auxiliaire de DHR (DAUX): Certaines DPDU incluent des informations auxiliaires pour faciliter la découverte de voisins, la propagation de temps, l'échange d'informations, et l'échange de commandes parmi des voisins immédiats. Le sous-en-tête DAUX est fréquemment absent. Un champ DAUX non nul doit être inclus dans des DPDU d'annonce ou de sollicitation dédiées ou, en variante, il peut être intégré dans des DPDU Data n'ayant aucun rapport.
  - Sous-en-tête de routage de DHR (DROUT): Le champ DROUT contient des informations nécessaires pour acheminer la charge utile DPDU à travers le sous-réseau D. Un champ DROUT non nul doit inclure une classe de priorités de DPDU Data et une limite de transmission, plus soit un GraphID, soit un routage de source.
  - Sous-en-tête d'adresse de DHR (DADDR): Le champ DADDR contient la source et la destination des adresses D des points d'extrémité au sein d'un sous-réseau D, avec les champs NL ECN, DE et LH qui sont tous acheminés et visibles par la DL.
- DSDU: La charge utile de la couche supérieure de DPDU est une NPDU unique 6LoWPAN, tel que défini dans l'Article 10, qui est passé à la DLE en tant que DSDU. La charge utile est acheminée de manière transparente au sein du sous-réseau D.
- DMIC: La DMIC près de la fin de la DPDU est logiquement associé au DMXHR. La DMIC est un code d'intégrité fort du point de vue cryptographique qui permet de déterminer que la DPDU reçue
  - a été générée par un appareil qui partage la clé de cryptage pertinente, et
  - n'a pas été altérée avant la réception.

NOTE Dans certains cas la clé de cryptage DMIC pertinente est statique et publiée, permettant la falsification par un attaquant non informé.

- FCS: La FCS à la fin de la DPDU est logiquement associé au MHR. La FCS est un code d'intégrité trivialement falsifiable qui permet la détection d'erreurs DPDU induites par PhL.

Certaines classes de DPDU qui sont générées par la DLE, telles que les annonces et sollicitations dédiées, ont des champs DROUT, DADDR et DSDU nuls.

9.3.2 Ordonnancement d'octets et de bits

9.3.2.1 Généralités

Excepté dans la DL, la présente norme utilise des conventions d'émission et de documentation d'octet de poids fort en premier lieu (MSB ou "big-endian" c'est-à-dire gros-boutiste), suivant le précédent établi par l'ISO/IEC, l'IETF, et beaucoup d'autres. A savoir:

- pour des valeurs à plusieurs octets, l'octet de poids fort est émis le premier; et
- la documentation des octets montre le bit 7 à gauche et le bit 0 à droite.

Cependant, l'IEEE 802.15.4 utilise les conventions de l'octet de poids faible en premier lieu (LSB ou "little-endian", petit-boutiste). A savoir:

- pour des valeurs à plusieurs octets, l'octet de poids faible est émis le premier.

NOTE La spécification de l'IEEE n'est pas entièrement cohérente sur ce point: les sous-en-tête de sécurité de l'IEEE 802.15.4:2011 utilisent des conventions d'émission et de documentation de MSB.

L'ordre d'émission des bits au sein d'un octet est traité à la PhL. Au sein de la DL le débat relatif au MSB et au LSB est limité à l'ordonnancement des octets.

En conséquence, la DL est inévitablement "mixed-endian" (boutiste mélangée), certaines sections utilisant l'ordonnancement de bit "big-endian" (gros-boutiste) alors que d'autres utilisent le "little-endian" (petit-boutiste).

En général, les en-têtes de DPDU normalisées suivent les conventions de l'IEEE 802.15.4:2011, comme suit:

– La présente norme, excepté les en-têtes DL et MAC, suit les conventions MSB.
– Les en-têtes de DL et MAC normalisés suivent les conventions LSB, avec certaines exceptions clairement indiquées dans l'en-tête de la DPDU.
– Au sein de la DPDU, les sous-en-têtes de sécurité suivent les conventions MSB, suivant le précédent de l'IEEE 802.15.4.
– Tous les champs au sein de l'en-tête de la DPDU sont documentés en montrant le bit 7 à gauche et le bit 0 à droite, suivant la convention de la présente norme.
– Les attributs de DLMO, accessibles au gestionnaire de système par l'intermédiaire du DMAP, sont des informations d'AL et, à ce titre, utilisent généralement la convention MSB. Certaines exceptions sont faites pour des champs qui interagissent directement avec les en-têtes DPDU qui utilisent la convention LSB.

L'ordonnancement des octets LSB est explicitement noté dans diverses parties de la spécification de la DL. Par convention, l'octet 0 est l'octet de poids faible. LSB indique que l'octet de poids faible (octet 0) est émis le premier et que l'octet de poids fort (octet n) est émis le dernier. Sans spécification, l'ordonnancement inverse est utilisé pour l'émission.

9.3.2.2 Nombres entiers non signés de DL extensibles

La spécification de DL utilise une construction appelée ExtDLUint pour l'émission compressée de nombres entiers non signés. Il ne s'agit pas d'un type utilisé dans d'autres normes, et à ce titre, l'ExtDLUint apparaît seulement dans des en-têtes de DPDU et au sein de chaînes d'octets définies par la DL. Il est utilisé pour indiquer le codage compressé d'un nombre entier non signé de 15 bits; il n'est pas utilisé pour acheminer d'autres données. Sachant que ce

type n'est pas utilisé en dehors de la DL, il n'est pas spécifié comme étant un type de données normalisé pris en charge par l'AL.

Un ExtDLUint doit être comme un seul octet lorsque sa valeur se situe dans la plage 0..127, et comme deux octets lorsque sa valeur se situe dans la plage de 128..32 767, avec le codage tel que montré dans le Tableau 108 et dans le Tableau 109. Le bit 0 dans le premier octet indique si un ou deux octets sont émis. L'ordonnancement des octets est toujours tel que montré ici, avec la taille indiquée dans le bit 0 du premier octet émis.

Tableau 108 – ExtDLUint, variante à un seul octet

Octets	Bits							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**
1	2^6	2^5	2^4	2^3	2^2	2^1	2^0	Sélection = 0

Tableau 109 – ExtDLUint, variante à deux octets

Octets	Bits							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**
1	2^6	2^5	2^4	2^3	2^2	2^1	2^0	Sélection = 1
2	2^{14}	2^{13}	2^{12}	2^{11}	2^{10}	2^9	2^8	2^7

9.3.3 En-têtes de la commande d'accès aux supports

9.3.3.1 Généralités

La présente norme utilise un format d'en-tête MAC dont les structures de données sont conformes à la structure détaillée et au codage de champ de l'IEEE 802.15.4:2011, 5.2.1 et 5.2.2.2, suivi d'extensions qui sont particulières à la présente norme. Seules des DPDU Data de l'IEEE 802.15.4:2011, 5.2.2.2 sont utilisées par la présente norme.

La présente norme n'utilise pas la sécurité de l'IEEE 802.15.4. A la place, une sécurité similaire est prise en charge dans le DMXHR. La sécurité de DPDU dans la présente norme est similaire à la sécurité selon l'IEEE 802.15.4; la principale différence est que la présente norme incorpore le sens partagé du temps de la DLE et autres informations spécifiques à un contexte d'utilisation dans les nonces cryptographiques, ce qui conduit à des DPDU plus compactes et à une résistance améliorée contre les attaques de rejet et de changement d'orientation. Pour renforcer la résistance aux attaques, les numéros de séquence DPDU de la présente norme sont dérivés de sources de contenu différentes de celles spécifiées par l'IEEE 802.15.4:2011, 5.2.1.2.

Les DPDU ACK/NAK de l'IEEE 802.15.4:2011, 5.2.3 ne peuvent pas être distinguées de façon fiable d'une DPDU identique temporisée de manière similaire, envoyée par un appareil qui n'est pas le destinataire prévu. Une telle indistinguabilité peut résulter d'une activité concurrente sur la même voie physique par d'autres appareils que le destinataire prévu (par exemple dans d'autres réseaux proches) ou du brouillage délibéré par un attaquant de la DPDU ACK/NAK après réception de la DPDU Data de la transaction. C'est pourquoi la présente norme utilise des DPDU Data authentifiables courtes pour mettre en œuvre des fonctionnalités ACK/NAK similaires mais étendues. Lorsque les adresses MAC source et de destination de telles DPDU ACK/NAK sont les adresses MAC source et de destination, respectivement, de la DPDU Data sollicitante, il n y a pas besoin d'acheminer ces adresses de manière explicite. Ainsi, la présente norme permet à de telles DPDU ACK/NAK de supprimer les deux champs d'adresses MAC, ce qui contredit la contrainte de l'IEEE 802.15.4:2011, 5.2.1.1.8.

NOTE Même si les amendements de l'IEEE 802.15.4 avaient pour but de couvrir des problèmes similaires à ceux qui ont engendré les écarts précédemment décrits, ils le font souvent dans des manières qui sont incompatibles

avec la norme ISA 100.11a:2011 sur laquelle est basée la présente norme internationale et sont donc également incompatibles avec la présente norme, qui s'efforce de maintenir la compatibilité avec les équipements déployés qui utilisent la norme ANSI/ISA en question.

9.3.3.2 En-tête de la commande d'accès aux supports

Le format du sous-ensemble de MHR normalisé est spécifié dans l'IEEE 802.15.4:2011 et l'IEEE 802.15.4:2011, Figure 35, tel qu'utilisé par la présente norme, est résumé dans le Tableau 110.

Tableau 110 – MHR de DPDU Data

Nombre d'octets	bits							
	7	6	5	4	3	2	1	0
2	Frame control (LSB ordering)							
1	Sequence number (Numéro de séquence)							
0 ou 2	PAN ID							
0, 2 ou 8	Adresse de destination							
0, 2 ou 8	Adresse source							
NOTE Le PAN ID, les champs d'adresse de destination et d'adresse source sont chacun émis dans l'ordre LSB.								

La longueur du MHR est habituellement de 9 octets, y compris un PAN ID et deux adresses DL16Address, avec les exceptions suivantes:

- Les DPDU Data de sollicitation ont un PAN ID nul (de longueur égale à zéro) et deux adresses MAC nulles, de telle sorte que le MHR est de 3 octets.
- Les DPDU Data d'annonce ont une adresse MAC de destination nulle, de telle sorte que le MHR est de 7 octets.
- Les autres DPDU Data à destination ou en provenance d'une DLE non rattachée ont une adresse DL16Address et une adresse EUI64Address et, de ce fait, la longueur d'un MHR adressé à destination ou en provenance d'une DLE non rattachée est de 15 octets.

NOTE 1 La capacité de charge utile de la DPDU par défaut, dlmo.MaxDsduSize, est basée sur une taille de MHR de 15 octets et peut être utilisée pour prendre des décisions de fragmentation pour des DLE non rattachées.

- Les DPDU ACK/NAK, qui sont utilisées pour les acquittements immédiats (SCS) ont un PAN ID nul, une adresse MAC de destination nulle, et une adresse MAC source qui est soit
  - nulle (de longueur égale à zéro), de telle sorte que le MHR est de 3 octets; ou
  - une adresse DL16Address, de telle sorte que le MHR est de 5 octets; ou
  - une adresse EUI64Address, de telle sorte que le MHR est de 11 octets.

NOTE 2 Le PAN ID est supprimé car l'authentification de sécurité des DPDU ACK/NAK sert à rejeter toute DPDU ACK/NAK prévue pour un appareil différent, que ce soit sur le même PAN ou un PAN différent.

Conformément au Tableau 110, les champs comprennent:

a) Contrôle de trame. Pour ce champ, les sous-champs sont tels que spécifiés dans l'IEEE 802.15.4:2011, 5.2.1.1:
   - Le FrameType (type de trame) doit être Data.
   - SecurityEnabled doit être "false", car l'IEEE 802.15.4 n'est pas utilisée.

     NOTE 3 La sécurité étendue de la présente norme est prise en charge par DMXHR.
   - FramePending doit être "false".

– Ack.Request doit être "false".

NOTE 4 Le type de DPDU d'acquittement immédiat de l'IEEE 802.15.4 facile à reproduire n'est pas utilisé par la présente norme.

– Lorsqu'une adresse de destination D et une adresse de source D sont toutes les deux incluses, la compression du PAN ID doit indiquer que le même PAN ID est utilisé pour les deux adresses. Le cas échéant, la compression du PAN ID doit être "false" (car une telle compression ne s'applique que lorsque deux adresses D sont présentes).

– Les adresses MAC sont habituellement des adresses DL16Address, avec les exceptions telles que décrites ci-dessous. Les adresses EUI64Address sont utilisées par une DLE se rattachant à un sous-réseau D. Les adresses de destination sont omises dans les annonces dédiées et les sollicitations.

– La version de trame doit être 0x01.

b) Numéro de séquence. Utilisé par le DSC, tel que décrit en 7.3.2.4.10.

NOTE 5 L'IEEE 802.15.4 exige que chaque DLE augmente son numéro de séquence après chaque utilisation afin que le numéro de séquence soit unique pour toutes les DPDU Data et les DPDU ACK/NAK générées par une DLE. Toutefois, la présente norme utilise le champ "sequence number" (numéro de séquence) dans un but quelque peu différent et fournit donc une méthode alternative (autre que la séquentialité cyclique) pour s'assurer que les nonces cryptographiques générés par chaque appareil réel sont uniques au sein de la durée de vie opérationnelle de la clé cryptographique avec laquelle ils sont employés.

NOTE 6 Dans la présente norme, à la fois les DLE et les TLE génèrent des nonces. Les dispositions dont il est fait référence en NOTE 5 s'assurent que les deux ensembles de nonces générés sont disjoints.

c) Le PAN ID doit concorder avec le dlmo.SubnetID et doit être absent des DPDU Data de sollicitation. Si la DPDU achemine à la fois une adresse MAC source et de destination, le PAN ID doit être le PAN ID de la destination (avec le PAN ID source inféré comme étant identique). S'il n'y a pas d'adresse de destination, telle que dans une DPDU Data d'annonce, le PAN ID doit être un PAN ID de source. Dans une DPDU Data de sollicitation, où il n'y a ni source ni adresse de destination, ce champ doit être nul (élidé). Ce champ doit être nul (élidé) dans toutes les DPDU ACK/NAK. Voir 9.1.10.2.

d) L'adresse de destination est normalement un pseudonyme d'adresse DL16Address pour une adresse IPv6Address. Une adresse EUI64Address doit être utilisée pour adresser des DLE qui n'ont pas encore reçu une adresse DL16Address. L'adresse de destination doit être absente dans les DPDU Data d'annonce dédiées, les DPDU Data de sollicitation et les DPDU ACK/NAK.

e) L'adresse source est normalement un pseudonyme d'adresse DL16Address pour une adresse IPv6Address. Une adresse EUI64Address doit être utilisée pour identifier des DLE qui n'ont pas encore reçu une adresse DL16Address. L'adresse de source D doit être absente des DPDU Data de sollicitation, des DPDU ACK/NAK où l'adresse D serait identique à l'adresse D de destination de la DPDU Data reçue qui a initié la transaction.

9.3.3.3 Sous-en-tête DPDU Data

La structure du DHDR pour une DPDU Data est montrée dans le Tableau 111.

Tableau 111 – DHDR de DPDU Data

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	DPDU ACK/NAK attendues	Demande de la qualité du signal dans la DPDU ACK	Demande de l'adresse EUI64Adress dans la DPDU ACK	Inclut DAUX	DMXHR inclut un décalage de saut de voie lent	Destinataire d'horloge	Version DL Toujours 01	

Cette DHDR est toujours de 1 octet.

Conformément au Tableau 111:

- Le bit 7 indique si les DPDU ACK/NAK sont attendues des destinataires adressés de façon explicite ou implicite.
- Le bit 6 indique s'il convient, oui ou non, que la DLE réceptrice rapporte les informations relatives à la qualité de signal dans la DPDU ACK/NAK.
- Le bit 5 indique s'il convient, oui ou non, pour la DLE destinataire d'inclure son adresse EUI64Address dans la DPDU ACK/NAK. Cette valeur de réglage doit être utilisée par l'émetteur chaque fois qu'un acquittement est demandé (bit 7 de valeur 1), et qu'aucune adresse EUI64Address pour le voisin n'existe dans dlmo.Neighbor. Voir 9.1.10.1.

NOTE Le bit 7 est sensé uniquement pour la DPDU Data initiale d'une transaction. Les bits 6 et 5 ne sont sensés que lorsque le bit 7 est sensé et à la valeur true.

- Le bit 4 indique la présence ou l'absence d'un sous-en-tête DAUX dans la DPDU Data.
- Le bit 3 indique si le décalage de saut de voie lent doit être inclus dans le DMXHR. Cette valeur doit être incluse dans les DPDU Data en monodiffusion où le saut de voie lent est utilisé. Voir 9.1.9.2.4.
- Le bit 2 indique si la DLE émettrice est un récepteur d'horloge de DL. Il s'agit d'une demande implicite au récepteur d'inclure une correction d'horloge dans l'acquittement.
- Les bits 0..1 indiquent le numéro de version de DL. Une valeur de 0x01 doit être utilisée, la valeur 0x10 étant réservée pour usage futur. Une valeur de 0x11 est utilisée dans le même emplacement dans la DPDU ACK/NAK et aide à distinguer une DPDU Data d'une DPDU ACK/NAK (voir 9.3.4).

9.3.3.4 Sous-en-tête d'extension MAC de la DPDU

Un DMXHR suivant le DHDR est résumé dans le Tableau 112.

Tableau 112 – DMXHR de DPDU Data

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Security control							
1	CryptoKeyIdentifier							
0..2	Slow-channel-hopping-offset (ExtDLUint)							

NOTE Pour les futures PHY avec plus de 16 voies, il est vraisemblable que le numéro de voie sera ajouté sous forme de champ virtuel.. Cela sera l'objet d'une normalisation future, mais a été pris en considération dans la conception de DMXHR.

La taille du DMXHR est de 2..4 octets. Une taille de DMXHR de 3 octets, correspondant à un taux de saut de voie lent d'environ 1,25 s ou moins, a été utilisée pour calculer la valeur par défaut de dlmo.MaxDsduSize.

Conformément au Tableau 112, les attributs comprennent:

- Security control et CryptoKeyIdentifier. Les champs de sécurité sont laissés non spécifiés par la DL et sont établis par le DSC. Voir 9.1.12 pour une vue d'ensemble de la relation entre la DL et les DSC. Alors que l'IEEE permet un attribut CryptoKeyIdentifier d'une longueur pouvant atteindre 9 octets, sa taille est toujours égale à 1 octet dans la présente norme.
- Le décalage de saut de voie lent spécifie le décalage de l'intervalle de temps au cours de la période de saut de voie lent, s'il est nécessaire d'identifier sans ambiguïté un intervalle de temps (car l'initiateur de transaction et le répondeur ont des perceptions locales différentes du même intervalle de temps). La présence ou l'absence de ce champ est indiquée dans le DHDR. Le décalage de saut de voie lent est décrit en 9.1.9.4.9.

9.3.3.5 Sous-en-tête auxiliaire de DPDU

Le sous-en-tête DAUX est utilisé pour:

- la découverte de voisins de DL;
- l'activation temporaire de liaisons;
- les rapports relatifs à la qualité de signal reçu dans les acquittements.

Le sous-en-tête DAUX, présent seulement lorsque le bit 4 de l'octet du DHDR est mis, est décrit en 9.3.5.

Une longueur de DAUX de 0 octet a été utilisée pour calculer la valeur par défaut de dlmo.MaxDsduSize.

NOTE dlmo.MaxDsduSize est utilisé pour prendre des décisions de fragmentation. Le sous-en-tête DAUX est utilisable pour activer des liaisons dans un scénario de fragmentation. Cependant, l'activation de liaison n'est pas possible au cours du processus de rattachement et, à ce titre, l'activation de liaison n'est jamais combinée avec les adresses EUI64Address. Parce que le calcul de dlmo.MaxDsduSize inclut une adresse EUI64Addresses, il permet la prise en charge d'un sous-en-tête d'activation de liaison DAUX lorsqu'une adresse EUI64Addresses n'est pas présente.

9.3.3.6 Sous-en-tête de routage de DPDU

Il existe deux variantes du sous-en-tête DROUT. Une variante compressée, de taille égale à deux octets, est utilisée lorsqu'un seul graphe est utilisé pour l'adressage. La variante compressée est également utilisée lorsque le routage à un seul saut est utilisé, le chemin étant implicite dans l'adressage de niveau MAC donné dans le MHR selon l'IEEE 802.15.4. Lorsqu'une série d'adresses est nécessaire, une variante non compressée du sous-en-tête DROUT doit être utilisée.

Le sous-en-tête DROUT doit être élidé dans une DPDU Data qui n'a pas de charge utile de couche supérieure, comme l'indique une DSDU de taille zéro.

La variante compressée du sous-en-tête DROUT doit être utilisée dans le cas commun où un seul graphe, avec un indice de 255 ou moins, est utilisé pour le routage. Elle est montrée dans le Tableau 113.

Tableau 113 – Structure de DROUT, variante compressée

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Compress=1	Priority				DlForwardLimit		
0..1	DlForwardLimitExt							
1	GraphID							

Une taille de DROUT de 2 octets a été utilisée pour calculer la valeur par défaut de dlmo.MaxDsduSize. MaxDsduSize a normalement besoin d'être réduit lorsque le routage source est utilisé.

Conformément au Tableau 113, la variante compressée du DROUT comprend:

- Compress. Si cette valeur est mise à 1, la variante compressée du format de DROUT doit être utilisée.
- Priority. Elle doit être mise à la priorité de 4 bis de la DPDU Data.
- DlForwardLimit et DlForwardLimitExt (limite de transmission) limitent le nombre de fois qu'une DPDU Data peut être transmise au sein d'un sous-réseau D. Si la limite de transmission est inférieure à 7, la valeur doit être transmise dans DlForwardLimit et DlForwardLimitExt doit être élidé. Si la limite des transmissions est supérieure ou

égale à 7, DlForwardLimit doit être émis comme étant 7, et la limite des transmissions doit être émise dans DlForwardLimitExt.

La limite des transmissions est initialisée par la DL lorsque le chemin est sélectionné, en fonction de la valeur de dlmo.Route[ ].ForwardLimit. Lorsqu'une DPDU Data en monodiffusion est reçue avec succès par la DL et a besoin d'être transmise, la DPDU Data doit être rejetée si sa limite de transmissions est zéro. Si sa limite de transmissions est positive, la limite de transmissions doit être décrémentée (éventuellement à zéro) et la DPDU Data doit être placée dans la file d'attente de messages.

- GraphID (8 bits). Les GraphID conformes à la présente norme sont des nombres entiers non signés de 12 bits. Dans le cas commun où le chemin est un seul ID de graphe dans la plage 1..255, la variante compressée du sous-en-tête DROUT doit être utilisée. En outre, la variante compressée est utilisée dans le routage de source à un seul saut, dans lequel GraphID=0 doit indiquer que la destination est située à une distance d'un saut. Sachant que l'adresse de destination à un seul saut peut être trouvée dans le MHR, elle peut ne pas être répétée dans DROUT. La valeur GraphID=0 doit être utilisée au cours du processus de rattachement pour un adressage à destination et en provenance d'un proxy voisin, et elle représente la seule manière dans la présente norme d'indiquer une adresse de destination EUI64Address dans DROUT.

NOTE il est possible pour un gestionnaire de système de configurer un chemin D circulaire, la DPDU Data étant transmise jusqu'à ce que ForwardLimit décrémente à zéro. Le champ LH dans l'en-tête de DL, décrit en 9.3.3.7, n'est pas destiné à empêcher les chemins circulaires au sein d'un sous-réseau D.

La variante non compressée du sous-en-tête DROUT est montrée dans le Tableau 114.

Tableau 114 – Structure de DROUT, variante non compressée

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Compress=0	Priority				DlForwardLimit		
0..1	DlForwardLimitExt							
1	*N* (nombre d'entrées dans la table de routage)							
2*N	Séries de *N* GraphIDs/addresses (Unsigned16, LSB)							
NOTE Chaque GraphID/address est transmise dans l'ordre LSB.								

Conformément au Tableau 114, la variante non compressée du sous-en-tête DROUT comprend:

- Compression: Si cette valeur est mise à 0, la variante non compressée du format de DROUT doit être utilisée.
- Priority, DlForwardLimit, et DlForwardLimitExt sont tels que décrits ci-dessus avec le Tableau 113.
- *N*: Ce champ doit être mis au nombre d'entrées dans Route. Les entrées peuvent être une combinaison de GraphID et d'adresses D DL16Address. La valeur de *N* ne doit pas dépasser 15.
- Route: Ce champ doit être mis à une série de GraphID et/ou d'adresses DL16Address, indiquant le chemin, dans l'ordre, le long duquel la DPDU Data se déplacera. L'IETF RFC 4944 limite las plages d'adresses en monodiffusion en plages $1..2^{15}-1$. Les GraphIDs 12 bits de ce champ doivent être représentés de manière disjointe du rang d'adresse 0x 1010 gggg gggg gggg, qui est le rang $10\times2^{12}..11\times2^{12}-1$.

Lorsque le routage de source est utilisé, le sous-en-tête DROUT doit être raccourci par la DL des routeurs intermédiaires à mesure que la DPDU Data progresse le long du chemin, comme décrit en 9.1.6.

La première entrée dans le sous-en-tête DROUT est utilisée pour déterminer le prochain saut. Par exemple, le chemin peut être spécifié à la source comme étant <000 123, 000 456, 000 789>. L'adresse de premier saut, <000 123>, est utilisée pour envoyer la DPDU Data vers un voisin immédiat. Le sous-en-tête DROUT, tel que reçu par la DLE <000 123>, contient la route source <000 123, 000 456, 000 789>. Lorsqu'il est reçu, ce chemin est raccourci à <000 456, 000 789> (voir 9.1.6.3), indiquant que l'adresse <000 456> est le prochain saut.

Lorsqu'un graphe est spécifié comme étant la première entrée dans un chemin de source, la DPDU Data doit suivre le graphe jusqu'à ce qu'il soit terminé comme décrit en 9.1.6.

9.3.3.7 Sous-en-tête d'adressage

Le sous-en-tête d'adressage (DADDR) inclut les adresses de source et de destination de NL, avec trois champs de NL qui sont visibles à la DL.

Le sous-en-tête DADDR doit être élidé dans une DPDU Data qui n'a pas de charge utile d'ordre supérieur, à savoir une DSDU de taille zéro.

La structure du sous-en-tête DADDR est montrée dans le Tableau 115.

Tableau 115 – Structure de DADDR

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	DE	LH	ECN		Reserved=0			
1..2	SrcAddr (ExtDLUint)							
1..2	DestAddr (ExtDLUint)							

Une taille de DADDR de 4 octets a été utilisée pour calculer la valeur par défaut de dlmo.MaxDsduSize, reflétant une hypothèse selon laquelle une adresse ou les autres adresses est (sont) encodée(s) en un octet.

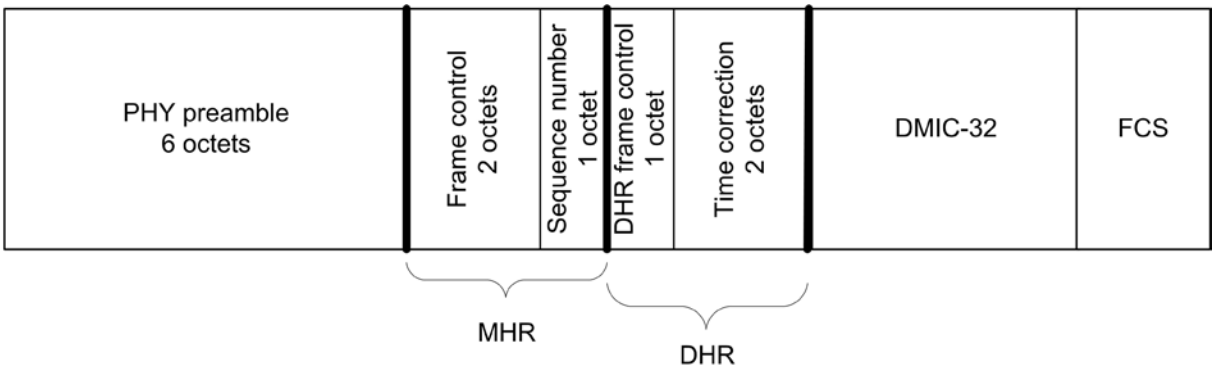
Les champs comprennent:

- Le champ Discard eligible (DE) doit être mis en fonction de la valeur fournie par la NL par l'intermédiaire de DD-DATA.request. DE=1 indique que la DSDU est éligible à être rejetée de la file d'attente de messages en faveur d'une DPDU Data entrante avec DE=0, et de priorité égale ou plus haute.
- Le champ LastHop (LH) doit être mis en fonction de la valeur fournie par la NL par l'intermédiaire de DD-DATA.request. Ce bit est transporté par la DL pour éviter les chemins circulaires à la NL, et n'affecte pas le comportement de la DL.
- Le champ ExplicitCongestionNotification (ECN) doit être mis en fonction de la valeur fournie par la NL par l'intermédiaire de DD-DATA.request. Un routeur subissant l'encombrement peut positionner l'ECN comme décrit dans l'IETF RFC 3168. Voir 9.1.9.4.5 pour un débat relatif à l'ECN.
- SrcAddr est mis en fonction de la valeur fournie par la NL par l'intermédiaire de DD-DATA.request. Si l'adresse D source de est dupliquée dans le champ adresse D de source de MHR, SrcAddr doit être encodé 0x00. Cela couvre le cas, au cours du processus de rattachement, dans lequel l'adresse source est une adresse EUI64Address.
- DestAddr est mis en fonction de la valeur fournie par la NL par l'intermédiaire de DD-DATA.request. Si l'adresse D de destination est dupliquée dans le champ d'adresse de destination de MHR, DestAddr doit être encodé 0x00. Cela couvre le cas, au cours du processus de rattachement, dans lequel l'adresse D de destination est une adresse EUI64Address.

En codant une adresse DL dupliquée comme étant zéro, un octet est compressé sur le premier saut et sur le dernier saut lorsque l'adresse est inférieure à 0x0080, économisant de l'énergie. Ainsi, une adresse de DADDR codée comme étant zéro référence l'adresse DL16Address ou l'adresse EUI64Address correspondante dans le MHR.

9.3.4 Les DPDU d'acquittement MAC

La Figure 89 montre la structure des DPDU ACK/NAK.



NOTE This figure includes only the most commonly used fields.

Légende

Anglais	Français
PHY preamble 6 octets	Préambule PHY 6 octets
Frame control 2 octets	Contrôle de trames 2 octet
Sequence number 1 octet	Numéro de séquence 1 octet
DHR frame control 1 octet	Contrôle de trame DHR 1 octet
Time correction 2 octets	Correction de temps 2 octets
NOTE This figure includes only the most commonly used fields	NOTE Cette figure n'inclut que les champs les plus communément utilisés

Figure 89 – Disposition type des DPDU ACK/NAK

L'adresse source d'une DPDU ACK/NAK est l'adresse de la DLE qui émet la DPDU. L'adresse de destination est l'adresse du destinataire prévu de la DPDU.

Chaque DPDU ACK/NAK doit être authentifiée avec un DMIC, mais pas chiffrée. Certains champs sont virtuels, utilisés pour créer le DMIC, mais pas réellement émis.

Bien que la DPDU ACK/NAK soit une trame de donnée de l'IEEE 802.15.4, elle peut être distinguée des autres trames de données de type IEEE 802.15.4 en se basant sur:

– la temporisation de la DPDU ACK/NAK, suivant l'émission de la DPDU, telle que spécifiée en 9.4.3.3; et
– Les bits 1..0 de son champ de contrôle de trame de DHR, tel que spécifié dans le Tableau 118; et
– un champ virtuel dans la DPDU ACK/NAK, qui fait écho au DMIC original de la DPDU Data, tel que spécifié dans le Tableau 117.

Comme décrit en 7.3.2.2, le DMIC dans une DPDU ACK/NAK utilise la même politique de sécurité que la DPDU Data d'origine de la transaction D dont cet ACK/NAK est la réponse , avec l'exception que la taille des DPDU ACK/NAK de DMIC doit toujours être de 32 bits, quelle que soit la politique de sécurité des DPDU Data.

Le format d'un MHR selon l'IEEE 802.15.4 est résumé dans le Tableau 116.

Tableau 116 – MHR de DPDU ACK/NAK

Nombre d'octets	Bits							
	7	6	5	6	3	2	1	0
2	Frame control (LSB ordering)							
1	Sequence number (Numéro de séquence)							
0	Adresse de destination (nulle)							
0 ou 2	PAN ID							
0, 2 ou 8	Adresse source							
NOTE Le PAN ID et les champs d'adresse source sont chacun émis dans l'ordre LSB.								

La description détaillée de ces champs est spécifiée dans l'IEEE 802.15.4. Conformément au Tableau 116, les attributs comprennent:

- Les attributs de commande de trame (Frame control) pour les DPDU ACK/NAK, comme suit:
  - Le FrameType (type de trame) doit être Data.
  - SecurityEnabled doit être désactivée, car elle est traitée dans le DHR.
  - FramePending doit être "false".
  - AckRequest doit être "false".

  NOTE 1 Le bit ci-dessus demande la génération de la forme non sécurisable de l'acquittement immédiat offert par l'IEEE 802.15.4:, qui n'est pas utilisée par la présente norme.

  - Le mode d'adressage de source doit être 0x00 (à savoir: implicite), excepté pour les cas décrits ci-dessous dans lesquels le PAN ID et l'adresse source sont inclus dans le MHR.
  - Le mode d'adressage de destination doit être 0x00 (à savoir: implicite).
  - FrameVersion doit être 0x01.
- Numéro de séquence, utilisé par le DSC, tel que décrit en 7.3.2.4.10. Sachant que la présente norme n'utilise pas le type de trame ACK non sécurisable spécifié par l'IEEE 802.15.4, la DPDU ACK/NAK ne transporte pas le numéro de séquence issu de la DPDU Data précédente. A la place, le numéro de séquence doit être lui-même similaire à celui d'une DPDU Data (voir 9.3.3.2) et doit être utilisé dans la construction du nonce D pour le DMIC de la DPDU ACK/NAK.
- PAN ID, présent uniquement lorsque l'adresse source est présente (non nulle).
- Adresse source. Normalement, une adresse D source n'est pas incluse dans une DPDU ACK/NAK parce qu'elle concorde avec l'adresse D de destination de la dernière DPDU Data reçue. Cependant, il existe deux exceptions où elle est incluse:
  - Un acquitteur immédiat d'une DPDU Data reçue doit inclure son adresse EUI64Address en tant qu'adresse source du MHR de la DPDU ACK/NAK de réponse, lorsque cela est demandé dans le DHDR de la DPDU Data reçue.
  - Un acquitteur immédiat d'une DPDU Data reçue dont l'adresse D est différente de l'adresse D de destination de la dernière DPDU Data reçue doit inclure son adresse DL16Address en tant qu'adresse source de la DPDU ACK/NAK de réponse.

  NOTE 2 Cette seconde exception se produit dans les acquittements duodiffusion/N-diffusion secondaires.

Un prototype de DHR suivant un MHR est résumé dans le Tableau 117.

Tableau 117 – DHR de DPDU ACK/NAK

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	ACK/NAK DPDU DHDR							
4 (virtuels)	DMIC en écho de la DPDU Data reçue							
0, 2	Correction du temps (Unsigned16, LSB) lorsque demandée							
0..2	Décalage d'intervalle de temps (ExtDLUint) lorsque nécessaire							
0..3	Sous-en-tête DAUX habituellement absent							

Conformément au Tableau 117, les attributs comprennent:

- Le DHDR de la DPDU ACK/NAK est décrit dans le Tableau 118.
- DMIC en écho de la DPDU Data reçue. Pour un débat relatif au traitement de ce champ virtuel, voir 7.3.2. Pour connecter sans ambiguïté la DPDU ACK/NAK à la DPDU Data à laquelle elle est une réponse, le DMIC de la DPDU Data est inclus dans le DHR de la DPDU ACK/NAK comme un champ virtuel, avec l'ordonnancement d'octets concordant au DMIC de la DPDU Data. Ce champ virtuel est utilisé pour calculer le DMIC de la DPDU ACK/NAK, mais il n'est pas émis. Si le DMIC reçu a une longueur de plus de 4 octets, seuls les 4 octets initiaux (les plus à gauche) du DMIC sont repris en écho comme un champ virtuel.
- Correction de temps (LSB). Utilisée par des sources d'horloge de DL pour corriger le temps du destinataire d'horloge de DL, si elle est demandée dans le DHDR de la DPDU reçue. Cette valeur non signée de 2 octets, lorsqu'elle est incluse dans la DPDU ACK/NAK, fait écho au temps auquel la DPDU Data a été reçue. La valeur, en 2^{-20}s (approximativement 0,954 μs), rapporte un décalage par rapport au temps de début programmé de l'intervalle de temps courant dans la base de temps de l'acquitteur. La valeur rapportée est basée sur le temps de début de la DPDU Data. Voir 9.1.9.3.2.
- Le décalage d'intervalle de temps de l'acquitteur est fourni si nécessaire au sein d'une période de saut de voie lent. Cette valeur, lorsqu'elle est incluse dans la DPDU ACK/NAK, indique l'intervalle de temps courant dans la base du temps de l'acquitteur. Elle doit être incluse seulement lorsque la DPDU Data est reçue dans un intervalle de temps de saut de voie lent différent de celui utilisé dans l'acquittement. Le premier intervalle de temps dans une période de saut de voie lent a un décalage de zéro. Lorsque le décalage corrigé d'intervalle de temps est non nul, la correction de temps (champ précédent), lorsqu'elle est incluse, doit être la valeur corrigée du temps programmé d'intervalle de temps. La sécurité exige que le temps d'une DLE augmente d'un intervalle de temps à l'autre. Par conséquent, si l'intervalle de temps est corrigé à un intervalle de temps plus précoce par un destinataire d'horloge, il doit y avoir une interruption de service, égale à la grandeur de la correction d'intervalle de temps plus au moins un intervalle de temps. Voir 9.1.9.4.9.
- Sous-en-tête auxiliaire (DAUX). Le DAUX peut être inclus dans une DPDU ACK/NAK, dans le but limité de reprendre en écho la qualité de signal reçu (voir 9.3.5.5).

Dans une DPDU ACK/NAK, l'octet DHDR communique le type d'ACK/NAK et d'autres informations relatives à la sous-structure de la DPDU (voir Tableau 118).

Tableau 118 – DHDR d'une DPDU ACK/NAK

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Correction d'horloge incluse	Décalage de saut de voie lent inclus	Type d'ACK/NAK: 0: ACK 1: ACKwithECN 2: NAK0 3: NAK1		Sous-en-tête DAUX inclus	Reserved (=0)	DPDU ACK/NAK (=11)	

Le numéro de version de protocole de DL et la clé de sécurité MAC concordent toujours avec la DPDU Data reçue à laquelle la DPDU ACK/NAK est un acquittement immédiate; ils ne sont donc pas indiqués explicitement dans la DPDU ACK/NAK.

Le contenu en bits est comme suit:

- Le bit 7 indique si la DPDU ACK/NAK inclut des informations relatives à la correction d'horloge.
- Le bit 6 indique si la DPDU ACK/NAK inclut un décalage de saut de voie lent.
- Les bits 5..4 indiquent la classe de la DPDU ACK/NAK:

  0b10: un acquittement négatif NAK0 signalant que la DPDU Data a été reçue, mais qui ne pourrait pas être acquittée en raison d'un encombrement de la file d'attente de messages (9.1.9.4.4);

  0b11: un NAK1, signalant que la DPDU Data a été reçue, mais n'a pas été acceptée en raison d'antécédents récents de problèmes de transmission le long du chemin (9.1.9.4.4);

  0b00: un acquittement positif ACK;

  0b01: un acquittement positif ACK avec une notification d'encombrement explicite (ECN) (9.1.9.4.5).

  Il convient qu'un routeur qui signale une ECN dans le sens direct signale également l'ECN par des DPDU ACK/NAK lorsque la priorité de la DPDU Data est 7 ou moins. Une DLE recevant une ECN par l'intermédiaire d'une DPDU ACK/NAK peut traiter ce signal comme une notification précoce qu'il est susceptible de recevoir une ECN à des couches supérieures;
- Le bit 3 indique si la DPDU ACK/NAK inclut un sous-en-tête DAUX qui peut être inclus dans une DPDU ACK/NAK dans le but limité de rapporter la qualité de signal reçu.
- Le bit 2 est réservé et doit être mis à zéro.
- Les bit 1..0 sont mis à des uns partout (11) pour distinguer les DPDU ACK/NAK des autres DPDU.

9.3.5 Sous-en-tête auxiliaire de DL

9.3.5.1 Généralités

Un sous-en-tête auxiliaire (DAUX) peut être inclus dans n'importe quelle DPDU Data ou DPDU ACK/NAK. Les bits 7..5 du premier octet de DAUX déterminent son type, avec le format de sous-en-tête subséquent différent pour chaque type. Les types définis sont:

- Advertisement: type 0 dans la DPDU Data: fournit des informations nécessaires à de nouvelles DLE pour se synchroniser avec le sous-réseau D et le rejoindre;
- Solicitation: type 1 dans la DPDU Data: sollicite une annonce issue d'une DLE voisine;
- Activate link: type 2 dans la DPDU Data: active une liaison inactive pendant une période de temps;
- Signal quality: type 3 dans la DPDU ACK/NAK: rapporte la qualité du signal reçu.

Toutes les combinaisons de type et de classe DPDU sont réservées pour usage futur.

NOTE Suivant les conventions d'en-tête de DL, les champs DAUX utilisent l'ordre LSB ("little-endian", petit-boutiste) pour l'émission. Il existe certaines structures similaires dans le DLMO qui utilisent l'ordre MSB ("big-endian", gros boutiste). Par exemple, des structures de supertrame sont spécifiées dans les deux endroits, en utilisant l'ordre LSB dans l'en-tête de DL et l'ordre MSB dans des attributs du DLMO.

9.3.5.2 Sous-en-tête auxiliaire de type annonce (advertisement)

9.3.5.2.1 Généralités

Les champs au sein d'un DAUX d'annonce peuvent être groupés logiquement comme:

- sélection d'annonce;
- synchronisation du temps
- informations de supertrame;
- informations de rattachement; et
- contrôle d'intégrité

Le Tableau 119 résume la structure du DAUX d'annonce.

Tableau 119 – Structure du DAUX d'annonce

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Sélection d'annonce; voir Tableau 120							
6	Synchronisation du temps; voir Tableau 122							
6..10	Informations de supertrame; voir Tableau 124							
4..10	Informations de rattachement; voir Tableau 127							
2	Contrôle d'intégrité; voir 9.3.5.2.4.4							
NOTE Telle que décrite en 9.3.5.2.4.2, la taille du champ informations de rattachement est limitée à 10 octets.								

L'ID sous-réseau D du routeur d'annonce et l'adresse DL16Address sont acheminés par la sous-couche MAC, et peuvent ne pas être émis de façon redondante au sein du DAUX.

Un DAUX d'annonce peut être inclus au sein d'une DPDU Data, mais ne doit être pas inclus dans une DPDU ACK/NAK.

Une annonce inclut des informations qui permettent à la DLE réceptrice de créer des supertrames et des liaisons devant être utilisées au cours du processus de rattachement. Ces informations doivent être conservées par la DLE à la fin du processus de rattachement et, avec des valeurs par défaut de DL, constituer une base de données de départ pour les informations de planification de liaisons de la DLE. Les mêmes liaisons utilisées pour le rattachement sont temporairement utilisées pour des communications générales jusqu'à ce que le gestionnaire de système fournisse une configuration de remplacement.

Les attributs mis par la DLE en fonction des informations figurant dans l'annonce reçue incluent:

- dlmo.SubnetID est positionné en fonction du SubnetID dans l'annonce.
- TAI time (c'est-à-dire temps TAI) est synchronisé par l'annonce.
- dlmo.Superframe number1 est créé avec des champs copiés à partir de l'annonce.
- dlmo.Link number1 est créé comme une liaison d'émission avec des champs copiés à partir de l'annonce.
- dlmo.Link number2 est créé comme une liaison de réception avec des champs copiés à partir de l'annonce.

- dlmo.Link number3 peut être créé comme des liaisons de réception à balayage passif avec des champs copiés à partir de l'annonce, si fournis.
- dlmo.Neighbor est initialisé par la DLE avec une entrée correspondant au routeur d'annonce.
- dlmo.Graph number1 est automatiquement créé par la DLE pour fournir un accès au routeur d'annonce.
- dlmo.Route number1 est automatiquement créé par la DLE comme chemin par défaut utilisant le graphe numéro 1.

9.3.5.2.2 Sélections d'annonces

Le Tableau 120 spécifie le champ sélections d'annonces dans le DAUX d'annonce.

Tableau 120 – Eléments de sélections d'annonce

Nom de l'élément	Codage d'élément
DauxType	Type: Unsigned3 0=DAUX d'annonce
ChMapOv	Type: Unsigned1 0=default
DauxOptSlowHop	Type: Unsigned1 0=default
Reserved (alignement d'octets)	Type: Unsigned3=0

Le Tableau 121 montre la structure du champ sélections d'annonces.

Tableau 121 – Sélections d'annonces

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	DauxType=0			DauxChMapOv	DauxOptSlowHop	Reserved=0		

Le champ sélections d'annonces fait 1 octet. Conformément au Tableau 120, les attributs comprennent:

- DauxType. Toujours mis à 0 pour un DAUX d'annonce. Indique la structure du DAUX dans le Tableau 119.
- DauxChMapOv. La valeur true indique que le champ DauxChMap est inclus dans la DPDU d'annonce. La valeur false sélectionne la carte de voies par défaut 0x7FFF. Ce champ correspond à dlmo.Superframe[ ].ChMapOv.
- DauxOptSlowHop. La valeur true indique que le sous-réseau D offre le saut de voie lent et que le champ DauxChMap est inclus dans la DPDU d'annonce. La valeur false indique la valeur par défaut pour le saut de voie en fonction du temps.

NOTE Le saut de voie lent peut être utilisé durant le processus de rattachement, mais aussi après.

- Les bits 2..0 sont réservés et doivent être mis à 0.

9.3.5.2.3 Synchronisation du temps d'annonce

Le Tableau 122 spécifie le champ synchronisation du temps dans le DAUX d'annonce.

Tableau 122 – Eléments de synchronisation du temps d'annonce

Nom de l'élément	Codage d'élément
DauxTAIsecond (temps TAI courant)	Type: Unsigned32 (LSB) Unités: 1 s
DauxTAIfraction (seconde TAI fractionnaire)	Type: Unsigned16 (LSB) Unités: 2^{-15} s

Le Tableau 123 montre la structure du champ synchronisation du temps d'annonce.

Tableau 123 – Structure de synchronisation du temps d'annonce

Octets	Bits								
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**	**Interprétation**
1	2^7	2^6	2^5	2^4	2^3	2^2	2^1	2^0	DauxTAIsecond; Partie intégrale du temps TAI avec une granularité de 1 s
2	2^{15}	2^{14}	2^{13}	2^{12}	2^{11}	2^{10}	2^9	2^8	
3	2^{23}	2^{22}	2^{21}	2^{20}	2^{19}	2^{18}	2^{17}	2^{16}	
4	2^{31}	2^{30}	2^{29}	2^{28}	2^{27}	2^{26}	2^{25}	2^{24}	
5	2^{-8}	2^{-9}	2^{-10}	2^{-11}	2^{-12}	2^{-13}	2^{-14}	2^{-15}	DauxTAIfraction; Partie fractionnelle du temps TAI avec une granularité de 2^{-15} s
6	0 réservé	2^{-1}	2^{-2}	2^{-3}	2^{-4}	2^{-5}	2^{-6}	2^{-7}	
NOTE La représentation ci-dessus est radicalement différente de celle de TAINetworkTime (Table 362), l'ordre d'octets étant inversé dans les quatre premiers octets et l'ordre d'octets étant à la fois inversé et décalé d'un bit dans les deux derniers octets.									

NOTE 1 DauxTAIfraction de 2^{-15} s a été retenu pour correspondre aux verres "de montre" très faible puissance et très précis de 32 kiHz qui sont généralement utilisés pour le matériel d'horloge continu des appareils WISN.

Le champ synchronisation du temps fait 6 octets. Conformément au Tableau 122, les sous-champs comprennent:

– DauxTAIsecond. Temps TAI courant en unités de 1 s.

– DauxTAIfraction. Seconde TAI fractionnaire en unités de 2^{-15} s, avec une plage de 0..32 667. Dans la seconde TAI, cela indique le temps de départ réel de la DPDU d'annonce. (Il convient qu'une mise en œuvre qui cadence réellement en fonction de la temporisation de SFD rende compte d'un temps de départ de DPDU qui est nominalement 1 octet, ou 32 μs, plus tardif que le temps où le délimiteur de début de trame, le SFD, est complètement émis/reçu.)

NOTE 2 Même si le temps TAI est normalement représenté sous la forme d'une fraction binaire à point fixe mise à l'échelle de 6 octets, modulo 2^{32} s, l'ordre d'octets de transmission à deux parties ci-dessus, où chaque partie est transmise séparément dans l'ordre LSB en premier et où la partie fractionnaire comporte un bit inutilisé inséré au point binaire, ne respecte pas l'ordre d'octets naturel de cette fraction à point fixe mise à l'échelle.

Voir 9.1.9 pour plus d'informations relatives au temps TAI et à l'alignement d'intervalles de temps.

L'identité et la temporisation programmée de l'intervalle de temps courant peuvent être dérivées du temps de départ réel de la DPDU Data combiné à la description de supertrame de rattachement. Voir 9.1.9.1.5.

Le temps dans une annonce doit être un reflet exact de l'horloge TAI interne de l'annonceur à ±96 μs (la durée de transmission de 3 octets) près, ce qui correspond à la fenêtre d'émission présumée pour les appareils conformes à la présente norme.

Une DPDU ACK/NAK en réponse à une demande de rattachement inclut une correction d'horloge qui peut être plus précise que l'annonce initiale, et également plus courante.

9.3.5.2.4 Supertrame et liaisons de rattachement d'annonce

9.3.5.2.4.1 Supertrame de rattachement d'annonce

NOTE Le processus de rattachement, y compris les sollicitations, les annonces et l'utilisation des informations transmises dans les annonces, est décrit en 7.4.

Trois liaisons sont spécifiées par l'annonce relativement à la découverte de voisins:

- liaison numéro 1 pour envoyer des demandes de rattachement, adressées au routeur d'annonce voisin;
- liaison numéro 2 pour recevoir les réponses de rattachement consécutives issues du routeur d'annonce; et
- liaison numéro 3 pour rechercher par balayage des voisins supplémentaires après que la DLE a réussi à rejoindre le sous-réseau D.

Toutes ces liaisons se réfèrent à la supertrame number1, qui est également spécifiée dans l'annonce.

Les noms de champ dans l'annonce correspondent aux champs équivalents dans dlmo.Superframe et dlmo.Link. Suivant les conventions d'en-tête de DL, l'ordonnancement d'octet LSB est utilisé sur certains champs qui sont émis en utilisant l'ordonnancement MSB dans la supertrame elle-même. Pour réduire au maximum les exigences relatives au traitement et compresser le sous-en-tête DAUX, un sous-ensemble de caractéristiques de supertrame et de liaison est pris en charge par l'intermédiaire de l'annonce.

Le Tableau 124 spécifie le champ d'informations de supertrame de rattachement.

Tableau 124 – Sous-champs d'informations de supertrame de rattachement

Nom de sous-champ	Codage de sous-champ
DauxTsDur (durée d'intervalle de temps)	Type: Unsigned16 Unités: 2^{-20} s
DauxChIndex (ID de modèle de saut de voie)	Type: ExtDLUint Plage valide: 1..5
DauxChBirth (point de début de référence de saut de voie)	Type: Unsigned8
DauxSfPeriod (nombre de base d'intervalles de temps dans chaque cycle de supertrame)	Type: ExtDLUint
DauxSfBirth (point de début du cycle de supertrame)	Type: ExtDLUint Plage valide: 0..127
DauxChRate (longueur de chaque période de saut de voie lent, en nombre d'intervalles de temps)	Type: Unsigned8 Non émis et prenant la valeur par défaut 1 lorsque DauxOptSlowHop est false
DauxChMap (carte des voies à saut de voie pour la gestion de spectre)	Type: Unsigned16 (LSB) Non émis et prenant la valeur par défaut 0x7FFF lorsque advChMapOv est false

Le Tableau 125 résume la structure du champ "informations de supertrame de rattachement" dans le DAUX d'annonce. Les champs ExtDLUint y sont montrés comme étant un seul octet.

Tableau 125 – Structure d'informations de supertrame de rattachement

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
2	DauxTsDur (LSB)							
1	DauxChIndex							
1	DauxChBirth							
1..2	DauxSfPeriod							
1	DauxSfBirth							
0..1	DauxChRate							
0..2	DauxChMap (LSB)							

Le champ informations de supertrame de rattachement fait 6..10 octets.

Chaque sous-champ d'informations de supertrame de rattachement d'annonce correspond à un champ dans dlmo.Superframe. Voir 9.4.3.5.

Pour créer la supertrame number1 à partir de l'annonce, la DL utilise des valeurs issues de l'annonce pour initialiser les champs de supertrame correspondants. Les champs dans la supertrame number1 qui n'ont pas des champs nommés d'une manière équivalente dans l'annonce prennent par défaut des valeurs fixes. Le Tableau 126 montre le mapping issu des sous-champs de l'annonce à la supertrame number1.

Tableau 126 – Supertrame dérivée de l'annonce

Nom du champ de supertrame	Valeur	Notes
* Index	1	-
TsDur	DauxTsDur	-
ChIndex	DauxChIndex	-
ChBirth	DauxChBirth	-
SFType	0	-
Priority	0	-
ChMapOv	DauxChMapOv	-
IdleUsed	0	-
SfPeriod	DauxSfPeriod	Type de données compressé utilisé dans l'annonce. Limite les supertrames utilisées pour le rattachement à une période de 300 s approximativement.
SfBirth	DauxSfBirth	Type de données compressé utilisé dans l'annonce, compatible avec SfPeriod
ChRate	DauxChRate	Type de données compressé utilisé dans l'annonce. Limite les supertrames utilisées pour le rattachement à une fréquence de saut de voie lent approximativement égale à un saut toute les 2,5 s.
ChMap	DauxChMap	Convertit les octets LSB en MSB
IdleTimer	null	-
rndSlots	null	-

9.3.5.2.4.2 Liaisons de rattachement d'annonce

NOTE 1 Le processus de rattachement, y compris les sollicitations, les annonces et l'utilisation des informations transmises dans les annonces, est décrit en 7.4.

Deux jeux de liaisons relatives au rattachement sont fournis dans chaque annonce:

- un jeu sortant de liaisons pour émettre des demandes de rattachement, utilisé pour initialiser dlmo.Link number1; et
- un jeu entrant de liaisons pour recevoir des réponses de rattachement, utilisé pour initialiser dlmo.Link number2;

en outre, le routeur d'annonce peut fournir un jeu de liaisons qu'une DLE peut utiliser pour rechercher par balayage des annonces lorsque le rattachement est achevé, utilisé pour initialiser dlmo.Link number3 lorsqu'il est fourni.

Chaque appareil qui tente de rejoindre un sous-réseau, à la réception d'une annonce d'un sous-réseau D qu'il choisit de rejoindre, doit configurer ses liaisons entrantes et sortantes en fonction des informations figurant dans l'annonce reçue. Il doit ensuite transmettre sa demande de rattachement au routeur d'annonce en utilisant ces liaisons sortantes.

Les liaisons utilisées pour le rattachement sont contraintes par rapport à un jeu élémentaire de caractéristiques. Des modèles d'intervalle de temps par défaut sont utilisés; voir Tableau 165, Tableau 166, et Tableau 167.

Trois types de liaisons sont identifiés:

– les liaisons JoinTx sont utilisées pour émettre des demandes de rattachement vers le routeur d'annonce;
– les liaisons JoinRx sont surveillées pendant l'attente d'une réponse de rattachement;
– les liaisons AdvRx, lorsqu'elles sont fournies, sont activées lorsque le rattachement est achevé pour rechercher par balayage passif des annonces issues de routeurs de remplacement.

Le Tableau 127 spécifie le champ informations de rattachement dans le DAUX d'annonce.

Tableau 127 – Eléments d'informations de rattachement

Nom de l'élément	Codage d'élément
DauxJoinBackoff (étendue maximale du repli et de répétition de tentative lors du rattachement)	Type: Unsigned4
DauxJoinTimeout (temporisation de rattachement)	Type: Unsigned4
DauxJoinFldXmit (indique des champs qui sont émis)	Type: Unsigned8
DauxJoinTx (liaison(s) JoinTx)	Type: Voir Tableau 184
DauxJoinRx (liaison(s) JoinRx)	Type: Voir Tableau 184
DauxAdvRx (liaison(s) d'annonce)	Type: Voir Tableau 184 (ou null)

L'élément DauxJoinFldXmit sélectionne les paramètres de programmation de liaisons utilisés pour des éléments DauxJoinTx, DauxJoinRx, et DauxAdvRx. Les valeurs de DauxJoinFldXmit de 0..3 correspondent à la sémantique décrite dans le Tableau 184.

Le Tableau 128 montre la structure du champ informations de rattachement. Les champs DauxJoinTx, DauxJoinRx, et DauxAdvRx peuvent faire 1..4 octet(s) (ou être vides seulement dans le cas de DauxAdvRx), selon la configuration et la sélection telles que décrites dans le Tableau 184.

Tableau 128 – Structure d'informations de rattachement

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	DauxJoinBackoff				DauxJoinTimeout			
1	DauxJoinFldXmit							
1..4	DauxJoinTx							
1..4	DauxJoinRx							
0..4	DauxAdvRx (peut être absent)							

Selon les solutions de rechange choisies, il apparaît à partir du Tableau 128 que la taille totale pourrait être une valeur quelconque entre quatre octets et quatorze octets. Cependant, des solutions de rechange doivent être choisies afin que la taille totale des champs montrés dans le Tableau 128 ne dépasse pas dix octets.

Conformément au Tableau 128, les attributs comprennent:

a) DauxJoinBackoff. Etendue maximale du repli exponentiel lors du rattachement. Si une demande de rattachement ne reçoit pas de DPDU ACK/NAK en raison d'une détection d'activité de voie CCA ou d'une émission échouée, la DLE doit se replier en sélectionnant un intervalle de temps uniformément aléatoire dans la plage de 0 s à 1 s pour la première répétition de tentative, et utiliser le premier intervalle de temps de JoinTx disponible après ce temps. Puis doubler la plage de temps avec chaque répétition de tentative. La DLE

peut répéter la tentative un nombre de fois pouvant atteindre DauxJoinBackoff fois et ne doit pas répéter la tentative plus de DauxJoinBackoff fois. A ce stade, il convient que la DLE abandonne la tentative d'envoyer un message au routeur d'annonce, retourne à l'état "provisioned" et recherche une autre annonce.

b) DauxJoinTimeout. Temps garanti, en s, pour recevoir une réponse de gestionnaire de système à une demande de rattachement. Exprimé comme un exposant, à la puissance de 2. Par exemple, si DauxJoinTimeout=5, alors la DLE peut s'attendre à un achèvement dans les 2^5 s (= 32 s). A la suite d'une temporisation, il convient que la DLE abandonne la tentative de se rattacher par l'intermédiaire du routeur d'annonce, retourne à l'état "provisioned" et recherche une autre annonce.

c) DauxJoinFldXmit:

- Bits 7..6: Unsigned2, décrivant le contenu de DauxJoinTx. Voir Tableau 184. Correspondant à dlmo.Link[ ].SchedType pour la liaison number1. La plage prise en charge est 0..2.
- Bits 5..4: Unsigned2, décrivant le contenu de DauxJoinRx. Voir Tableau 184. Correspondant à dlmo.Link[ ].SchedType pour la liaison number2. La plage prise en charge est 0..2.
- Bit 3: Si Bit3=1, émettre DauxAdvRx. Si Bit3=0, DauxAdvRx est ”null” (c'est-à-dire: vide) et n'est pas émis.
- Bits 2..1: Unsigned2, décrivant le contenu de DauxAdvRx. Voir Tableau 184. La plage prise en charge est 0..2. Correspondant à dlmo.Link[ ].SchedType pour la liaison number3. Si Bit3=0, les bits 2 et 1 n'ont pas de sens et doivent être également 0.
- Le bit 0 est réservé et doit être mis à zéro.

d) DauxJoinTx. Le ou les intervalles de temps d'émission de rattachement dans chaque cycle de supertrame, correspondant à dlmo.Link[ ].Schedule pour la liaison number1. Ce sont les occasions d'émission dans lesquelles envoyer des demandes de rattachement. Les bits 7, 6 de DauxJoinFIdXmit spécifient le format de DauxJoinTx, conformément au Tableau 184.

e) DauxJoinRx. Le ou les intervalles de temps de réception de rattachement dans chaque cycle de supertrame, correspondant à dlmo.Link[ ].Schedule pour la liaison number2. Les bits 5, 4 de DauxJoinFIdXmit spécifient le format de DauxJoinRx, conformément au Tableau 184.

f) DauxAdvRx. Liaisons de réception, pour rechercher par balayage des voisins supplémentaires après le rattachement, correspondant à dlmo.Link[ ].Schedule pour la liaison number3 lorsqu'elle est fournie. Les bits 2, 1 de DauxJoinFIdXmit spécifient le format de DauxAdvRx, conformément au Tableau 184. Il est émis et a un sens seulement lorsque DauxJoinFldXmit.Bit 3=1; sinon, sa valeur est null (vide) et aucune liaison correspondante n'est créée dans le Tableau 129.

Des liaisons sont ajoutées à dlmo.Link[ ] en fonction des paramètres dans l'annonce. Les champs sont mis conformément au Tableau 129.

Tableau 129 – Valeurs par défaut pour les liaisons créées à partir d'annonces

Nom de champ	DauxJoinTx	DauxJoinRx	DauxAdvRx (lorsque DauxJoinFldXmit.Bit3 =1)
* Index	1	2	3

Graph Type	0	0	0
SchedType	A partir de l'annonce DauxJoinFldXmit Bits 7..6	A partir de l'annonce DauxJoinFldXmit Bits 5..4	A partir de l'annonce DauxJoinFldXmit Bits 2..1
ChType	0	0	0
PriorityType	0	0	0
Neighbor	Adresse du voisin d'annonce	Null	Null
GraphID	Null	Null	Null
Schedule	A partir de l'annonce DauxJoinTx	A partir de l'annonce DauxJoinRx	A partir de l'annonce DauxAdvRx
ChOffset	Null	Null	Null
Priority	Null	Null	Null

La liaison number3, prévue pour être utilisée pour rechercher par balayage des voisins après le rattachement, est configurée comme une liaison "idle". Normalement, les liaisons inactives sont activées par l'intermédiaire d'un sous-en-tête DAUX tel que décrit en 9.3.5.4. En outre, lorsque la DL passe à l'état de rattachement, elle doit activer la liaison number3 pendant une période de temps égale à la valeur initiale de dlmo.DiscoveryAlert.Duration (60 s par défaut). Cela conduit la DL à recueillir des informations dans la table de dlmo.Candidates et ensuite à les rapporter au gestionnaire de système par l'intermédiaire de l'alerte NeighborDiscovery, à moins que la DL ne soit reconfigurée par le gestionnaire de système pendant l'intervalle pour un résultat différent.

NOTE 2 GraphType dans le Tableau 129 est mis à zéro, indiquant que la caractéristique n'est pas applicable dans ce contexte. Voir 9.4.3.7.2.

Les liaisons créées à partir de l'annonce ont également besoin d'entrées dans dlmo.Neighbor, dlmo.Graph, et dlmo.Route. Ces entrées sont automatiquement ajoutées par la DL en même temps que les liaisons, avec des valeurs telles que montrées dans le Tableau 130, le Tableau 131 et le Tableau 132 ci-dessous.

Tableau 130 – Entrée de dlmo.Neighbor créée à partir d'annonces

Nom de champ	Valeur
*** Index**	**Adresse du routeur d'annonce**
EUI64Address	Acquise en provenance du routeur d'annonce comme décrit en 9.1.10.1
GroupCode	0
ClockSource	2
ExtGrCnt	0
DiagLevel	1
LinkBacklog	0
ExtendGraph	Null
LinkBacklogIndex	Null
LinkBacklogDur	Null

NOTE 3 ExtendGraph dans le Tableau 130 est mis à null, indiquant que la caractéristique n'est pas applicable dans ce contexte. Voir 9.4.3.4.2.

Tableau 132 – Entrée de dlmo.Route créée à partir d'annonces

Nom de champ	Valeur
*** Index**	**1**
Size	1
Alternative	3
ForwardLimit	16
Route	Une seule entrée: 0xA001 (graphe number1)
Selector	Null

NOTE 4 Les informations relatives au chemin dans le Tableau 132 sont prévues pour être utilisées comme le chemin par défaut après que la DLE a rejoint le sous-réseau D. Les messages de rattachement destinés au proxy voisin utilisent le routage de source tel que décrit en 9.3.3.6. Des échantillons d'en-têtes de DL pour des messages de rattachement sont fournis en Annexe T.

Les mises à jour de DLMO à partir des informations de rattachement de DAUX sont réalisées en deux points dans la durée de vie de la DL. En premier lieu, lorsqu'une DLE dans l'état par défaut reçoit une annonce issue d'un mini sous-réseau D de configuration (SubnetID=1), elle a besoin de mettre à jour des attributs de DLMO avec des informations de rattachement de DAUX afin de rejoindre le mini sous-réseau D. En second lieu, lorsqu'une DLE dans l'état "provisioned" rejoint un sous-réseau D cible par l'intermédiaire d'un routeur d'annonce, elle a besoin de mettre à jour le DLMO avec des informations de rattachement de DAUX afin de rejoindre le sous-réseau D cible.

Il y a divers autres temps où une DL pourrait recevoir et traiter des annonces, tels que lors de la recherche de plusieurs voisins candidats dans l'état "provisioned", lors de la recherche de voisins candidats dans l'état "joined" ou lors de la réception de mises à jour du temps de sous-réseau D dans n'importe quel état. La réception et le traitement de telles annonces peuvent déclencher une demande de rattachement seulement dans l'état par défaut ou l'état "provisioned", et les informations de rattachement de DAUX dans l'annonce sont présentées au DLMO du destinataire seulement lorsque la DLE tente de rejoindre un mini sous-réseau D à partir de l'état par défaut ou tente de rejoindre un sous-réseau D cible dans l'état "provisioned".

9.3.5.2.4.3 Sauts discrétisés, sauts lents et processus de rattachement

Une annonce transmet une forme compressée d'une définition de supertrame. DauxChRate dans l'annonce correspond exactement à ChRate dans la supertrame, ce qui permet de distinguer une supertrame à sauts lents d'une supertrame à sauts discrétisés. Si DauxChRate=1 l'annonce indique une supertrame à sauts discrétisés; lorsque DauxChRate>1, l'annonce indique une supertrame à sauts lents.

Une annonce peut indiquer une plage de liaisons dans une supertrame, conformément au Tableau 184. Cela fournit un mécanisme pour spécifier et activer un ensemble d'intervalles de temps contigus.

Les sauts discrétisés ou sauts lents spécifiés par une DPDU d'annonce sont un sous-ensemble fonctionnel des sauts discrétisés ou sauts lents spécifiés par la supertrame et les structures de données de liaison. La différence principale réside dans le fait que l'information contenue dans la DPDU d'annonce est un peu compressée. Cette identité fonctionnelle (pour le sous-ensemble) permet que les informations transmises dans une DPDU d'annonce reçue soient utilisées pour initialiser la supertrame/les structures de données de liaison dans l'appareil qui tente d'effectuer l'opération de rattachement.

La manipulation des supertrames et liaisons d'annonce est décrite en 9.1.14. Le cross-mapping des données est indiqué dans Tableau 126 et Tableau 129. La seule différence significative réside dans le fait que, à cause de la représentation compressée, la structure de la DPDU d'annonce limite la réponse en sauts lents à 255 intervalles de temps (d'environ 2,5 s) ce qui est noté dans la description de la structure de DPDU. Ce seuil supérieur de 2,5 s n'est pas considéré comme une limite significative.

L'utilisation des sauts discrétisés, des sauts lents et des sauts hybrides est décrite de 9.1.8.4.4 à 9.1.8.4.6. La Figure 74 montre que les sauts lents peuvent être combinés avec les sauts discrétisés pour donner des sauts hybrides. Dans un routeur d'annonce configuré pour un fonctionnement hybride, une annonce peut indiquer à l'appareil se rattachant d'utiliser les liaisons à sauts lents, les liaisons à sauts discrétisés ou une combinaison des deux. Par exemple, les liaisons Tx (vers le routeur d'annonce) pourraient utiliser des sauts lents tandis que les liaisons Rx (depuis le routeur d'annonce) pourraient utiliser des sauts discrétisés. Une telle configuration est raisonnable pour un routeur configuré comme hôte de balayage actif (voir 9.1.13.3), où les liaisons à sauts lents peuvent remplir la double mission de transmettre les DPDU de sollicitation et les autres DPDU Data.

Le modèle de sauts discrétisés, de sauts lents ou de sauts hybrides est défini par les attributs de supertrame dans le Tableau 174. Le mapping est représenté dans le Tableau 126. La temporisation des liaisons dans la supertrame à sauts discrétisés, à sauts lents ou à sauts hybrides est définie dans le Tableau 181 et le Tableau 184. Le Tableau 127 montre le mapping vers le Tableau 181 tout en faisant spécifiquement référence au Tableau 184.

Dans une configuration hybride (voir Figure 74), les liaisons à sauts lents peuvent être limitées à une plage particulière d'intervalles de temps. Il s'agit de l'utilisation prévue de la "plage" dans le Tableau 184. On peut également concevoir des intervalles de temps (liaisons) spécifiques dans une période à sauts lents, et non pas une plage d'intervalles, ce qui apporte davantage de souplesse pour le concepteur d'un WISN déployé actuel.

9.3.5.2.4.4 Contrôle d'intégrité

Les DPDU qui intègrent un DAUX incluent le CRC UIT-T de 16 bits selon l'IEEE (FCS) en tant que contrôle d'intégrité sur la MPDU globale, plus un DMIC pour l'authentification en tant que contrôle d'intégrité supplémentaire. Cependant, ce DMIC ne peut pas être authentifié par une DLE destinataire sans un sens de temps partagé, une clé de sécurité partagée, et la connaissance de l'adresse EUI64Address de la DLE émettrice, qui ne sont pas disponibles à toutes les DLE qui peuvent entendre par hasard la DPDU et dériver le temps à partir de son sous-en-tête DAUX.

NOTE 1 Le temps au sein du DAUX est utilisable comme sens de temps partagé pour l'authentification de la DPDU qui contient le DAUX.

La présente norme permet à une DLE de visionner et utiliser le DAUX même si elle ne peut pas authentifier la DPDU globale. Il a été jugé insuffisant de s'appuyer sur la FCS de l'IEEE 802.15.4 comme étant le seul contrôle d'intégrité pour des annonces. Pour cette raison, un contrôle d'intégrité de 16 bits supplémentaire est inclus au sein du DAUX, couvrant seulement le contenu du DAUX lui-même.

Le contrôle d'intégrité de DAUX est similaire à la somme de contrôle selon l'UDP décrite dans l'IETF RFC 768. La somme de contrôle est le complément à un de 16 bits de la somme des compléments à un des octets qui composent le sous-en-tête de DAUX, à l'exclusion du contrôle d'intégrité lui-même, bourré d'octets zéro de remplissage à la fin (s'il y a lieu) pour obtenir un multiple de deux octets. L'ordonnancement des octets est tel qu'émis. Si la somme de contrôle calculée est zéro, elle est émise sous forme de uns partout. Une somme de contrôle émise ne comportant que des zéros partout signifie que le créateur de la DPDU n'a généré aucune somme de contrôle.

L'ordre d'émission du contrôle d'intégrité est MSB, à savoir avec le premier octet reflétant les opérations binaires sur des octets de numéro impair, avec le compte d'octets débutant à 1,

dans le sous-en-tête DAUX (octets 1, 3, 5, etc.) et le deuxième octet issu d'octets de numéro pair dans le sous-en-tête DAUX (octets 2, 4, 6, etc.).

NOTE 2 L'utilisation d'une clé secrète de sous-réseau D pour des annonces permet à ces annonces d'être dignes de confiance après que la DLE a rejoint le sous-réseau D. Les annonces sont utilisables pour des surveillances périodiques de routeurs voisins, ou pour des mises à jour périodiques du temps par des DLE avec un faible facteur d'utilisation.

L'annonce fournit seulement l'adresse DL16Address du routeur d'annonce. Cependant, une adresse EUI64Address est nécessaire pour l'échange ultérieur des DPDU avec ce routeur. Comme décrit en 9.1.14.2 la DLE répondeuse doit acquérir l'adresse EUI64Address de la DLE d'annonce.

9.3.5.2.5 Configuration des annonces

NOTE Le processus de rattachement, y compris les sollicitations, les annonces et l'utilisation des informations transmises dans les annonces, est décrit en 7.4.

La temporisation des annonces est déterminée par la structure des supertrames et des liaisons de la DLE d'annonce. Toute liaison peut inclure un fanion d'annonce, qui indique que l'annonce est incluse dans le DAUX.

Une valeur d'indice dans l'attribut dlmo.AdvSuperframe (voir Tableau 141) choisit une supertrame dans dlmo.Superframe qui doit être utilisée comme référence pour construire l'annonce. La supertrame de référence est configurée par le gestionnaire de système en établissant une supertrame, qui peut être inactive, et en se référant à son indice dans l'attribut dlmo.AdvSuperframe. La supertrame de référence ne doit pas utiliser des caractéristiques qui ne peuvent pas être représentées dans le champ d'informations dans le Tableau 124.

Une valeur zéro dans dlmo.AdvSuperframe est la valeur par défaut et elle indique que l'annonce n'a pas été configurée.

Les informations de liaison sont placées dans l'attribut dlmo.AdvJoinInfo, exactement dans le format dans lequel elles sont émises dans l'annonce dans la position correspondant au Tableau 128. De cette manière, les nouvelles liaisons de DLE JoinTx, Join Rx, et AdvRx sont spécifiées.

Le gestionnaire de système configure les supertrames dans le routeur d'annonce qui concordent avec ceux spécifiés dans la DPDU d'annonce. Au moment des liaisons JoinTx, le routeur d'annonce doit être configuré avec des liaisons pour recevoir des DPDU de rattachement. Au moment des liaisons JoinRx, le routeur d'annonce doit être configuré avec des liaisons où JoinResponse=1 (voir Tableau 182).

9.3.5.3 Sous-en-tête auxiliaire de type sollicitation

9.3.5.3.1 Généralités

NOTE Le processus de rattachement, y compris les sollicitations, les annonces et l'utilisation des informations transmises dans les annonces, est décrit en 7.4.

Une sollicitation est une demande relative à une annonce devant être émise par un hôte de balayage actif dans une portée, sur la même voie que la sollicitation elle-même (voir 9.1.13.3).

Les attributs au sein d'un DAUX de sollicitation peuvent être groupés logiquement comme:

- en-tête de sollicitation; et
- ID de sous-réseau D.

La sollicitation n'a pas un sens fiable du temps et n'a pas nécessairement une clé de sécurité secrète. Par conséquent, pour permettre au destinataire de la sollicitation de décoder son DMIC, le DMIC d'une sollicitation doit être construit en utilisant une clé de sécurité de K_global et un temps TAI nominal de zéro. Cela permet un traitement cohérent et fournit un fort contrôle d'intégrité pour la DPDU. Aucun contrôle d'intégrité supplémentaire n'est inclus dans le DAUX de la sollicitation.

Un MHR d'une sollicitation (en-tête MAC selon l'IEEE) ne doit pas fournir une adresse source ou une adresse de destination, et il ne doit pas spécifier un sous-réseau D. Voir 9.1.5.

9.3.5.3.2 Champs de sollicitation

Le Tableau 133 spécifie l'en-tête de sollicitation dans le DAUX de sollicitation.

Tableau 133 – Sous-champs de l'en-tête de sollicitation

Nom de sous-champ	Codage de sous-champ
DauxType	Type: Unsigned3 1=DAUX de sollicitation
DauxSubnetInclude indique d'émettre ou de ne pas émettre le DauxSubnetID dans la sollicitation)	Type: Unsigned1
Réservé	Type: Unsigned4=0

L'en-tête de sollicitation fait 1 octet. Conformément au Tableau 133, les éléments comprennent:

- DauxType. Mis à 1 pour indiquer un DAUX de sollicitation.
- DauxSubnetInclude. Indique d'émettre ou de ne pas émettre le champ DauxSubnetID dans la sollicitation. Si DauxSubnetInclude=0, le champ DauxSubnetID n'est pas émis, et le destinataire (hôte de balayage actif) doit utiliser la valeur par défaut de DauxSubnetID=0 pour le filtrage.

Le Tableau 134 montre la structure de l'en-tête de sollicitation.

Tableau 134 – Structure de l'en-tête de sollicitation

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	DauxType=1			DauxSubnetInclude	Reserved=0			

Le Tableau 135 spécifie les autres champs dans le DAUX de sollicitation.

Tableau 135 – Champs du DAUX de sollicitation

Nom de champ	Codage de champ
DauxSubnetID (spécifie le SubnetID)	Type: Unsigned16 (LSB)

DauxSubnetID émet un ID de sous-réseau D qui peut être utilisé comme un filtre par le destinataire, en fonction de l'attribut dlmo.SolicFilter du destinataire. Lorsque DauxSubNetInclude=0, DauxSubnetID prend la valeur par défaut de 0x0000 et n'est pas émis.

Le Tableau 136 résume la structure du DAUX de sollicitation.

Tableau 136 – Structure du DAUX de sollicitation

Nombre d'octets	bits							
	7	6	5	4	3	2	1	0
1	En-tête de sollicitation (voir Tableau 134)							
0, 2	DauxSubnetID (LSB)							

9.3.5.3.3 Configuration des sollicitations

En raison d'exigences de réglementation et de sécurité, certaines applications ne peuvent pas tolérer des DLE qui émettent des DPDU alors qu'elles sont inactives ou en transit. Par conséquent, la valeur par défaut dans la présente norme n'inclut pas des sollicitations dans sa configuration. L'intention est que les DLE soient configurées avec des sollicitations, selon le cas, au moment où elles sont configurées ou ultérieurement dans le cycle de vie.

La temporisation des sollicitations est déterminée par la structure des supertrames et des liaisons de la DLE d'annonce. L'émission d'une sollicitation est déclenchée par un champ dlmo.Link[ ].Discovery mis à une valeur de 3.

Lorsqu'une sollicitation est émise, le contenu de dlmo.SolicTemplate doit être copié textuellement dans le sous-en-tête de DAUX. Si la taille de SolicTemplate est zéro, cela doit être interprété comme une erreur de configuration et la liaison doit être ignorée.

Pour prendre en charge des exigences de réglementation et de sécurité, des sollicitations peuvent être activées et désactivées sur une base synchronisée par le gestionnaire de système par l'intermédiaire des attributs dlmo.RadioSilence, dlmo.RadioSleep, et dlmo.Superframe[ ].IdleTimer.

9.3.5.4 Sous-en-tête auxiliaire de type "activate link" (activation de liaison)

9.3.5.4.1 Généralités

Le DAUX d'activation de liaison fournit un mécanisme qui permet à un initiateur de transaction d'activer des intervalles de temps inactifs pendant une courte période de temps afin de transmettre efficacement des messages en souffrance qui se sont accumulés dans une file d'attente de messages d'un initiateur de transaction. Ces liaisons inactives, lorsqu'elles sont ainsi configurées par le gestionnaire de système, sont activées par le routeur en réponse à une salve de messages circulant à travers une DL à destination d'un voisin particulier.

Le gestionnaire de système configure:

- Une liaison d'émission inactive du côté émission, adressée à un voisin particulier ou à un groupe de voisins, avec un indice et un programme de liaison particuliers.
- Une liaison de réception inactive du côté réception, avec les mêmes indice et programme de liaison.
- Un jeu de paramètres dans la table de voisins, indiquant
  - l'indice de la liaison (LinkBacklogIndex),
  - la taille de l'accumulation qu'il convient d'avoir pour déclencher l'activation de liaison (LinkBacklog) et
  - la durée de l'activation de liaison (LinkBacklogDur).

  Voir 9.4.3.4.2 pour la définition de ces paramètres.

Lorsque l'initiateur de transaction détecte qu'il y a des DPDU Data de LinkBacklog sur sa file d'attente de messages qui peuvent être transmises à l'adresse de destination de la DPDU Data, il convient que l'initiateur de transaction utilise le sous-en-tête auxiliaire d'activation de liaison pour activer la liaison de réception inactive par l'intermédiaire du sous-en-tête

auxiliaire d'activation de liaison. Lorsque l'initiateur de transaction reçoit une DPDU ACK/NAK pour la DPDU Data, cela implique que le message a été traité et que le côté réception de la liaison inactive a été activé. Il convient que l'initiateur de la transaction active alors le côté d'émission de la liaison inactive pour le nombre désigné d'occasions de communication.

La liaison d'émission activée pourrait être adressée à un groupe de voisins, mais le côté réception de la liaison activée ne se produit toutefois que sur un seul voisin. Par conséquent, il convient de ne considérer comme étant des candidates pour la liaison activée que les seules DPDU Data adressées au voisin en question.

Le DAUX d'activation de liaison fournit un indice de liaison et un certain nombre d'occasions de communication qui sont utilisés pour activer une liaison inactive par le destinataire de la DPDU Data. Le résultat en est l'activation immédiate d'une liaison inactive pour la réception, pour le nombre d'occasions de communication indiquées par DauxActivateDur. L'initiateur de transaction du message d'activation de liaison informe, par essence, le destinataire que les messages en file d'attente suivront en étant envoyés au cours d'occasions de communication (intervalles de temps) associées à une liaison de réception particulière.

L'activation des liaisons inactives est déclenchée du côté de l'initiateur de transaction par plusieurs DPDU Data placées en file d'attente qui peuvent être acheminées vers le destinataire. Voir 9.4.3.4.2 pour une description du côté émission du message d'activation de liaison (LinkBacklogIndex, LinkBacklogDur).

9.3.5.4.2 Champs

Le Tableau 137 résume le DAUX d'activation de liaison.

Tableau 137 – Champs de DAUX d'activation de liaison

Nom de champ	Codage de champ
DauxType	Type: Unsigned3 2=DAUX d'activation de liaison
Reserved (alignement d'octets)	Type: Unsigned5=0
DauxLink_ID (identificateur pour une liaison)	Type: ExtDLUint
DauxActivateDur (nombre d'occasions de communication (intervalles de temps) pour activer la liaison, occurrences de liaison)	Type: Unsigned8

La liaison est activée pour le nombre d'occurrences de la liaison, indépendamment du fait que la liaison soit utilisée ou non. Par exemple, l'occurrence de la liaison est comptée même si elle n'est pas utilisée en raison d'une liaison de plus haute priorité dans le même intervalle de temps. La période d'activation de liaison commence par le prochain intervalle de temps complet après que le DAUX d'activation de liaison a été reçu. Voir 9.4.3.4.2.

Le Tableau 138 montre la structure du champ DAUX d'activation de liaison.

Tableau 138 – Structure de DAUX d'activation de liaison

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	DauxType			Reserved=0				
1 ou 2 octets	DauxLinkID							
1t	DauxActivateDur							

9.3.5.5 Sous-en-tête auxiliaire du type "signal quality" (qualité de signal)

9.3.5.5.1 Généralités

Le DAUX de qualité de signal rapporte la qualité du signal reçu dans une DPDU ACK/NAK, pour prendre en charge l'ensemble de diagnostics de qualité de signal aller-retour. Deux octets sont rapportés, un pour l'intensité du signal (RSSI) et un pour la qualité de signal (RSQI). RSSI et RSQI sont décrits en 9.1.15.2.

9.3.5.5.2 Champs

Le Tableau 139 résume le DAUX de rapport de qualité de signal reçu.

Tableau 139 – Champs du DAUX de rapport de qualité de signal reçu

Nom de champ	Codage de champ
DauxType	Type: Unsigned3 3=DAUX de qualité de signal
Reserved (alignement d'octets)	Type: Bit5=0
DauxRSSI (RSSI)	Type: Integer8
DauxRSQI (RSQI)	Type: Unsigned8

Le Tableau 140 montre la structure du DAUX de rapport de qualité de signal reçu.

Tableau 140 – Structure du DAUX de rapport de qualité de signal reçu

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	DauxType			Reserved=0				
1	DauxRSSI							
1	DauxRSQI							

9.4 Base d'informations de gestion de DL

9.4.1 Généralités

Pour des informations relatives au traitement général des objets de gestion normalisés dans la DL, voir 9.1.11.

9.4.2 Attributs d'objet de gestion de DL

9.4.2.1 Généralités

Le Tableau 141 résume les attributs de l'objet de gestion de DL (DLMO). Les OctetString avec une taille de zéro sont dits "null" (vides).

Tableau 141 – Attributs du DLMO *(1 de 7)*

Nom du type d'objet normalisé: DL management object (DLMO)				
Identificateur du type d'objet normalisé: 124				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ActScanHostFract	1	Comportement de la DLE comme hôte de balayage actif	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 0	Voir 9.4.2.2
AdvJoinInfo	2	Informations de rattachement devant être placées dans l'annonce	Type: OctetString Classification: Static Accessibilité: Read/write Valeur par défaut: Null	Voir 9.4.2.3
AdvSuperframe	3	Référence de supertrame pour l'annonce	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 0 Plage valide: 0..32 767	Voir 9.4.2.3
SubnetID	4	Identificateur du sous-réseau D que la DLE a rejoint ou tente de rejoindre	Type: Unsigned16 Classification: Dynamic Accessibilité: Read Only Valeur par défaut: 0	Voir 9.4.2.4
SolicTemplate	5	Modèle de sous-en-tête DAUX utilisé pour des sollicitations	Type: OctetString Classification: Static Accessibilité: Read/write Valeur par défaut: Null	Voir 9.4.2.5
AdvFilter	6	Filtre utilisé sur des annonces entrantes pendant la découverte de voisins	Type: OctetString Voir Tableau 142 Classification: Static Accessibilité: Read/write Valeur par défaut: Voir 9.4.2.20	Voir 9.4.2.20
SolicFilter	7	Filtre utilisé sur des sollicitations entrantes	Type: OctetString Voir Tableau 142 Classification: Static Accessibilité: Read/write Valeur par défaut: Voir 9.4.2.20	Voir 9.4.2.20
TaiTime	8	Temps TAI pour la DLE	Type: TAINetworkTime Classification: Static Accessibilité: Read Only	Unités: 2^{-16} s Voir 9.4.2.6
TaiAdjust	9	Réajuste TaiTime à un instant programmé par le gestionnaire de système	Type: OctetString Voir Tableau 143 Classification: Dynamic Accessibilité: Read/write Valeur par défaut: Null	Voir 9.4.2.21

Tableau 141 *(2 de 7)*

Nom du type d'objet normalisé: DL management object (DLMO)				
Identificateur du type d'objet normalisé: 124				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
MaxBackoffExp	10	Exposant de repli maximal pour les répétitions de tentative	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 5 Plage valide: 3..8	Voir 9.4.2.7
MaxDsduSize	11	Nombre maximal d'octets qui peuvent être pris en charge dans une seule DSDU	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 96 Plage valide: 76..96	Voir 9.4.2.8
MaxLifetime	12	Durée de vie maximale d'une DPDU Data	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 120 (30 s) Plage valide: 8..1 920 (2 s..480 s)	Unités: 0,25 s Voir 9.4.2.9
NackBackoffDur	13	Durée de repli après avoir reçu un NAK	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 60 (15 s) Plage valide: 8..1 920 (2 s..480 s)	Unités: 0,25 s Voir 9.4.2.10
LinkPriorityXmit	14	Priorité par défaut pour des liaisons d'émission	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 8 Plage valide: 0..15	Voir 9.4.2.11
LinkPriorityRcv	15	Priorité par défaut pour des liaisons de réception	Type: Unsigned8 Classification: Static Accessibilité: Read/write Valeur par défaut: 0 Plage valide: 0..15	Voir 9.4.2.11
EnergyDesign	16	Capacité en énergie de la DLE telle que conçue	Type: OctetString Classification: Constant Accessibilité: Read Only Valeur par défaut: Voir 9.4.2.22	Voir 9.4.2.22

Tableau 141 *(3 de 7)*

Nom du type d'objet normalisé: DL management object (DLMO)				
Identificateur du type d'objet normalisé: 124				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
EnergyLeft	17	Energie restante pour la DLE	Type: Integer16 Classification: Dynamic Accessibilité: Read Only	Voir 9.1.17
DeviceCapability	18	Capacités d'un appareil	Type: OctetString Voir Tableau 147 Classification: Constant Accessibilité: Read Only Valeur par défaut: Voir 9.4.2.23	Voir 9.4.2.23
IdleChannels	19	Voies radio qui doivent être inactives	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: 0	Voir 9.4.2.12
ClockExpire	20	Dernier délai pour expiration d'horloge	Type: Unsigned16(MSB) Classification: Static Accessibilité: Read/write Valeur par défaut: Voir description	Unités: 1 s Voir 9.4.2.13
ClockStale	21	Temporisation de source d'horloge de DL	Type: Unsigned16 Classification: Static Accessibilité: Read/write Valeur par défaut: Voir description Plage valide: 5..300	Unités: 1 s Voir 9.4.2.14
RadioSilence	22	Temporisation de silence radio	Type: Unsigned32 Classification: Static Accessibilité: Read/write Valeur par défaut: 600 Plage valide: Limité à 1..600 pour le profil de silence radio; autrement 0..232-1	Unités: 1 s Voir 9.4.2.16 et 9.1.15.4
RadioSleep	23	Période de sommeil radio. Note: La radio de la DLE sera désactivée lorsque cet attribut est mis.	Type: Unsigned32 Classification: Dynamic Accessibilité: Read/write Valeur par défaut: 0	Unités: 1 s Voir 9.4.2.17

Tableau 141 *(4 de 7)*

Nom du type d'objet normalisé: DL management object (DLMO)

			Classification: Static	
			Accessibilité: Read/write	
			Valeur par défaut: Voir description	
			Plage valide: > 0	

[a] Métadonnées contenant un compte du nombre d'entrées dans le tableau et la capacité (nombre total de rangées autorisées) pour le tableau; voir 6.2.6.3 pour les détails relatifs à ce type de données.

9.4.2.2 dlmo.ActScanHostFract

dlmo.ActScanHostFract configure le comportement de la DLE comme un hôte de balayage actif, tel que spécifié en 9.1.13.3. La valeur de réglage indique la fraction du temps dans laquelle il convient que la DLE réponde lorsqu'elle a reçu un sollicitation de balayage actif. La valeur par défaut de 0 indique que la DLE n'est pas configurée pour être un hôte de balayage actif.

9.4.2.3 dlmo.AdvJoinInfo et dlmo.AdvSuperframe

dlmo.AdvJoinInfo et dlmo.AdvSuperframe configurent le contenu d'un sous-en-tête DAUX d'annonce. Leur signification est décrite en 9.3.5.2.5.

9.4.2.4 dlmo.SubnetID

dlmo.SubnetID est l'identificateur pour le seul sous-réseau D que DLE utilise actuellement ou tente de rejoindre. Les SAP de gestion de DL traitent un seul sous-réseau D actif à la fois. Si un appareil donné participe simultanément à plusieurs sous-réseaux D, cela peut être modélisé comme plusieurs instances de la DLE. La valeur dlmo.SubnetID=0 ne doit jamais être utilisée comme un ID de sous-réseau D; son utilisation indique que la DLE ne participe

pas à un sous-réseau D. La valeur dlmo.SubnetID=1 doit être utilisée exclusivement pour identifier des sous-réseaux D de configuration. Le gestionnaire de système ne met pas directement le SubnetID de la DLE; celui-ci est plutôt mis par la DLE elle-même dans le processus consistant à découvrir et rejoindre le sous-réseau D. Voir 9.1.10.2.

NOTE Dans la conception selon l'IEEE 802.15.4, SubnetID est utilisable comme filtre pour des MPDU entrantes. Comme débattu en 9.1.10.2, un DMIC fournit un filtre supplémentaire, plus fort et plus fiable une fois que la DLE a rejoint le sous-réseau D.

9.4.2.5 dlmo.SolicTemplate

dlmo.SolicTemplate est un modèle pour le sous-en-tête DAUX dans une sollicitation. Lorsqu'une sollicitation est émise, les données exactes contenues dans cet OctetString (sans taille explicite en préfixe) doivent être utilisées comme étant le sous-en-tête DAUX. La valeur est nulle (taille égale à zéro) par défaut. Voir 9.3.5.3.

9.4.2.6 dlmo.TaiTime

dlmo.TaiTime, lorsqu'il est lu par le DMAP, est rapporté comme étant la meilleure estimation de la DLE pour le temps de DL à l'instant en question. Voir 12.22.4.2 pour le codage de TAINetworkTime.

NOTE L'attribut dlmo.TaiTime est décrit comme étant en lecture seule, le temps étant acquis par la DLE auprès de ses voisins et fourni comme un service aux autres couches par l'intermédiaire du DMAP. Ce style de spécification n'est pas censé interdire les mises en œuvre, telles que celles sur des DLE qui sont des horloges-mères, où le temps est fourni à la DLE à partir d'une source alternative.

9.4.2.7 dlmo.MaxBackoffExp

dlmo.MaxBackoffExp est l'exposant de repli maximal pour les répétitions de tentative; voir 9.1.8.2 pour un débat relatif au repli exponentiel.

9.4.2.8 dlmo.MaxDsduSize

dlmo.MaxDsduSize est le nombre maximal d'octets qui peuvent être pris en charge dans une seule DSDU. Il est utilisé par la NL pour prendre des décisions de fragmentation. Sa valeur par défaut de 96 tient compte des contraintes suivantes:

- Une seule adresse EUI64Address dans le MHR. Voir 9.3.3.2.
- Un CryptoKeyIdentifier d'un octet et un décalage de saut de voie lent dans le DMXHR. Voir 9.3.3.4.
- Un seul chemin compressé dans le DROUT (c'est-à-dire: aucun routage de source au-delà du cas d'un seul saut). Voir 9.3.3.6.
- Aucun DAUX, si bien qu'une DSDU ne peut pas être combinée avec une annonce, à l'exception du DAUX d'activation de liaison lorsque l'adressage de 16 bits est utilisé.
- Un DMIC-32, pas un DMIC-64 ni un DMIC-128.

NOTE MaxDsduSize a été calculé comme suit: 15 octets pour le MHR (voir 9.3.3.2); 1 octet pour le DHR (voir 9.3.3.3); 3 octets pour le DMXHR (voir 9.3.3.4); 0 octet pour le DAUX (voir 9.3.3.5); 2 octets pour le DROUT (voir 9.3.3.6); 4 octets pour le DADDR (voir 9.3.3.7); 4 octets pour le DMIC; et 2 octets pour la FCS. Ce total de 31 octets est soustrait de la capacité de PhSDU de 127 octets, pour arriver à un MaxDsduSize de 96 octets.

Le gestionnaire de système doit réduire la valeur de dlmo.MaxDsduSize selon les besoins si des contraintes supplémentaires s'appliquent à une configuration particulière.

9.4.2.9 dlmo.MaxLifetime

dlmo.MaxLifetime est la durée maximale, en unités de 0,25 s, pendant laquelle une DPDU Data doit être maintenue dans la file d'attente de messages d'une seule DLE avant de devoir être rejetée. Le dlmo.MaxLifetime peut être neutralisé par le dlmo.Graph[ ].MaxLifetime (voir 9.4.3.6).

9.4.2.10 dlmo.NackBackoffDur

dlmo.NackBackoffDur est la durée du repli, en unités de 0,25 s, après réception d'un NAK (voir 9.1.9.4.4).

9.4.2.11 dlmo.LinkPriorityXmit et dlmo.LinkPriorityRcv

dlmo.LinkPriorityXmit et dlmo.LinkPriorityRcv sont les priorités par défaut devant être utilisées pour sélectionner des liaisons. Si aucune priorité n'est spécifiée dans dlmo.Link[ ].Priority, utiliser ces priorités. Pour les liaisons T/R, utiliser dlmo.LinkPriorityRcv comme étant la priorité pour le côté réception de la liaison. Les priorités de liaison sont décrites fonctionnellement en 9.1.8.5.

9.4.2.12 dlmo.IdleChannels

dlmo.IdleChannels fournit une liste des voies qui doivent être inactives, comme une façon rapide pour le gestionnaire de système de bloquer l'utilisation de certaines voies sur une DLE particulière sans exiger un changement coordonné des programmes de saut de voie. Une liaison se produisant sur l'une quelconque des voies désignées comme étant inactives (valeur 1) par dlmo.ActiveChannels doit être traitée comme étant inactive. Des valeurs 1 dans dlmo.IdleChannels ne doivent pas conduire au raccourcissement de séquences de saut, mais doivent laisser intactes les séquences de saut et simplement conduire à ce que toutes les liaisons sur des voies désignées soient traitées comme étant inactives. (Le raccourcissement des séquences de saut elles-mêmes est accompli par l'intermédiaire d'un attribut différent dlmo.Superframe[ ].ChMap.) Les positions des bits 0..15 correspondent aux voies 0..15. Une valeur de bit 1 indique que les liaisons utilisant la voie doivent être traitées comme étant inactives. dlmo.IdleChannels est complémentaire de dlmo.DeviceCapability.ChannelMap; dans le fonctionnement de la DLE, les deux sont logiquement combinés comme suit, le résultat étant un jeu de voies qui sont traitées comme étant inactives par la DLE:

ActiveChannels = ((NOT dlmo.IdleChannels) AND (dlmo.DeviceCapability.ChannelMap))

9.4.2.13 dlmo.ClockExpire

L'attribut dlmo.ClockExpire est le nombre maximal de secondes pendant lesquelles la DLE peut fonctionner en toute sécurité sans mise à jour d'horloge. La valeur par défaut est (1 000 s/DeviceCapability.ClockStability) et vise à maintenir la DLE synchronisée à 1 ms près au cours du processus de rattachement et ultérieurement lors de la participation à un sous-réseau D qui fournit seulement le saut de voie discrétisé. Dans les autres cas, la valeur nécessaire se met à l'échelle de manière linéaire avec la précision d'horloge exigée la plus proche ou la plus large. Voir 9.1.9.2.2.

NOTE Un appareil qui exige l'utilisation du saut de voie discrétisé est susceptible d'avoir une durée ClockExpire supérieure à la valeur par défaut ci-dessus.

9.4.2.14 dlmo.ClockStale

L'attribut dlmo.ClockStale détermine le moment où il convient que la DLE commence à accepter des mises à jour du temps issues de sources secondaires d'horloges de DL. Par exemple, si dlmo.ClockTimeout est mis à la valeur par défaut de 45 s, il convient qu'un destinataire d'horloge de DL n'accepte pas de mises à jour d'horloge issues d'une source secondaire d'horloges de DL jusqu'à ce qu'elle n'ait pas reçu une mise à jour d'horloge issue d'une source primaire d'horloges de DL pendant au moins 45 s. La valeur par défaut est 0,5 × ClockExpire. Voir 9.1.9.2.3 pour plus d'informations.

9.4.2.15 dlmo.ClockTimeout

L'attribut dlmo.ClockTimeout est le nombre maximal de secondes pendant lesquelles la DLE peut fonctionner raisonnablement dans un sous-réseau D avant de se réinitialiser à l'état configuré. La valeur par défaut est 2,0 × ClockExpire. Voir 9.1.9.2.2.

9.4.2.16 dlmo.RadioSilence

L'attribut dlmo.RadioSilence désigne le moment où la DLE doit désactiver son émetteur après avoir perdu sa connexion de sous-réseau D. Voir 9.1.15.4 pour plus d'informations.

9.4.2.17 dlmo.RadioSleep

L'attribut dlmo.RadioSleep est utilisé pour désactiver la radio de la DLE pendant une période de temps. Voir 9.1.15.4 pour plus d'informations. L'activation de cet attribut doit être légèrement retardée pour permettre la prise en charge de l'émission d'un acquittement de couche application de la TPDU du DMAP qui a fait positionner l'attribut.

9.4.2.18 dlmo.RadioTransmitPower

L'attribut dlmo.RadioTransmitPower est utilisé pour commander le niveau de puissance d'émission radio de la DLE, en dBm EIRP. Il prend comme valeur par défaut le niveau de puissance d'émission maximal autorisé de l'appareil dans le cadre d'un régime de réglementation spécifié par dlmo.CountryCode (9.1.15.6), et il est rapporté au cours du processus de rattachement par l'intermédiaire de dlmo.DeviceCapability.RadioTransmitPower. Voir 9.1.15.5.

9.4.2.19 dlmo.CountryCode

L'attribut dlmo.CountryCode fournit les contraintes sur un appareil selon le régime de réglementation applicable. Lorsqu'il est mis au cours de la configuration de la DLE, l'utilisation de la fonctionnalité de verrouillage de contenu prise en charge peut contraindre le fonctionnement de l'appareil jusqu'à la prochaine fois où il sera configuré (par exemple, éventuellement après réparation et déploiement vers une juridiction de réglementation différente). Voir 9.1.15.6 et Annexe V.

9.4.2.20 Filtres de sous-réseau

Un attribut de filtre de sous-réseau D est une chaîne de 4 octets qui indique comment une DLE doit filtrer les annonces entrantes ou les sollicitations entrantes. L'attribut AdvFilter est utilisé pour filtrer les annonces entrantes, et SolicFilter est utilisé pour filtrer les sollicitations entrantes.

AdvFilter et SolicFilter comportent chacun deux champs, un champ BitMask de 16 bits et un champ TargetID de 16 bits. Le Tableau 142 montre la structure de chaque filtre de sous-réseau D.

Tableau 142 – Octets de filtre de sous-réseau D

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
2	BitMask							
2	TargetID							

Contrairement à la plupart des attributs DLMO, les filtres de sous-réseau D utilisent des conventions d'ordonnancement d'octet LSB. Cela reflète leur utilisation, qui est d'accomplir des opération de comparaison de bits avec les éléments d'en-tête de DPDU qui sont émis dans l'ordre LSB.

Lorsqu'une DLE reçoit une annonce, elle doit vérifier le SubnetID de la DPDU entrante. L'annonce doit être ignorée, sauf si:

(DPDU.SubnetID AND AdvFilter.BitMask) égal (AdvFilter.TargetID AND AdvFilter.BitMask)

AdvFilter.BitMask doit prendre la valeur par défaut 0xFFFF, et AdvFilter.TargetID doit prendre par défaut la valeur 0x0001, le résultat étant qu'une DLE non configurée qui est dans l'état par défaut filtrera toutes les annonces à l'exception de celles reçues provenant d'un sous-réseau D de configuration avec SubnetID=1.

Lorsqu'une DLE reçoit une sollicitation, elle doit vérifier le SubnetID de la DPDU entrante. La sollicitation doit être ignorée, sauf si:

(DPDU.DauxSubnetID AND SolicFilter.BitMask) ==
(SolicFilter.TargetID AND SolicFilter.BitMask)

SolicFilter.BitMask doit prendre la valeur par défaut 0x0000, le résultat étant que les sollicitations ne sont pas filtrées par défaut.

9.4.2.21 Réajustements du temps

L'attribut dlmo.TaiAdjust inclut des champs qui sont utilisés pour réajuster dlmo.TaiTime à un instant qui est programmé par le gestionnaire de système. Cet attribut est normalement "null" (c'est-à-dire vide), sauf si une correction de temps est en cours. Son utilisation est décrite en 9.1.9.3.6. L'OctetString comporte une série de champs qui sont décrits dans le Tableau 143.

Tableau 143 – Champs de l'OctetString dlmo.TaiAdjust

Nom de champ	Codage de champ
TaiCorrection (indique l'amplitude et le sens d'une correction d'horloge TAI)	Type: Integer32 Unités: 2^{-15} s
TaiTimeToApply (indique le temps auquel la correction doit être appliquée)	Type: TAITimeRounded Unités: 1 s

NOTE L'unité TaiCorrection de 2^{-15} s a été retenue pour correspondre aux verres "de montre" très faible puissance et très précis de 32 kiHz qui sont généralement utilisés pour le matériel d'horloge continu des appareils WISN.

Le Tableau 144 montre la structure de l'OctetString.

Tableau 144 – Structure de l'OctetString dlmo.TaiAdjust

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
4	TaiCorrection							
4	TaiTimeToApply							

9.4.2.22 Capacité en énergie de la DLE

L'attribut dlmo.EnergyDesign, tel que montré dans le Tableau 145, comporte divers éléments qui indiquent la capacité en énergie de l'appareil. Les champs au sein de cet attribut sont décrits en 9.1.17.

Tableau 145 – Champs de l'OctetString dlmo.EnergyDesign

Nom de champ	Codage de champ
EnergyLife (durée de vie d'énergie de la DLE par conception; positive pour les mois, négative pour les jours)	Type: Integer16 (constant)
ListenRate (capacité en énergie de la DLE pour actionner son récepteur, en secondes par heure)	Type: ExtDLUint (constant)
TransmitRate (capacité en énergie de la DLE pour émettre des DPDU, en DPDU par minute)	Type: ExtDLUint (constant)
AdvRate (capacité en énergie de la DLE pour émettre des annonces, en DPDU par minute)	Type: ExtDLUint (constant)

Le Tableau 146 montre la structure de l'OctetString.

Tableau 146 – Structure de l'OctetString dlmo.EnergyDesign

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
2	EnergyLife							
1..2	ListenRate							
1..2	TransmitRate							
1..2	AdvRate							

9.4.2.23 Capacités de l'appareil de DLMO

L'attribut dlmo.DeviceCapability inclut divers éléments qui indiquent les capacités de l'appareil. Il s'agit d'un attribut en lecture seule, dont la plupart des valeurs des composants ne changent pas en fonctionnement normal. Elles peuvent être changées en raison de la gestion de système à distance, y compris par le téléchargement d'un nouveau firmware. L'attribut dlmo.DeviceCapability doit être rapporté au gestionnaire de système comme partie intégrante du processus de rattachement.

L'OctetString comporte une série de champs qui sont décrits dans le Tableau 147. Certains de ces champs, énumérés comme étant "static" (statiques), ne changent pas lors du fonctionnement et sont rapportés uniquement au rattachement. D'autres champs, énumérés comme étant "dynamic" (dynamiques), peuvent changer lors du fonctionnement et sont également disponibles après le rattachement par l'intermédiaire des attributs DLMO portant le même nom.

Tableau 147 – Champs de l'OctetString dlmo.DeviceCapability

Nom de champ	Codage de champ
QueueCapacity (capacité de la file d'attente qui est disponible pour des opérations de transmission)	Type: ExtDLUint (constant)
ClockStability (stabilité d'horloge nominale de cet appareil, sous la forme d'un multiple de 1×10^{-6})	Type: Unsigned8 (constant)
ChannelMap (carte des voies radio prises en charge par l'appareil)	Type: Unsigned16 (constant)
DLERoles (rôles de DLE pris en charge par la DLE)	Type: BooleanArray8 (constant)
EnergyDesign (copie de l'attribut dlmo.EnergyDesign)	Type: OctetString (constant)
EnergyLeft (copie de l'attribut dlmo.EnergyLeft)	Type: Integer16
Ack_Turnaround (voir Tableau 161) [a]	Type: ExtDLUint (constant)
NeighborDiagCapacity (capacité mémoire pour dlmo.NeighborDiag)	Type: ExtDLUint (constant)
RadioTransmitPower (copie de l'attribut RadioTransmitPower, voir 9.1.15.5)	Type: Integer8
SupportedCCAmodes (description de carte de bits des modes CCA pris en charge par l'appareil)	Type: BooleanArray8 (constant)
ConstructionOptions (à savoir les caractéristiques facultatives prises en charge par la DLE)	Type: BooleanArray8 (constant)

[a] Cela correspond à la plus grande durée exigée pour basculer du mode émission/réception au mode réception/émission, selon le mode qui survient (dans différentes DLE) à l'issue d'une DPDU Data avant la DPDU ACK/NAK suivante.

Le Tableau 148 montre la structure de l'OctetString. L'attribut EnergyDesign comporte un champ de taille d'un octet, ajouté en préfixe au début de l'OctetString de longueur non spécifiée.

Tableau 148 – Structure de l'OctetString dlmo.DeviceCapability

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1..2	QueueCapacity							
1	ClockStability							
2	ChannelMap							
1	DLERoles							
6..9	EnergyDesign (taille de l'OctetString, plus un contenu de 5..8 octets)							
2	EnergyLeft							
1..2	AckTurnaround							
1..2	NeighborDiagCapacity							
1	RadioTransmitPower							
1	SupportedCCAmodes							
1	ConstructionOptions							

Les champs comprennent:

- dlmo.DeviceCapability.QueueCapacity est le nombre de tampons dans la file d'attente qui sont disponibles pour des opérations de transmission. Cette capacité ne doit pas inclure de tampons internes qui peuvent être utilisés pour les messages qui circulent à travers la NLE. Cette valeur doit être basée sur le cas le plus défavorable, où toutes les DPDU sont de taille maximale. Lors du fonctionnement, la capacité réelle de file d'attente peut être plus grande que cette valeur rapportée. Voir 9.1.8.5.
- L'attribut dlmo.DeviceCapability.ClockStability est la stabilité nominale d'horloge à court terme de l'appareil, sous forme d'un multiple de 1×10^{-6}, en l'absence d'une correction de temps issue du sous-réseau D. Voir 9.1.9.2.2.

- L'attribut dlmo.DeviceCapability.ChannelMap est une liste de voies que l'appareil peut légalement prendre en charge dans le domaine de réglementation de l'appareil (tel que déterminé par dlmo.CountryCode, 9.1.15.6), où une valeur de zéro indique que l'appareil n'est pas autorisé à utiliser la voie. Les positions de bits 0..15 correspondent aux voies 0..15 de la présente norme (qui correspondent à leur tour aux voies DSSS 2,4 GHz 11..26 de l'IEEE 802.15.4). Si la DLE est configurée avec des liaisons qui se réfèrent à de tels voies bloquées, la DLE doit traiter ces liaisons comme étant inactives. Voir 9.1.7.2.3, 9.1.15.6, 9.4.2.19 et Annexe V.
- L'attribut dlmo.DeviceCapability.DLERoles énumère les profils de rôles de DL pris en charge par la DLE, où une valeur true indique que la DLE prend en charge le profil de rôles de DL. Voir 9.1.16 pour un débat relatif aux rôles de DLE.
  - L'Index 0 indique si la DLE prend en charge le profil de rôle d'E/S.
  - L'Index 1 indique si la DLE prend en charge le profil de rôle de routeur.
  - L'Index 2 indique si la DLE prend en charge le profil de rôle de routeur dorsal.
  - L'Index 3 indique si la DLE prend en charge le profil de rôle de silence radio. Voir 9.1.15.4.
  - Les indices 4 à 7 sont réservés et doivent être mis à la valeur false.
- Les attributs dlmo.DeviceCapability.EnergyDesign et EnergyLeft sont décrits en 9.1.17 et en 9.4.2.22.
- L'attribut dlmo.DeviceCapability.DAckTurnaround indique le temps nécessaire à la DLE pour traiter une DPDU Data reçue et répondre avec une DPDU ACK ou NAK, en unités de 2^{-15} s. Toutes les DLE doivent être capables d'utiliser les modèles d'intervalles de temps par défaut (voir Tableau 165, Tableau 166, et Tableau 167).

  La valeur DAckTurnaround est une borne supérieure sur l'intervalle de temps mesuré extérieurement exigé par l'appareil pour répondre à un signal issu de son PHY associé indiquant que la réception de DPDU est achevée et pour initier une émission PHY concernant la DPDU ACK/NAK située immédiatement après. Cette mesure implique la notation du temps lorsque le dernier symbole d'une PhPDU correspondant à la DPDU initiale d'une transaction est présenté à l'appareil de réception et que le premier signal PhPDU issu de cet appareil est détecté, où le modèle de transaction utilisé est un modèle de réception en monodiffusion utilisant la temporisation de DPDU ACK/NAK référencée à la fin de la DPDU Data venant d'être reçue.
- L'attribut dlmo.DeviceCapability.NeighborDiagCapacity indique la capacité, en octets, de l'attribut de NeighborDiag. Seuls les octets montrés dans le Tableau 187 sont inclus dans NeighborDiagCapacity. Le gestionnaire de système crée indirectement des OctetString dans NeighborDiag en positionnant les champs DiagLevel dans l'attribut Neighbor. Il convient que le gestionnaire de système ne configure pas une DLE pour remplir NeighborDiag au-delà de sa capacité énoncée, et une DLE peut échouer à accumuler des données si le gestionnaire de système excède cette capacité énoncée. Une valeur de 0x7FFF indique que la capacité est suffisante pour recueillir tous les diagnostics disponibles pour chaque dlmo.Neighbor.
- L'attribut dlmo.DeviceCapability.RadioTransmitPower est le niveau maximal de puissance pris en charge de la DLE, en dBm p.i.r.e., que la DLE peut légalement prendre en charge dans le domaine de réglementation de la DLE, tel que déterminé par dlmo.CountryCode. Voir 9.1.15.5, 9.1.15.6, 9.4.2.19 et Annexe V.
- L'attribut dlmo.DeviceCapability.SupportedCCAmodes est une liste des modes CCA que l'appareil prend en charge (voir 9.1.9.4.3):
  - Le bit 0 (Index 0) indique que le Mode CCA 1 est pris en charge.
  - Le bit 1 (Index 1) indique que le Mode CCA 2 est pris en charge.
  - Le bit 2 (Index 2) indique que le Mode CCA 3 est pris en charge.
  - Le bit 3 (Index 3) indique que le Mode CCA 4 est pris en charge.
  - Les bits 4..7 (Indices 4 à 7) sont réservés et doivent être mis à la valeur false.

- L'attribut dlmo.DeviceCapability.ConstructionOptions indique des caractéristiques facultatives que l'appareil prend en charge par construction.
  - Le bit 0 (Index 0) indique si les codes de groupe sont pris en charge dans dlmo.Neighbor.
  - Le bit 1 (Index 1) indique si les extensions de graphe sont prises en charge dans dlmo.Neighbor.
  - Le bit 2 (Index 2) indique si l'appareil est capable de recevoir des DPDU ACK/NAK en duodiffusion ou en N-diffusion.
  - Le bit 3 (Index 3) indique si l'appareil est capable de prendre en charge dlmo.Superframe.SfType=1 qui peut être nécessaire dans certaines régions pour la conformité à la réglementation.
  - Le bit 4 (Index 4) indique si l'appareil est capable de prendre en charge le champ de dlmo.Graph.Queue qui, lorsqu'il est mis à une valeur autre que zéro, réserve la capacité de tampon de file d'attente.

    Il convient que cette capacité de file d'attente ne soit pas réservée ainsi, sauf si dlmo.DeviceCapability.QueueCapacity excède l'exigence maximale pour un profil de rôle d'une DLE (voir Tableau B.8).
  - Les bits 5..7 (indices 5 à 7) sont réservés et doivent être mis à la valeur false.

9.4.2.24 Voisins candidats

L'attribut dlmo.Candidates est utilisé pour fournir au gestionnaire de système une liste de voisins candidats. La DLE peuple en toute autonomie cet attribut alors qu'il reçoit des annonces issues d'un certain nombre de voisins candidats. Cet attribut est alors transmis au gestionnaire de système afin que des décisions relatives au routage puissent être prises. Le gestionnaire de système peut réinitialiser dlmo.Candidates.N=0, signalant ainsi à la DLE d'effacer son historique d'annonces reçues et reprendre le processus de découverte de voisins.

L'attribut dlmo.DiscoveryAlert (Tableau 149) fournit au gestionnaire de système le contrôle sur la découverte de voisins et les rapports. Le gestionnaire de système met dlmo.DiscoveryAlert, et reçoit plus tard une copie de l'attribut dlmo.Candidates par l'intermédiaire de l'alerte dlmo.NeighborDiscovery. En variante, le gestionnaire de système peut lire l'attribut dlmo.Candidates sur son propre programme, ou s'arranger pour le rapporter périodiquement par l'intermédiaire du HRCO.

Tableau 149 – Champs de dlmo.DiscoveryAlert

Nom de champ	Codage de champ
Descriptor	Type: Alert report descriptor (voir Tableau 269) Par défaut: [false, 0]
Durée	Type: Unsigned16 Unités: 1 s Par défaut: 60

Le Tableau 150 montre la structure de DiscoveryAlert.

Tableau 150 – Structure de dlmo.DiscoveryAlert

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Alert report disabled							
1	Alert report priority							
2	Durée							

Lorsque dlmo.DiscoveryAlert est activé (Descriptor.Disabled=False), la DLE doit rapporter le contenu de dlmo.Candidates.Duration des secondes plus tard en utilisant l'alerte dlmo.NeighborDiscovery. Une fois que la DLE parachève l'alerte, la DLE remet dlmo.DiscoveryAlert à zéro.

Lorsque l'alerte NeighborDiscovery est déclenchée par l'état de Duration (dlmo.DiscoveryAlert.Duration), la DLE doit automatiquement mettre le champ Duration à zéro, ce qui donne une seule alerte NeighborDiscovery chaque fois que le champ Duration est mis à une valeur autre que zéro.

L'attribut dlmo.DiscoveryAlert doit être activé et prendre par défaut la valeur Duration=60 lorsque la DLE entre dans l'état rattaché. Cette valeur par défaut indique que la DLE doit, quand elle entre dans l'état rattaché, accumuler les informations issues des annonces dans dlmo.Candidates pendant une période de 60 s, et ensuite rapporter les résultats en utilisant l'alerte dlmo.NeighborDiscovery. Voir 9.1.14.6. Le gestionnaire de système peut neutraliser cette valeur par défaut en écrivant dans dlmo.DiscoveryAlert conjointement avec la réponse de rattachement.

Les annonces issues de routeurs voisins incluent les liaisons qui peuvent être utilisées pour communiquer avec le routeur en question. Lorsque DiscoveryAlert est activé, la DLE peut utiliser ces liaisons pour interroger, avec une DSDU Data transportant une DSDU nulle, chaque routeur candidat, sur plusieurs voies, et recevoir la métrique de qualité de signal dans le DAUX. Ces informations permettent à la DEL d'élaborer une image plus exacte de la qualité de signal dans dlmo.Candidates.

Lorsque dlmo.DiscoveryAlert est désactivé, il convient néanmoins que la DLE dresse passivement une liste de dlmo.Candidates comme un processus d'arrière-plan après qu'elle a rejoint le sous-réseau D, en se basant sur des annonces de quelque nature que ce soit qu'elle reçoit au cours de l'actionnement du diagramme d'états de la DLE.

S'il y a une alerte dlmo.DL_Connectivity et DiscoveryAlert est activé, la DLE doit également envoyer une alerte dlmo.NeighborDiscovery au même moment.

Lorsque dlmo.DiscoveryAlert.Duration est mis à 0, la DLE ne doit pas envoyer d'alertes dlmo.NeighborDiscovery sur une base synchronisée. Il convient que la DLE continue de maintenir l'attribut Candidates afin qu'il puisse être lu, le cas échéant, par le gestionnaire de système en lisant directement l'attribut dlmo.Candidates directement ou en configurant la DLE pour le rapporter périodiquement par l'intermédiaire du HRCO.

Le processus de recherche par balayage des annonces est décrit en 9.1.13.

L'attribut dlmo.Candidates comporte une série de champs qui sont décrits dans le Tableau 151. Par essence, le tuple <Candidate>, <RSQI> est répété N fois, fournissant une indication de qualité de signal à plusieurs voisins.

L'attribut dlmo.Candidates peut raisonnablement exclure des entrées courantes dans la table dlmo.Neighbor, lorsque la même information pour ces voisins est disponible par l'intermédiaire du diagnostic de voisin.

Tableau 151 – Champs de l'OctetString dlmo.Candidates

Nom de champ	Codage de champ
N (nombre des voisins découverts)	Type: Unsigned8
$Neighbor_1$ (adresse 16 bits du premier candidat)	Type: ExtDLUint
$RSSI_1$ (force de signal radio du premier candidat)	Type: Integer8
$RSQI_1$ (qualité de signal radio du premier candidat)	Type: Unsigned8
…	…
$Neighbor_N$ (adresse 16 bits du $N^{ème}$ candidat)	Type: ExtDLUint
$RSSI_1$ (force de signal radio du $N^{ème}$ candidat)	Type: Integer8
$RSQI_N$ (qualité de signal radio du $N^{ème}$ candidat)	Type: Unsigned8

Le Tableau 152 montre la structure de Candidates.

Tableau 152 – Structure de dlmo.Candidates

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	N							
1..2	$Neighbor_1$							
1	$RSSI_1$							
1	$RSQI_1$							
…	…							
1..2	$Neighbor_N$							
1	$RSSI_N$							
1	$RSQI_N$							

Les champs comprennent:

- dlmo.Candidates.N est le nombre de voisins qui ont été découverts. Une DLE doit prendre en charge au moins cinq (5) entrées candidates. Si plusieurs voisins sont découverts, la DLE peut rapporter seulement les meilleurs candidats sur la base de la qualité de la liaison radio.
- dlmo.Candidates.$Neighbor_N$ est l'adresse de 16 bits de chaque voisin candidat dans le sous-réseau D.
- dlmo.$RSSI_N$ Indique l'intensité du signal radio en dBm provenant de chaque voisin candidat, sur la base des annonces reçues et possiblement d'autres DPDU. Voir 9.1.15.2 pour une description de l'attribut RSSI, y compris le biais de dBm fixe dans les valeurs de mesure reportées.
- dlmo.$RSQI_N$ indique la qualité du signal radio provenant de chaque voisin candidat, sur la base des annonces reçues et possiblement d'autres considérations. Un nombre plus élevé indique un signal radio meilleur. Voir 9.1.15.2 pour une description de l'attribut RSQI.

9.4.2.25 Facteurs de lissage

L'attribut dlmo.SmoothFactors fournit les facteurs de lissage pour l'attribut dlmo.NeighborDiag. L'utilisation de ces facteurs est décrite en 9.1.15.3.

Trois champs dans dlmo.NeighborDiag impliquent le lissage exponentiel: RSSI, RSQI, et ClockBias. Le facteur de lissage α (alpha) pour chacune de ces valeurs est configurable individuellement. Alpha est exprimé en pourcentage entier dans la plage 0..100. RSSI et RSQI prennent par défaut la valeur de 10 %, si bien que les valeurs tendent à refléter l'historique récent. ClockBias prend par défaut la valeur de 1 %, car cette valeur est destinée à montrer le biais d'horloge sur une période de temps prolongée.

Chaque facteur de lissage implique trois valeurs: x_AlphaHigh, x_AlphaLow et x_Threshold pour différents x. Si les nouvelles données se situent en dessous du seuil, utiliser x_AlphaLow comme étant le facteur de lissage; autrement, utiliser x_AlphaHigh.

Les champs dans dlmo.SmoothFactors sont décrits dans le Tableau 153.

Tableau 153 – Champs de l'OctetString dlmo.SmoothFactors

Nom de champ	Codage de champ	Par défaut
RSSI_Threshold (seuil pour RSSI)	Type: Integer16	0
RSSI_AlphaLow (AlphaLow pour RSSI)	Type: Unsigned8	10
RSSI_AlphaHigh (AlphaHigh pour RSSI)	Type: Unsigned8	10
RSQI_Threshold (seuil pour RSQI)	Type: Integer16	0
RSQI_AlphaLow (AlphaLow pour RSQI)	Type: Unsigned8	10
RSQI_AlphaHigh (AlphaHigh pour RSQI)	Type: Unsigned8	10
ClockBias_Threshold (seuil pour ClockBias)	Type: Integer16	0
ClockBias_AlphaLow (AlphaLow pour ClockBias)	Type: Unsigned8	1
ClockBias_AlphaHigh (AlphaHigh pour ClockBias)	Type: Unsigned8	1

Le Tableau 154 montre la structure de SmoothFactors.

Tableau 154 – Structure de dlmo.SmoothFactors

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
2	RSSI_Threshold							
1	RSSI_AlphaLow							
1	RSSI_AlphaHigh							
2	RSQI_Threshold							
1	RSQI_AlphaLow							
1	RSQI_AlphaHigh							
2	ClockBias_Threshold							
1	ClockBias_AlphaLow							
1	ClockBias_AlphaHigh							

9.4.2.26 dlmo.QueuePriority

9.4.2.26.1 Généralités

dlmo.QueuePriority est un attribut qui permet au gestionnaire de système de spécifier la capacité de tampon nominale dans la file d'attente de transmission de la DLE pour les niveaux spécifiques de priorité. Comme décrit en 9.1.8.5, le gestionnaire de système peut configurer la capacité de tampon nominale de la DLE pour limiter le nombre des tampons qui peuvent être utilisés pour transmettre des DPDU Data de basse priorité. Par exemple, le gestionnaire de système peut configurer dlmo.QueuePriority si bien que pas plus de 3 tampons ne doivent être utilisés pour transmettre des DPDU Data avec une priorité ≤ 2.

La capacité nominale de la file d'attente de transmission peut être trouvée dans dlmo.DeviceCapability.QueueCapacity (voir 9.4.2.23).

9.4.2.26.2 Sémantique

Le Tableau 155 spécifie les champs pour dlmo.QueuePriority.

Tableau 155 – Champs de dlmo.QueuePriority

Nom de champ	Codage de champ
N (nombre des priorités spécifiées, 0..15, valeur par défaut N=0)	Type: Unsigned8
Priority1 (première priorité)	Type: Unsigned8
QMax1 (capacité de premier tampon)	Type: Unsigned8
...	
$Priority_N$ ($N^{ème}$ priorité)	Type: Unsigned8
$QMax_N$ (capacité de $N^{ème}$ tampon)	Type: Unsigned8

Par exemple, si la priorité est 2 et QMax est 3, alors pas plus de 3 tampons de file d'attente ne doivent être utilisés pour transmettre des DPDU Data avec une priorité ≤ 2. Ce compte ne doit pas inclure des DPDU Data qui utilisent la capacité de file d'attente qui a été mise de côté pour des données DPDU Data transmises le long d'un graphe particulier, en se basant sur dlmo.Graph[ ].Queue. La priorité doit être énumérée dans l'ordre croissant, si bien que PriorityX doit être inférieur à $Priority_{X+1}$. De même, $QMax_X$ doit être inférieur à $QMax_{X+1}$.

Le compte $QMax_X$ établit les intervalles de temps disponibles maximaux pour les messages de faible priorité, pas les intervalles de temps réservés pour les messages de faible priorité. En fait, $QMax_X$ assure que le reste de la file d'attente est disponible pour les DPDU ayant la priorité 1 + $Priority_X$.

Comme décrit en 9.2.2, l'indicateur DE dans un en-tête de DPDU indique si une DPDU Data dans la file d'attente est éligible à être rejetée en faveur d'une DPDU entrante ayant une plus haute priorité.

La valeur par défaut, où $N = 0$, indique que le gestionnaire de système n'a pas configuré une limite sur le nombre de tampons de transmission qui peuvent être utilisés pour des DPDU de faible priorité.

Le Tableau 156 montre la structure de dlmo.QueuePriority.

Tableau 156 – Structure de dlmo.QueuePriority

	7	6	5	4	3	2	1	0
1	N							
2 (opt)	$Priority_1$							
3 (opt)	$QMax_1$							
...	...							
2N (opt)	$Priority_N$							
2N+1 (opt)	$QMax_N$							

9.4.2.27 dlmo.ChannelDiag

9.4.2.27.1 Généralités

L'attribut dlmo.ChannelDiag est un attribut dynamique en lecture seule qui rapporte les taux d'échec d'émission de DPDU sur chaque voie radio prise en charge par la norme. Cela permet au gestionnaire de système d'avoir conscience des problèmes de connectivité cohérente sur une base voie par voie, comme un diagnostic pour la gestion de spectre dans un sous-réseau D.

Deux diagnostics sont rapportés pour chaque voie, chacun indiquant un type différent d'échec. $NoACK_N$ indique le pourcentage du temps pendant lequel les émissions de DPDU en monodiffusion sur la voie N n'ont pas entraîné la réception d'une DPDU ACK/NAK. $CCABackoff_N$ indique le pourcentage de temps pendant lequel l'appareil a abandonné une émission initiatrice de transaction sur la voie N en raison de la CCA.

Dans un certain nombre de situations, le repli de CCA est une partie intégrante du fonctionnement normal du sous-réseau D et n'est pas l'indicateur d'une qualité médiocre de voie. En particulier, un conflit pour des liaisons partagées conduira au repli de la CCA. Par conséquent, la DLE peut être sélective dans son compte de replis de CCA. Il est recommandé qu'il convient que les replis de CCA ne soient pas comptés normalement s'ils se produisent dans des liaisons partagées au sein de supertrames de saut de voie discrétisé. Les liaisons partagées sont décrites en 9.1.8.2.

Les valeurs de ChannelDiag sont des entiers signés de 8 bits.

- Une valeur de 0 indique qu'aucune émission n'a été tentée sur la voie.
- Les valeurs positives dans la plage 1..101 indiquent le taux d'échec en pourcentage plus un. Par exemple, une valeur de $CCABackoff_6$ indique que 25 % des émissions initiatrices de transactions sur la voie 6 ont été abandonnées en raison de la CCA.
- Les valeurs négatives dans la plage -1 à -101 indiquent le taux d'échec en pourcentage comme étant un nombre négatif moins un. Les taux d'échec sont rapportés sous forme de nombres négatifs s'ils sont basés sur 5, ou moins de 5, émissions tentées. Par exemple, une valeur $NoACK_8$ de -34 indique que 33 % des émissions en monodiffusion sur une voie particulière n'ont pas reçu d'acquittement et que 5, ou moins de 5, émissions ont été tentées sur cette voie.

La DLE peut sélectivement sauter des liaisons d'émission par anticipation d'une émission échouée, comme décrit en 9.1.7.2.4. Il convient que de telles liaisons sautées soient traitées comme l'équivalent du NAK pour la voie applicable.

Chaque fois que ChannelDiag est lu par le gestionnaire de système ou rapporté périodiquement par le HRCO, ses accumulateurs sous-jacents doivent être remis à zéro.

9.4.2.27.2 Sémantique

Le Tableau 157 spécifie les champs pour dlmo.ChannelDiag.

Tableau 157 – Champs de dlmo.ChannelDiag

Nom de champ	Codage de champ
Count (nombre des émissions en monodiffusion tentées pour toutes les voies)	Type: Unsigned16
NoACK0 (pourcentage du temps pendant lequel des émissions de temps sur la voie 0 n'ont pas reçu une DPDU ACK)	Type: Integer8
CCABackoff0 (pourcentage du temps pendant lequel des émissions sur la voie 0 ont été abandonnées en raison de la CCA)	Type: Integer8
…	…
NoACK15 (pourcentage du temps pendant lequel des émissions de temps sur la voie 15 n'ont pas reçu une DPDU ACK)	Type: Integer8
CCABackoff15 (pourcentage du temps pendant lequel des émissions sur la voie 15 ont été abandonnées en raison de la CCA)	Type: Integer8

Le Tableau 158 montre la structure de dlmo.ChannelDiag.

9.4.3 Attributs de DLMO (OctetStrings indexés)

9.4.3.1 Généralités

Les attributs d'objet de gestion d'OctetString indexés sont des ensembles structurés de données, de conception similaire à des tables SQL. Par exemple, la DLE maintient une liste de voisins dans un attribut OctetString indexé appelé dlmo.Neighbor, où chaque voisin peut être vu comme une rangée dans une table, avec la structure de chaque rangée telle que montrée dans le Tableau 168 et dans le Tableau 169. Un indice de 15 bits pour chaque rangée, correspondant dans le présent cas à l'adresse de 16 bits du voisin, est fourni pour chaque attribut OctetString indexé dans le DLMO.

Pour la cohérence du traitement, tous les attributs OctetString indexés dans la DL incluent un indice dans le premier champ qui est de type ExtDLUint. Cependant, dans le cas de dlmo.Ch, dlmo.TsTemplate, et dlmo.Superframe, l'indice est limité à une plage de 1..127, garantissant donc que l'indice peut être représenté dans un seul octet. Les références à ces structures peuvent également être compressées en un seul octet.

Pour un OctetString indexé, l'indice égal à zéro ne doit pas être utilisé dans le DLMO, sauf pour indiquer une entrée "null" (c'est-à-dire vide).

La Figure 90 montre la relation entre certains des attributs OctetString indexés de DLMO. Les relations référentielles sont montrées par des flèches. Par exemple, dlmo.Link se réfère à dlmo.TsTemplate, aussi une flèche est-elle montrée pointant dans le sens de la référence. Cela correspond grossièrement à une relation un à plusieurs, où un même modèle peut être référencé par plusieurs liaisons.

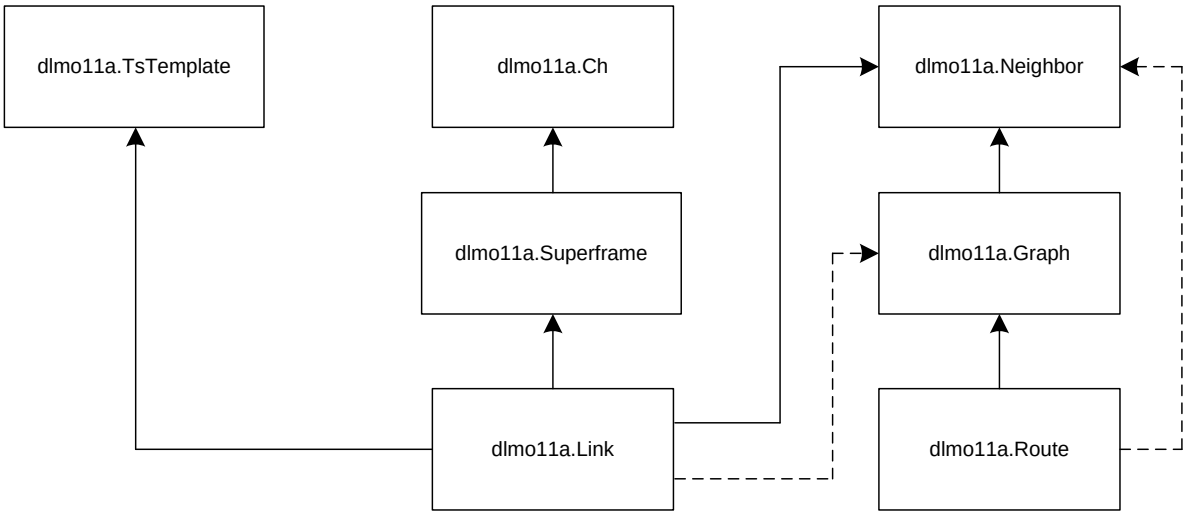

Figure 90 – Relation entre attributs indexés de DLMO

Comme montré à la Figure 90, dlmo.TsTemplate est référencé par dlmo.Link. Les modèles d'intervalle de temps spécifient la structure et la temporisation de transaction lorsqu'une liaison est utilisée.

dlmo.Link, dlmo.Superframe, et dlmo.Ch sont reliés. Les supertrames sélectionnent un modèle de saut de voie et un programme cyclique. Les liaisons décrivent les diverses actions qui sont entreprises au cours de chaque cycle de supertrame. Chaque liaison se réfère à une supertrame.

Pour les transactions en monodiffusion (et en duodiffusion), dlmo.Link se réfère à dlmo.Neighbor. Une seule et même référence peut englober un groupe de voisins. Si une liaison est réservée pour l'utilisation d'un certain graphe ou donne un accès préférentiel à un certain graphe, alors dlmo.Link se référera également à dlmo.Graph. Sachant qu'on peut configurer une liaison sans une référence à un graphe, cette référence est montrée sous la forme d'une ligne à traits pointillés à la Figure 90.

Les attributs dlmo.Route et dlmo.Graph sont reliés en ce que les chemins se réfèrent habituellement à des graphiques. Les attributs dlmo.Graph et dlmo.Neighbor sont reliés en ce que les graphes se réfèrent à des voisins. Les attributs dlmo.Route et dlmo.Neighbor sont reliés d'une manière lâche (indiquée par une ligne à traits pointillés à la Figure 90) en ce que le routage de source peut se référer implicitement à un voisin.

Une relation supplémentaire, non montrée à la Figure 90, existe entre dlmo.Neighbor et dlmo.NeighborDiag. Tous les deux sont indexés par l'adresse de 16 bits des voisins de la DLE, mais dans des buts différents.

- dlmo.Neighbor: Le gestionnaire de système fournit cet attribut OctetString indexé "static" pour permettre à la DLE de communiquer avec ses voisins immédiats.
- dlmo.NeighborDiag: Le gestionnaire de système configure cet attribut OctetString indexé "dynamic" pour permettre à la DLE de recueillir et rapporter périodiquement le diagnostic pour ses voisins immédiats.

9.4.3.2 dlmo.Ch

9.4.3.2.1 Généralités

L'attribut dlmo.Ch est un ensemble OctetString indexé contenant des modèles de saut de voie qui sont disponibles.

Les modèles de saut de voie 1 à 5 sont réservés comme valeurs par défaut normalisées, telles que décrites en 9.1.7.2.5. Des modèles complémentaires de saut de voie peuvent être ajoutés.

Chaque DLE peut stocker plusieurs modèles de saut de voie, avec un indice propre à chaque modèle. Les annonces supposent que des modèles de saut de voie pour le processus de rattachement sont configurés dans la DLE lorsque l'annonce est reçue. Donc, tout modèle de saut de voie référencé dans une annonce doit concorder avec une des valeurs par défaut.

Le gestionnaire de système insère, met à jour ou efface des modèles de saut de voie en envoyant au DMAP un modèle de saut de voie, accompagné d'un indice unique et (si sélectionné) d'un temps TAI de basculement.

Pour un modèle donné de saut de voie, la norme fournit un mapping entre les numéros de voie de DL et les numéros de voie plus généraux de la MAC selon l'IEEE 802.15.4. Tels qu'appliqués à la radio DSSS dans la bande de 2,4 GHz selon l'IEEE 802.15.4, les numéros de voie doivent être limités à la plage 0..15, correspondant aux numéros de voies 11..26 (page de voies 0) de l'IEEE 802.15.4, dans le même ordre. Les modèles de saut de voie pour cette radio ne doivent pas excéder une taille de 16.

NOTE Les types de données dlmo.Ch sont limités à la radio avec 16 voies ou moins de 16 voies. Les radios du futur avec plus de voies impliqueront de fournir la prise en charge pour une représentation moins compressée.

Cinq modèles de saut de voie par défaut sont réservés et définis par la norme. Des modèles de saut de voie par défaut sont énumérés et décrits en 9.1.7.2.5.

9.4.3.2.2 Sémantique

Le Tableau 159 spécifie les champs pour dlmo.Ch. Un indice, utilisé pour identifier chaque modèle de saut de voie, est cohérent avec les conventions de DL pour les OctetStrings indexés.

Tableau 159 – Champs de dlmo.Ch

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice) Plage valide: 1..127
Size	Type: Unsigned8 Plage valide: 1..16
Seq (modèle de saut de voie, avec des entrées Size)	Type: SEQUENCE OF Unsigned4 (SIZE (Size))

Le Tableau 160 montre la structure de dlmo.Ch.

Tableau 160 – Structure de dlmo.Ch

<table>

</table>

9.4.3.3 dlmo.TsTemplate

9.4.3.3.1 Généralités

dlmo.TsTemplate est un ensemble OctetString indexé qui contient des modèles d'intervalle de temps. Les modèles d'intervalle de temps décrivent la temporisation de la transaction D.

Les modèles d'intervalle de temps 1, 2, et 3 doivent être réservés comme valeurs par défaut normalisées, comme énuméré au Tableau 165, au Tableau 166 et au Tableau 167. D'autres modèles d'intervalle de temps peuvent être ajoutés par le gestionnaire système.

Le gestionnaire de système insère, met à jour ou efface des modèles d'intervalle de temps en envoyant au DMAP un modèle, accompagné d'un indice unique et (si sélectionné) d'un temps TAI de basculement.

Des décalages de temps de modèle sont spécifiés en unités de 2^{-20} s, ce qui représente approximativement 1 μs. La durée d'intervalle de temps est fixée par les supertrames qui utilisent le modèle.

Les types de modèle incluent des modèles d'initiateur de réception et de transaction. Les deux types de modèle incluent des acquittements pour des transactions en monodiffusion. Les mêmes modèles peuvent également être utilisés pour des liaisons de diffusion, telles que des sollicitations, qui n'ont pas besoin d'acquittements et n'utilisent pas les temporisations de DPDU ACK/NAK.

Les modèles peuvent être définis sur trois niveaux:

- Des modèles par défaut sont définis dans la norme. Ce sont les modèles d'intervalle de temps exigés pour le rattachement (Tableau 165, Tableau 166 et Tableau 167). Le modèle d'indice=1 décrit une transaction de réception générique et est utilisé pour recevoir des réponses de rattachement. Le modèle d'indice= 2 décrit une transaction d'émission générique et est utilisé pour émettre des demandes de rattachement. Le modèle d'indice=3 décrit une transaction qui actionne son récepteur pendant un intervalle de temps entier, destiné aux opérations telles que rechercher par balayage des annonces ou recevoir des DPDU de saut de voie lent à temporisation lâche. Ces modèles génériques doivent être utilisés au cours de la configuration et du rattachement, et peuvent également être utilisés pour d'autres buts.
- Des modèles configurés peuvent être ajoutés lors du processus de configuration, avec une durée de vie jusqu'à ce que la DLE ait rejoint le sous-réseau D. Voir 9.1.14.4.
- Des modèles spécifiques à un sous-réseau peuvent être fournis à la DLE après que le processus de rattachement a été parachevé.

La temporisation des émissions de DPDU Data est basée sur l'horloge interne de l'initiateur de transaction. La temporisation des DPDU ACK/NAK est spécifiée comme étant le décalage de temps par rapport au point de référence qui est indiqué dans le modèle. Habituellement, la plage de temps configurée pour un initiateur de transaction est plus étroite que la plage de temps pour les récepteurs de transaction, afin de rendre compte des temps de garde.

Les modèles d'intervalle de temps doivent fournir une fenêtre de réception d'au moins 192 μs, ce qui implique que les DLE doivent être capables de commander la temporisation d'émission avec une exactitude d'au moins ±96 μs, à savoir ±6 périodes symboles PHY.

Par convention, la temporisation de modèle d'intervalle de temps est spécifiée en étant basée sur les temps de début et de fin des DPDU. La temporisation de PhPDU, dépendante des détails de la couche physique qui contient la DPDU, peut être inférée à partir des temps de DPDU. Le temps de début de DPDU, tel que spécifié dans des modèles d'intervalle de temps, utilise une convention selon laquelle la DPDU commence à l'instant juste avant que le premier octet dans l'en-tête de la DPDU ne soit émis. Cette convention s'applique aux émissions de DPDU Data ainsi qu'aux DPDU ACK/NAK.

NOTE Dans les mises en œuvre réelles basées sur l'IEEE 802.15.4 (2,4 GHz), les signaux de temporisation de PhL sont parfois déclenchés lorsqu'un SFD (délimiteur de début de trame) est complètement émis ou reçu. Dans de tels cas, le temps de début de la DPDU se situe à 1 octet, ou 32 μs, après le point de référence.

Le temps de réponse ACK/NAK est communément spécifié par rapport au temps de fin de la DPDU Data, la DPDU ACK/NAK se produisant approximativement 1 ms après.

En variante, les DPDU ACK/NAK peuvent être synchronisées par rapport au temps de fin programmé de l'intervalle de temps. En plaçant des DPDU ACK/NAK à un décalage fixe au sein de l'intervalle de temps, il est possible de respecter les exigences de réglementation qui interdiraient l'émission d'une DPDU ACK/NAK après une très courte DPDU Data, si l'expéditeur de la DPDU ACK/NAK avait aussi émis près de la fin de l'intervalle antérieur.

Un tel placement par rapport à la fin de l'intervalle de temps prend également en charge les routeurs qui opèrent sur plusieurs voies multiples même temps, partageant une antenne commune, ou des appareils dont les antennes sont situées à étroite proximité l'une de l'autre. Dans les deux cas, sans un tel alignement programmé, les DPDU Data et/ou DPDU ACK/NAK émises sur une même voie pourraient involontairement bloquer une réception à chevauchement de temps dont la réception est tentée sur une autre voie.

Quand les temps de DPDU ACK/NAK sont définis comme des décalages par rapport à la fin de l'intervalle de temps, les décalages de temps, qui sont des nombres entiers non signés, doivent être interprétés comme se référant à un temps avant la fin de l'intervalle de temps.

Les modèles de récepteur de transaction spécifient:

- La plage de temps où le premier octet d'une DPDU Data peut être reçu, indiquant une plage de temps pour activer et désactiver le récepteur de radio. Une plage de temps qui excède la durée de l'intervalle de temps indique que la plage se prolonge seulement jusqu'à la fin programmée de l'intervalle de temps.
- La plage de temps de retard de DPDU ACK/NAK.

Il convient qu'un répondeur de transaction pour une transaction en monodiffusion réponde par une DPDU ACK/NAK aussitôt que possible dans cette plage, à l'exception des DPDU ACK/NAK en n-diffusion volontairement échelonnées. Le temps de retard d'une DPDU ACK/NAK peut être spécifié en référence à la fin de la DPDU reçue ou comme étant un décalage arrière par rapport à la fin programmée de l'intervalle de temps.

- S'il est acceptable de fonctionner après la frontière de l'intervalle de temps une fois que la réception d'une DPDU commence, prolongeant la durée d'intervalle de temps.

Le dépassement d'une frontière d'intervalle peut être utilisé pour prendre en charge le saut de voie discrétisé, où des DLE initiatrices de transactions peuvent avoir un sens temporel biaisé des frontières d'intervalle de temps. La prise en charge de ces DLE implique d'autoriser la réception même si la transaction dépasse une frontière d'intervalle.

Les modèles d'initiateur de transaction spécifient:

- La plage de temps pour commencer l'émission. Une DLE conforme peut commencer son émission à tout moment au sein de la plage de temps, en fonction de son horloge interne de DLE. La plage de temps est basée sur le temps de début de la DPDU Data. L'opération de CCA, le cas échéant; le SHR et le PHR de la PhPDU précèdent l'événement et peuvent donc se produire avant que la plage de temps antérieure admise ait commencé l'émission.
- La plage de temps de retard de DPDU ACK/NAK. Un répondeur de transaction répondra habituellement aussitôt que possible au sein de cette plage, conformément à son modèle d'intervalle de temps mais sous réserve des contraintes de réglementation sur le retard exigé minimal depuis la dernière émission antérieure par le même appareil. Le temps de retard d'une DPDU ACK/NAK peut être spécifié en relation avec la fin de la réception de la DPDU Data ou avec la fin programmée de l'intervalle de temps.
- L'indication du mode CCA à utiliser avant l'émission permet de contrôler les émissions concurrentes ou en cours.
- L'indication de savoir si, oui ou non, il convient que la DLE continue périodiquement d'actionner son récepteur pour la plage entière de temps de retard de DPDU ACK/NAK, même après avoir reçu une DPDU ACK/NAK (destinée à la prise en charge de duodiffusion; voir 9.1.9.4.7).

9.4.3.3.2 Sémantique

Il y a deux variantes de dlmo.TsTemplate, l'une pour un modèle de récepteur de transaction et l'autre pour un modèle d'initiateur de transaction. Les variantes sont distinguées par un type de 2 bits qui est le premier élément. Type=0 indique un modèle de récepteur de transaction, alors que le type=1 indique une modèle d'initiateur de transaction. Les types 2 et 3 sont réservés pour usage futur.

Le Tableau 161 spécifie les champs pour le modèle de récepteur de transaction.

Tableau 161 – Champs du modèle de récepteur de transaction

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice) Plage valide: 1..127
Type (indique qu'il s'agit d'un modèle de récepteur de transaction)	Type: Unsigned2 Valeurs nommées: 0: modèle de récepteur de transaction 1: voir Tableau 163; les autres choix sont réservés
AckRef (indique la référence pour la plage de temps de DPDU ACK/NAK)	Type: Unsigned1: Valeurs nommées: 0: décalage par rapport à la fin de la DPDU entrante; 1: décalage négatif par rapport à la fin de l'intervalle de temps
RespectBoundary (spécifie si, oui ou non, les frontières d'intervalle de temps doivent être respectées (c'est-à-dire si, oui ou non, une transaction D peut se prolonger au-delà de la frontière d'intervalle de temps))	Type: Boolean1: false: les frontières d'intervalle de temps peuvent ne pas être respectées; true: les frontières d'intervalle de temps doivent être respectées
Reserved (alignement d'octets)	Type: Unsigned4=0
WakeupDPDU (temps le plus tôt auquel la réception de DPDU peut être censée commencer, indiquant quand activer le récepteur de radio décalage par rapport au temps de début programmé de l'intervalle de temps)	Type: Unsigned16 Unités: 2^{-20} s
TimeoutDPDU (temps le plus tard auquel la réception de DPDU peut être censée commencer, indiquant quand désactiver le récepteur si aucune DPDU entrante n'est détectée; décalage par rapport au temps de début programmé de l'intervalle de temps)	Type: Unsigned16 Unités: 2^{-20} s
AckEarliest (début de la plage de temps de retard de DPDU ACK/NAK, le début de cette PhSDU (DPDU) étant la référence de temps. La sémantique dépend du champ AckRef: si AckRef=1, soustraire la valeur à la valeur du temps de fin programmé de l'intervalle de temps pour déterminer AckEarliest)	Type: Unsigned16 Unités: 2^{-20} s
AckLatest (fin de la plage de temps de retard de DPDU ACK/NAK, le début de cette PhSDU (DPDU) étant la référence de temps. La sémantique dépend du champ AckRef: si AckRef=1, soustraire la valeur à la valeur du temps de fin programmé de l'intervalle de temps pour déterminer AckLatest)	Type: Unsigned16 Unités: 2^{-20} s

Le Tableau 162 spécifie la structure du modèle de récepteur de transaction.

Tableau 162 – Structure du modèle de récepteur de transaction

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	* Index (range 1..127)							
1	Type=0		AckRef	RespectBoundary	Réservé			
2	WakeupDPDU							
2	TimeoutDPDU							
2	AckEarliest							
2	AckLatest							

Le Tableau 163 spécifie les champs pour le modèle d'initiateur de transaction.

Tableau 163 – Champs du modèle d'initiateur de transaction

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice) Plage valide: 1..127
Type (indique qu'il s'agit d'un modèle d'initiateur de transaction)	Type: Unsigned2 Valeurs nommées: 0: voir Tableau 161; 1: modèle d'initiateur de transaction; les éléments restant sont réservés.
AckRef (indique la référence pour la plage de temps de retard de DPDU ACK/NAK)	Type: Unsigned1: Valeurs nommées: 0: décalage positif par rapport à la fin de la DPDU émise/reçue; 1: décalage négatif par rapport à la fin de l'intervalle de temps.
CCAmode (indique de vérifier, oui ou non, la CCA avant émission)	Type: unsigned2 (voir 9.1.9.4.3): Valeurs nommées: 0: mode CCA 4; 1: mode CCA 1; 2: mode CCA 2; 3: mode CCA 3
KeepListening (indique s'il convient, oui ou non, que la DLE continue d'actionner périodiquement son récepteur jusqu'à la fin de l'intervalle de temps, même après qu'une DPDU ACK/NAK a été reçue; voir 9.1.9.4.7)	Type: Boolean1
Reserved (alignement d'octets)	Type: Unsigned2=0
XmitEarliest (temps le plus tôt pour commencer l'émission de DPDU; décalage par rapport au temps de début programmé de l'intervalle de temps)	Type: Unsigned16 Unités: 2^{-20} s
XmitLatest (temps le plus tard pour commencer l'émission de DPDU; décalage par rapport au temps de début programmé de l'intervalle de temps)	Type: Unsigned16 Unités: 2^{-20} s
WakeupAck (temps au plus tôt auquel la réception de DPDU ACK/NAK peut être censée commencer; active le récepteur suffisamment tôt pour recevoir une DPDU ACK/NAK commençant à cet instant. La sémantique dépend du champ ACKref: si AckRef=1, soustraire la valeur à la fin programmée de l'intervalle de temps pour déterminer WakeupAck)	Type: Unsigned16 Unités: 2^{-20} s
TimeoutAck (temps le plus tard auquel la réception d'une DPDU ACK/NAK peut être censée commencer. La DLE peut désactiver le récepteur si la réception de DPDU ACK/NAK n'a pas commencé au plus tard à cet instant. La sémantique dépend du champ ACKref: si AckRef=1, soustraire la valeur à la fin programmée de l'intervalle de temps pour déterminer TimeoutAck)	Type: Unsigned16 Unités: 2^{-20} s
NOTE Une valeur AckEarliest de 402 (384 μs) prend en charge l'exigence SIFS de l'IEEE 802.15.4 de 6 octets, plus 6 octets pour le SHR et le PHR d'une PhPDU avant le début de la PhSDU de la DPDU ACK/NAK.	

Le Tableau 164 spécifie la structure du modèle d'initiateur de transaction.

Tableau 164 – Structure du modèle d'initiateur de transaction

Nombre d'octets	bits							
	7	6	5	4	3	2	1	0
1	* Index (range 1..127)							
1	Type		AckRef	CheckCCAmode		KeepListening	Réservé	
2	XmitEarliest							
2	XmitLatest							
2	WakeupAck							
2	TimeoutAck							

Le Tableau 165, le Tableau 166 et le Tableau 167 spécifient les valeurs pour les trois modèles d'intervalle de temps de DLE par défaut. Ces modèles d'intervalle de temps en lecture seule utilisent les indices 1, 2, et 3, et doivent être utilisés pour des liaisons qui sont spécifiées dans des annonces. Leur structure est d'usage général et ils peuvent aussi être référencés par d'autres liaisons.

La DLE doit être capable d'émettre et de recevoir des ACK/NAK dans la temporisation de 1 032 µs ± 100 µs indiquée dans ces modèles par défaut, ou plus lentement si spécifiée dans un modèle d'intervalle de temps de remplacement. L'attribut dlmo.DeviceCapability.DAckTurnaround informe le gestionnaire de système si un appareil est capable de traiter plus rapidement des DPDU ACK/NAK.

Ces modèles par défaut sont exigés pour les processus initiaux de mise en service de l'appareil et de rattachement au sous-réseau. Il n'existe aucune exigence pour toute utilisation non rattachée dans un système opérationnel.

Tableau 165 – Modèle de répondeur de transaction par défaut, utilisé au cours du processus de rattachement

Champ	Valeur par défaut	Explication
* Index	1	-
Type	0	-
AckRef	0	-
RespectBoundary	1	-
WakeupDPDU	1 271	1 212 µs

RespectBoundary	0	Si la réception de DPDU débute dans les limites de l'intervalle de temps, parachever le traitement de transaction
WakeupDPDU	0	Début d'intervalle de temps; permettant la prise en charge d'intervalles de temps qui sont contigus. Dans le premier intervalle de temps d'une série contiguë, un appareil peut insérer que le temps d'installation au début du premier intervalle de temps ne dépasse pas 1 271 µs
TimeoutDPDU	0xFFFF	Fin d'intervalle de temps
AckEarliest	977	Le même que pour le modèle de répondeur de transaction par défaut
AckLatest	1 187	Le même que pour le modèle de répondeur de transaction par défaut

9.4.3.3.3 Temporisations de modèle par défaut

Les modèles d'intervalle de temps par défaut visent à concorder avec la structure des intervalles de temps de l'IEC 62591.

Le temps d'émission de la DPDU Data par défaut est basé sur un décalage de 2 312 µs à partir du début de l'intervalle de temps jusqu'au début de la DPDU Data. Le modèle d'initiateur de transaction par défaut rend compte des ± 100 µs de la gigue d'initiateur de transaction, conduisant à une plage par défaut de 2 312 µs ± 100 µs. Le modèle de récepteur de transaction par défaut rend compte des ± 100 µs de gigue d'émission, plus une dérive d'horloge de ± 1 000 µs, conduisant à une plage de réception pour la DPDU Data de 2 312 µs ± 1 100 µs.

Le temps d'émission de la DPDU ACK/NAK par défaut est basé sur un décalage de 1 032 µs à partir de la fin de la DPDU Data jusqu'au début de la DPDU ACK/NAK. Les modèles de transaction d'intervalle par défaut permettent la prise en charge de ± 100 µs de gigue d'émission, pour un modèle par défaut de 1 032 µs ± 100 µs. La dérive d'horloge est considérée sans importance dans un court intervalle de temps à partir de la fin d'une DPDU Data jusqu'au début d'une DPDU ACK/NAK immédiatement consécutive.

Dans la radio selon l'IEEE 802.15.4 utilisée dans la présente norme, l'en-tête de couche physique a une durée de 6 octets, ou 192 µs. Ainsi, l'émission ou la réception radio

commence 192 μs plus tôt que les temps spécifiés dans les modèles. La CCA, si elle est exigée, précède le démarrage radio.

Les modèles ne rendent pas compte des éléments internes au fonctionnement radio, les laissant comme une question interne à un appareil. Par exemple, la valeur de 932 μs pour WakeupACK signifie que l'en-tête de couche physique peut commencer l'émission 192 μs plus tôt ou dès 932 μs -192 μs = 740 μs suivant la fin de la DPDU. Le récepteur de la DPDU ACK/NAK, aussi avec un WakeupAck nominal de 932 μs, a donc besoin que sa radio fonctionne à 740 μs suivant la fin de la DPDU et qu'elle soit prête alors à commencer à recevoir la DPDU ACK/NAK. Si le récepteur a besoin de plus de temps pour rendre compte du démarrage de la radio et de la gigue du récepteur, la radio a besoin d'être activée assez en avance de 740 μs pour assurer qu'elle peut recevoir l'en-tête complet de couche physique.

9.4.3.3.4 Considérations pour l'espace minimum exigé entre des émissions

Certains régimes de réglementation exigent qu'il y ait une période de temps minimale après qu'une émission a cessé avant que l'appareil ne puisse de nouveau émettre. Il est de la responsabilité de chaque DLE de noter le temps auquel l'émission la plus récente a cessé, d'utiliser cette information pour déterminer le moment au plus tôt auquel l'appareil peut émettre de nouveau et de s'abstenir d'activer son émetteur avant le moment en question.

NOTE Cela peut être réalisé en enregistrant séparément le temps de fin de l'émission la plus récente, en ajoutant une constante de délai Tx dépendant du mode de fonctionnement déclaré, puis en comparant ce temps qui en résulte avec le temps projeté de la prochaine émission pour déterminer si l'émission est autorisée dans le cadre des réglementations applicables. Voir l'Annexe V.

Alors que le gestionnaire de système peut configurer les divers dlmo.TsTemplates pour fournir un comportement en accord avec ces exigences de réglementation, il est de la responsabilité de l'appareil individuel d'assurer que les exigences sont respectées quelle que soit la configuration. L'attribut dlmo.CountryCode (9.1.15.6 et 9.4.2.19) fournit les informations de configuration nécessaires pour déterminer les aspects de réglementation en vigueur.

9.4.3.4 dlmo.Neighbor

9.4.3.4.1 Généralités

L'attribut dlmo.Neighbor est un ensemble OctetString indexé qui contient des informations relatives aux voisins immédiats en monodiffusion. Les entrées de dlmo.Neighbor sont référencées par des graphes et des liaisons.

Le gestionnaire de système insère, met à jour ou efface des entrées dlmo.Neighbor en envoyant au DMAP des entrées de voisins, avec un indice unique et (si sélectionné) un temps TAI de basculement. L'adresse 16 bits du voisin est utilisée comme indice.

Les voisins dans l'attribut de dlmo.Neighbor sont mis par le gestionnaire de système, pas par la DLE elle-même. La DLE construit de façon autonome une liste de voisins candidats dans l'attribut dlmo.Candidates, tel que décrit en 9.4.2.24. Cette liste est ensuite transmise au gestionnaire de système. Le gestionnaire de système considère la connectivité radio qui est rapportée dans dlmo.Candidates, mais peut également considérer d'autres critères tels que les contraintes de ressource, les performances historiques ou la topologie du sous-réseau D.

Lorsque la DLE traite une annonce au cours du processus de rattachement, la DLE ajoute automatiquement le routeur d'annonce comme entrée dans le tableau de dlmo.Neighbor, permettant ainsi la communication par l'intermédiaire du proxy. Cette entrée persiste après que la DLE a rejoint avec succès le sous-réseau D, à moins qu'elle ne soit supprimée ou mise à jour par le gestionnaire de système. Le gestionnaire de système infère l'existence et le contenu de cette entrée en se basant sur l'identité du proxy que la DLE utilise pour rejoindre le sous-réseau D. Voir 9.3.5.2.1.

La présente norme suit la convention de l'IETF RFC 4944, selon laquelle les adresses de 16-bits en monodiffusion sont limitées à la plage de 0x 0xxx xxxx xxxx xxxx. Voir 9.3.3.6.

L'information de diagnostic relative aux voisins peut être trouvée dans l'attribut dlmo.NeighborDiag (voir 9.4.3.9).

9.4.3.4.2 Sémantique

Le Tableau 168 spécifie les champs pour dlmo.Neighbor.

Tableau 168 – Champs de dlmo.Neighbor

Nom de champ	Codage de champ
* Index (DL16Address du voisin)	Type: ExtDLUint (utilisé comme un indice) Plage valide: 1..32 767
EUI64 (EUI64Address du voisin)	Type: EUI64Address
GroupCode1 (associer un code de groupe à un ensemble de voisins; utilisé par dlmo.Link)	Type: Unsigned8
GroupCode2 (associer un code de groupe à un ensemble de voisins; utilisé par dlmo.Link)	Type: Unsigned8
ClockSource (indique si le voisin est une source d'horloge de DL)	Type: Unsigned2 Valeurs nommées: 0: pas une source d'horloge 1: secondaire 2: préférentielle 3: réservée
ExtGrCnt (nombre total de graphes virtuellement étendus pour ce voisin)	Type: Unsigned2
DiagLevel (sélection de diagnostics de voisins à recueillir)	Type: BooleanArray2 Indices nommés: 0: recueillir des diagnostics de liaison 1: recueillir des diagnostics d'horloge
LinkBacklog (indique que les informations relatives à la liaison sont fournies pour faciliter l'effacement de l'accumulation dans la file d'attente de messages pour le voisin)	Type: Unsigned1; Valeurs nommées: 0: aucune information supplémentaire relative à la liaison 1: des informations supplémentaires relatives à la liaison sont fournies
Reserved (alignement d'octets)	Type: Unsigned1=0
ExtendGraph	Type: SEQUENCE OF Octet2 (SIZE ExtGrCnt) – paires d'octets Plage valide: Voir Tableau 170
LinkBacklogIndex (activer cette liaison pour effacer l'accumulation de file d'attente)	Type: ExtDLUint Plage valide: 1..127 Null (vide) et n'est pas émis si LinkBacklog=0 Indice de liaison si LinkBacklog=1
LinkBacklogDur (durée de l'activation de liaison)	Type: Unsigned8 Unités: Occurrences de liaison Null (vide) et n'est pas émis si LinkBacklog=0 1..255 si LinkBacklog=1
LinkBacklogActivate (critère d'activation de liaison)	Type: Unsigned8 Unités: DPDU en file d'attente Null (vide) et n'est pas émis si LinkBacklog=0 1..255 si LinkBacklog=1

Le Tableau 169 montre la structure de dlmo.Neighbor.

Tableau 169 – Structure de dlmo.Neighbor

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1–2	* Index							
8	EUI64							
1	GroupCode1							
1	GroupCode2							
1	ClockSource.		ExtGrCnt		DiagLevel		LinkBacklog	Reserved
2 × ExtGrCnt	$ExtendGraph_1$							
	...							
	$ExtendGraph_{ExtGrCnt}$							
0..1	LinkBacklogIndex							
0..1	LinkBacklogDur							
0..1	LinkBacklogActivate							

Les champs comprennent:

- EUI64. Afin de communiquer avec un voisin, le DSC a besoin de l'adresse EUI64 du voisin en question. Cette information est stockée dans la table Neighor. Elle est peuplée par le gestionnaire de système, à une seule exception près. Pendant les processus de rattachement et de mise en service, où l'entrée de voisin est créée automatiquement à partir de l'annonce, EUI64Address doit être acquise par la DLE par l'intermédiaire de la DPDU ACK/NAK selon la description en 9.1.10.1.
- GroupCode1, GroupCode2. Les liaisons avec un code de groupe concordant peuvent être utilisées pour s'adresser à ce voisin. La portée du code de groupe se situe au sein d'une seule DLE. Lorsqu'une liaison a un groupe NeighborType=2, la liaison indique un code de groupe au lieu d'un voisin, et la liaison s'applique à toute DPDU placée en file d'attente où le voisin a un code de groupe concordant. Cela permet à une seule et même liaison d'émission d'être partagée par un groupe de voisins. Une valeur de zéro indique qu'aucun code de groupe ne s'applique. La prise en charge des codes de groupe est obligatoire dans les routeurs, mais il s'agit d'une option de construction dans des appareils E/S. La présence ou l'absence de cette capacité est rapportée au gestionnaire de système lorsque la DLE rejoint le sous-réseau D par l'intermédiaire du champ dlmo.DeviceCapability.ConstructionOptions (voir 9.4.2.23).
- ClockSource. Si cet indicateur est > 0, le voisin doit être une source d'horloge de DL pour cette DLE. Une valeur de 1 indique une source d'horloge de DL secondaire, et une valeur de 2 indique une source d'horloge de DL préférentielle. Voir 9.1.9.2.3.
- ExtGrCnt et ExtendGraph. Voir 9.1.6.3 pour un débat relatif aux extensions de graphe. Voir Tableau 170 pour les champs dans chaque entrée d'extension de graphe dans ExtendGraph. Si l'adresse du voisin concorde avec l'adresse de destination codée dans le sous-en-tête DADDR, et le Graph_ID indiqué dans ExtendGraph concorde au chemin de DL de la DPDU, prolonger le graphe désigné jusqu'au voisin en question pour la DPDU en question. Pour chaque voisin, jusqu'à trois graphes de ce type peuvent être prolongés. La prise en charge d'ExtendGraph est une option de construction d'appareil, et la présence ou l'absence de cette capacité est rapportée au gestionnaire de système lorsque la DLE rejoint le sous-réseau D par l'intermédiaire du champ dlmo.DeviceCapability.ConstructionOptions (voir 9.4.2.23).

Pour chaque entrée de ExtendGraph, inclure:

– GraphID est l'identificateur de graphe de 12 bits qui est prolongé. Voir 9.4.3.6.

– LastHop. Si cet indicateur est 1, la DLE doit seulement utiliser des liaisons vers le voisin pour des DPDU applicables. Dans ce cas, la DLE doit traiter l'indice de graphe prolongé comme la seule alternative de transmission.

– PreferredBranch. Si cet indicateur est 1, il convient que la DLE traite cette extension de graphe comme la branche préférentielle pour les DPDU applicables. (Voir le champ PreferredBranch en 9.4.3.6.2).

Le Tableau 170 spécifie les champs pour chaque élément dans la séquence ExtendGraph.

Tableau 170 – Champs de ExtendGraph

Nom de champ	Codage de champ
Graph_ID (*Indice de l'attribut dlmo.Graph)	Type: Unsigned12
LastHop (indique si le voisin doit être le dernier saut)	Type: Boolean1
PreferredBranch (indique s'il faut traiter le voisin comme étant la branche préférentielle)	Type: Boolean1
Reserved (alignement d'octets)	Type: Unsigned2=0

Les graphes sont prolongés implicitement, indépendamment du fait que ExtendGraph soit indiqué ou pas. La caractéristique ExtendGraph explicite facultative vise à prendre en charge les optimisations qui cherchent à commander l'ID de graphe de ce saut final, et/ou le désigner comme étant le dernier saut ou la branche préférentielle.

– DiagLevel. Si cet indicateur a un nombre quelconque de bits différents de zéro, la DLE doit recueillir les diagnostics de liaison pour ce voisin dans l'attribut en lecture seule dlmo.NeighborDiag. Si Bit0=1, les diagnostics de résumés doivent être accumulés. Si Bit1=1, les diagnostics d'horloge doivent être accumulés. Voir 9.4.3.9;
– LinkBacklog, LinkBacklogIndex, LinkBacklogDur, et LinkBacklogActivate fournissent un indice à une liaison qui peut être activée par l'intermédiaire du sous-en-tête DAUX (type 2). Voir 9.3.5.4 pour une description générale relative à l'activation de liaison. La DLE, lorsqu'elle émet une DPDU vers un voisin, peut détecter une accumulation de DPDU applicables dans sa file d'attente de messages, et donc signaler au voisin d'activer la liaison Index=LinkBacklogIndex pour recevoir des DPDU pour les prochaines occurrences de LinkBacklogDur de la liaison (voir 9.3.5.4). LinkBacklogActivate indique la taille de l'accumulation de DPDU applicables dans la file d'attente, à l'exclusion de la DPDU en cours d'émission, qu'il convient de déclencher via l'envoi du DAUX d'activation de liaison, à moins que la liaison ne soit déjà activée.

Il convient que le gestionnaire de système, lorsqu'il configure LinkBacklogIndex, LinkBacklogDur et LinkBacklogActivate, configure également une liaison d'émission avec le même indice; de sorte qu'une liaison de réception sur le voisin a le même indice qu'une liaison d'émission correspondante dans la DLE qui est à l'origine du message d'activation de liaison, les deux étant activées pour le nombre d'occurrences indiquées par LinkBacklogDur. Il convient que les DPD placées en file d'attente à destination de ce voisin reçoivent une haute priorité pour cet indice de liaison au cours de la période définie par LinkBacklogDur. Lorsqu'elle compte les DPDU candidates dans la file d'attente de messages, il convient que la DLE rende compte de toutes les DPDU placées en file d'attente qui peuvent être adressées au voisin.

Il convient que l'initiateur de transaction (la DLE qui initie l'activation des liaisons inactives) active sa propre liaison inactive pour un nombre total d'occasions d'émission de LinkBacklogDur (occurrences de liaison). Il convient que le récepteur (la DLE sur laquelle la liaison de réception inactive a été activée) active sa liaison inactive pour des occasions de réception de LinkBacklogDur (occurrences de liaison). Il convient que les occasions d'émission et de réception soient comptées même si une liaison de plus haute priorité est réellement utilisée dans un intervalle de temps particulier. En général, il convient que la liaison inactive soit configurée avec une haute priorité.

Le Tableau 171 spécifie la structure de ExtGraph.

Tableau 171 – Structure de ExtGraph

Nombre d'octets	bits							
	7	6	5	4	3	2	1	0
1	Graph_ID (bits 11..4)							
1	Graph_ID (bits 3..0)				LastHop	PreferredBranch	Reserved = 0	

9.4.3.4.3 dlmo.NeighborDiagReset

L'attribut dlmo.NeighborDiagReset fournit l'accès en lecture/écriture au champ de l'attribut de dlmo.Neighbor qui est utilisé pour établir le niveau de diagnostic de voisin. Il est conceptuellement similaire à une vue SQL de dlmo.Neighbor. Il peut être utilisé pour lire et écrire un champ spécifique au sein de dlmo.Neighbor, mais il ne doit pas être utilisé pour ajouter ou supprimer des entrées.

Le Tableau 172 spécifie les champs au sein de l'OctetString dlmo.NeighborDiagReset.

Tableau 172 – Champs de dlmo.NeighborDiagReset

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice) Plage valide: 1..32 767
Reserved (alignement d'octets)	Unsigned4 = 0
DiagLevel (sélection de diagnostics de voisins à recueillir)	Type: BooleanArray3; Indices nommés: 0: recueillir des informations de résumé 1: recueillir des informations d'horloge
Reserved (alignement d'octets)	Type: Unsigned2 = 0

Le Tableau 173 montre la structure de dlmo.NeighborDiagReset.

Tableau 173– Structure de dlmo.NeighborDiagReset

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1..2	* Index							
1	Reserved = 0				DiagLevel		Reserved = 0	

Les champs sont exactement tels que spécifiés pour les champs de même nom dans l'attribut dlmo.Neighbor, et les valeurs instantanées de ces champs sont les mêmes que dans dlmo.Neighbor.

9.4.3.5 dlmo.Superframe

9.4.3.5.1 Généralités

dlmo.Superframe est un ensemble OctetString indexé qui contient des supertrames. La structure de supertrames permet au gestionnaire de système de relier un jeu de liaisons (dlmo.Link) à un programme répétitif d'intervalle de temps (dlmo.Superframe) de durée fixe. La supertrame désigne également un programme de saut de voie de ligne de base pour ces liaisons.

Le gestionnaire de système insère, met à jour ou efface des entrées de dlmo.Superframe en envoyant au DMAP une supertrame, accompagnée d'un indice unique et, si sélectionné, d'un temps TAI de basculement.

Chaque supertrame décrit un programme qui est spécifié en référence au temps TAI zéro. La dérivation de l'état d'intervalle de temps courant à partir de la définition d'une supertrame est décrite en 9.4.3.5.3.

Une supertrame peut être configurée avec des temporisations randomisées, destinées exclusivement aux liaisons qui émettent ou reçoivent des sollicitations et/ou des annonces. Sachant qu'un programme de supertrames randomisées n'est pas synchronisé par rapport à ses voisins, une telle supertrame ne doit pas être utilisée pour émettre une charge utile dans des DSDU.

9.4.3.5.2 Sémantique

Le Tableau 174 spécifie les champs pour dlmo.Superframe.

Tableau 174 – Champs de dlmo.Superframe

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice) Plage valide: 1..127
TsDur (durée des intervalles de temps au sein de la supertrame; les intervalles de temps sont réalignés avec une référence de temps TAI toutes les 250 ms)	Type: Unsigned16 Unités: 2^{-20} s
ChIndex (sélectionne le modèle de saut de voie dans dlmo.Ch)	Type: ExtDLUint
ChBirth (numéro d'intervalle de temps absolu auquel le modèle de saut de voie a nominalement commencé)	Type: Unsigned8
SfType (type de supertrame)	Type: Unsigned2; Valeurs nommées: 0: ligne de base 1: saut sur liaison seulement 2: randomiser la durée de saut lent 3: randomiser la période de supertrame
Priority (priorité pour sélectionner parmi plusieurs liaisons disponibles)	Type: Unsigned4
ChMapOv (indique s'il faut neutraliser la valeur par défaut de ChMap)	Type: Boolean1; Plage valide: false: ChMapOv non émis, donc prenant la valeur par défaut égale à 0x7FFF; true: ChMapOv émis et utilisé
IdleUsed	Type: Boolean1; Plage valide: false: IdleTimer non émis, donc prenant la valeur par défaut égale à -1; true: IdleTimer émis et utilisé
SfPeriod (nombre de base d'intervalles de temps dans chaque cycle de supertrame)	Type: Unsigned16 Plage valide: > 0
SfBirth (numéro d'intervalle de temps absolu auquel le premier cycle de supertrame a nominalement commencé)	Type: Unsigned16
ChRate (indique le nombre d'intervalles de temps par saut)	Type: ExtDLUint Plage valide: 0 = invalide 1 = saut de voie discrétisé > 1 = saut de voie lent [a]
ChMap (carte de voies utilisée pour éliminer certaines voies du modèle de saut de voie afin de limiter le spectre de fréquences utilisé)	Type: Unsigned16 ou null
IdleTimer (temporisateur inactivité/éveil pour supertrame)	Type: Integer32 ou null Voir texte
RndSlots (indique l'étendue de la randomisation, en nombre d'intervalles de temps)	Type: Unsigned8 ou null
a Dans certains régimes de réglementation, tels que spécifiés par l'intermédiaire de dlmo.CountryCode (9.4.2.19), la valeur maximale de ChRate est contrainte à être inférieure ou égale à (400 ms / TsDur).	

Le Tableau 175 montre la structure de dlmo.Superframe.

Tableau 175 – Structure de dlmo.Superframe

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	* Index							
2	TsDur							
1	ChIndex (plage 1..127)							
1	ChBirth							
1	SfType		Priority				ChMapOv	IdleUsed
2	SfPeriod							
2	SfBirth							
1..2	ChRate							
0 ou 2	ChMap							
0 ou 4	IdleTimer							
0 ou 1	RndSlots							

Les champs comprennent:

- durée d'intervalle de temps (dlmo.Superframe[ ].TsDur). Tous les intervalles de temps dans une supertrame ont la même durée, et une DLE ne doit pas traiter plusieurs durées d'intervalles de temps en même temps. Les intervalles de temps doivent être réalignés à l'horloge TAI toutes les 250 ms. Voir 9.1.9.1 pour des informations relatives à l'alignement d'intervalles de temps;
- identificateur de modèle de saut de voie (dlmo.Superframe[ ].ChIndex). Sélectionner un modèle disponible dans dlmo.Ch (voir 9.4.3.2.2);
- anniversaire de saut de voie (dlmo.Superframe[ ].ChBirth). Spécifie le point de départ du modèle de saut de voie, sous la forme d'un décalage d'intervalle de temps par rapport à TAI=0. Le calcul de la position courante dans la séquence de saut est décrit en 9.4.3.5.3;
- le type de supertrame (dlmo.Superframe[ ].SfType) indique le type de supertrame. Le traitement de chaque type de supertrame est décrit en 9.4.3.5.3;
- la priorité de supertrame (dlmo.Superframe[ ].Priority) indique la priorité de la supertrame. Une plus grande valeur de Priority donnera à ces liaisons de supertrame une plus haute priorité. Voir 9.1.8.5 (pseudocode) pour des informations complémentaires relatives aux niveaux de priorité;
- valeur par défaut de neutralisation de carte de voies (dlmo.Superframe[ ].ChMapOv). Indique de neutraliser, oui ou non, la valeur par défaut de ChMap de 0x7FFF. Si ChMapOv=1, changer la valeur par défaut basée sur ChMap;
- la période de supertrame (dlmo.Superframe[ ].SfPeriod) indique le nombre des intervalles de temps dans chaque cycle de base de la supertrame. Avec des intervalles de temps de 10 ms, une période de supertrame de 16-bits prend en charge des supertrames d'une longueur pouvant atteindre 10 minutes;
- l'anniversaire de supertrame (dlmo.Superframe[ ].SfBirth) indique le point de départ nominal pour la "première" supertrame qui a commencé son premier cycle peu après TAI=0. Il fournit le décalage d'intervalle de temps par rapport à l'intervalle de temps absolu 0, qui s'est produit au temps nominal TAI=0. SfBirth doit être égal à ChBirth lorsque fType= 1. Voir 9.4.3.5.3;
- la fréquence de saut de voie (dlmo.Superframe[ ].ChRate) indique le nombre des intervalles de temps par saut. Une fréquence de saut de voie 1 indique un saut de voie discrétisé; une fréquence de saut de voie supérieure à 1 indique un certain degré de saut de voie lent. ChRate doit être = 1 lorsque SfType= 1;
- la carte de voies (dlmo.Superframe[ ].ChMap) est utilisée pour éliminer certaines voies du modèle de saut de voie, ce qui raccourcit le modèle de saut de voie en utilisation.

Les positions de bits 0..15 correspondent aux voies 0..15, où un bit de 0 en n'importe quelle position indique que la voie correspondante ne doit pas être utilisée par la supertrame, avec la séquence de saut de voie raccourcie en conséquence. Cet attribut ne doit pas être émis et prend par défaut la valeur 0x7FFF si ChMapOv=0 (à savoir: la voie facultative 15 est exclue par défaut);

- le temporisateur de supertrame inactive (dlmo.Superframe[ ].IdleUsed, dlmo.Superframe[ ].IdleTimer) fournit au gestionnaire de système le contrôle sur l'instant où une supertrame est activée ou inactive, où une supertrame inactive traite toutes ses liaisons comme étant inactives. Le gestionnaire de système peut positionner IdleTimer par l'intermédiaire de l'attribut dlmo.Superframe ou de l'attribut dlmo.SuperframeIdle. IdleTimer n'est pas émis et prend par défaut une valeur de -1 si IdleUsed=0;
- lorsque IdleTimer est mis à un nombre positif, la supertrame doit être active et IdleTimer doit être décrémenté par la DLE toutes les secondes TAI jusqu'à ce qu'il atteigne une valeur de 0. Lorsque la valeur de IdleTimer est 0, la supertrame doit être inactive;
- lorsque IdleTimer est mis à un nombre négatif qui est inférieur à -1, la supertrame doit être inactive et IdleTimer doit être incrémenté par la DLE toutes les secondes TAI jusqu'à ce qu'il atteigne une valeur de -1. Lorsque la valeur de IdleTimer est -1, la supertrame doit être active.

La randomisation des supertrames est commandée par dlmo.Superframe[ ].RndSlots. RndSlots est sans signification et ne doit pas être émise si dlmo.Superframe[ ].SfType<2. Les supertrames randomisées visent exclusivement à permettre des processus randomisés de découverte de sous-réseaux D. Par exemple, une DLE dans l'état de mise en service peut être configurée avec une supertrame randomisée qui est utilisée pour rechercher des annonces issues d'un sous-réseau D cible. Une telle randomisation peut être utilisée pour garantir que le cycle de sommeil du balayage n'est pas synchronisé avec le programme d'annonce du sous-réseau D cible, assurant ainsi qu'une annonce est finalement reçue. Il convient que seules les liaisons de réception, les annonces dédiées et les sollicitations soient configurées pour être utilisées avec une supertrame où RndSlots>0. Toutes les autres liaisons pour de telles supertrames randomisées doivent être traitées comme étant inactives.

– lorsque SfType=2, un nombre randomisé d'intervalles de temps dans la plage de 0 à RndSlots doit être ajouté à la fin de chaque cycle de supertrame;
– lorsque SfType=3, un nombre randomisé d'intervalles de temps dans la plage de 0 à RndSlots doit être ajouté à la longueur de chaque période de saut de voie lent. Si le saut de voie discrétisé est utilisé, chaque saut doit être traité comme une période de saut de voie lent prolongée par un nombre randomisé d'intervalles de temps.

9.4.3.5.3 Etat courant des intervalles de temps de supertrame

L'état courant des intervalles de temps de supertrame doit être dérivé des champs de supertrame tels que décrits dans le présent document. Cette description est censée ne pas contraindre les mises en œuvre, mais seulement les résultats. Toutes les caractéristiques décrites dans le présent document doivent être prises en charge par toutes les DLE qui sont conformes à la présente norme, à moins d'être spécifiquement indiquées comme étant une option de construction.

Ces dérivations de l'état courant d'intervalle de temps utilisent des champs dans dlmo.Superframe [ ], qui sont basés sur l'état au temps TAI zéro ou peu après. Les mises en œuvre peuvent raisonnablement utiliser ces formules pour établir un état de début lorsque la supertrame est initialisée, et ensuite mettre à jour cet état en allant vers l'avant par incréments. Cependant, l'approche de la mise à jour par incréments ne fonctionnera pas lorsqu'il y a un changement dans un champ quelconque utilisé dans le calcul de base, ou dans des champs dans d'autres attributs (dlmo.Ch [ ] en général et dlmo.Link [ ] pour SfType=1) qui sont utilisés dans le calcul de base. Lorsque ces champs sont modifiés, l'état courant a besoin d'être dérivé à nouveau.

NOTE La notion d'un intervalle de temps absolu est utilisée ici comme une variable pour calculer l'état courant d'intervalle de temps. D'autres normes utilisent un intervalle de temps absolu pour identifier l'intervalle de temps. La présente norme utilise un intervalle de temps absolu seulement comme une valeur intermédiaire dans un calcul; il n'est référencé nulle part ailleurs dans la présente norme.

Chaque période de quart de seconde TAI a un nombre fixe d'intervalles de temps qui peuvent être décrits par la formule:

SlotsPer0_25s = floor((2^{18} s) / TsDur)

où floor(x) est le plus grand nombre entier qui n'est pas supérieur à x.

Un nombre d'intervalle de temps absolu (SlotNumAbs) peut être dérivé du temps de départ programmé du courant intervalle de temps (ScheduledTaiTime), simplifié par le fait que ScheduledTaiTime doit être réaligné au temps TAI tous les quarts de seconde. Le décalage d'intervalle de temps par rapport à TAI=0 peut être dérivé en conséquence:

Tai0_25sStart = floor(ScheduledTaiTime / (0,25 s)) × (0,25 s)

SlotWithin0_25s = (ScheduledTaiTime – Tai0_25sStart) / TsDur

SlotNumAbs = ((Tai0_25sStart / (0,25 s)) × SlotsPer0_25s) + SlotWithin0_25s

SfType=0 désigne le cas de ligne de base, où tous les cycles de supertrame incluent un nombre fixe d'intervalles de temps et le programme de saut de voie a également un cycle fixe.

La superframe fournit une période de supertrame fixe (SfPeriod) qui est le nombre d'intervalles de temps dans chaque cycle de supertrame. Elle fournit également un nombre d'intervalles de temps absolu de (SfBirth), suivant TAI=0, comme temps de départ de référence pour la première supertrame. Le décalage de supertrame du courant intervalle de temps est:

SfOffset = (SlotNumAbs – SfBirth) mod SfPeriod

où (x mod y) est égal à (x – (floor(x / y) × y)) pour y positif.

Le modèle de saut de voie commence nominalement au nombre d'intervalles de temps absolu ChBirth. Le nombre d'éléments dans le programme de saut de voie (ChCount) peut être déterminé à partir de la taille du modèle de saut de voie sélectionné par ChIndex, et en soustrayant le nombre d'entrées qui sont enlevées de la séquence tel qu'indiqué par ChMap.

Le nombre d'intervalles de temps dans un cycle du modèle de saut de voie dépend de la question de savoir si le saut de voie lent ou le saut de voie discrétisé est utilisé, tel qu'indiqué par ChRate.

ChCycle = ChCount × ChRate

Le décalage d'intervalle de temps dans ce saut de voie est:

ChOffset = (SlotNumAbs – ChBirth) mod ChCycle

SfType=1 désigne une variante de saut de voie discrétisé, dans laquelle le saut de voie ne se produit que lorsqu'il y a une liaison.

La prise en charge d'appareil pour SfType=1 est une option de construction, telle que rapportée au gestionnaire de système par l'intermédiaire de l'attribut dlmo.DeviceCapability.ConstructionOptions (bit 5). SfType=1 ne doit pas être combiné avec le saut de voie lent, à savoir ChRate=1.

Le décalage de supertrame est tel que décrit dans SfType=0.

Le nombre de sauts de voie par cycle de supertrame (ChPerSuperframe) est déterminé en comptant le nombre des intervalles de temps dans chaque cycle de supertrame qui sont

référencés par au moins une liaison. Il ne s'agit pas d'un simple compte de liaisons, parce que certaines liaisons peuvent se référer à plusieurs intervalles de temps, et certains intervalles de temps peuvent être référencés par plusieurs liaisons.

Sachant que le nombre de sauts de voie est un multiple du nombre de supertrames, la prochaine étape est de calculer le nombre de cycles de supertrame qui ont été accomplis depuis TAI=0.

CurrentSfStartAbs = (SlotNumAbs – SfOffset)

SfCyclesSinceBirth = (CurrentSfStartAbs – SfBirth) / SfPeriod

Pour SfType=1, les cycles de cycle de supertrame et de saut de voie doivent débuter en même temps (SfBirth=ChBirth). Le décalage de voie au début de la supertrame courante est une fonction du nombre de voies mises en correspondance (voir 9.4.2.12). Il est déterminé par la formule:

$$\text{ChOffset}_{\text{StartSf}} = (\text{SfCyclesSinceBirth} \times \text{ChPerSuperframe}) \bmod \text{NumMappedChannels}$$

où NumMappedChannels = $\sum \text{dlmo.Superframe}[\,].\text{ChMap}_{k}$ pour la supertrame spécifique.

En partant de $\text{ChOffset}_{\text{StartSf}}$, le décalage de saut de voie courant peut être déterminé en parcourant la supertrame du début du cycle de supertrame jusqu'à l'intervalle de temps courant. Le décalage de saut de voie au sein de chaque cycle de supertrame ne peut pas être réduit à une simple formule linéaire simple, car les liaisons ne sont pas nécessairement uniformément étalées sur le cycle.

SfType=2 prolonge chaque intervalle de saut de voie lent par un nombre randomisé d'intervalles de temps dans la plage de 0 à dlmo.Superframe[ ].RndSlots. Le point de départ initial de la séquence de saut de voie peut également être randomisé lorsque SfType=2, et la temporisation de supertrame doit être telle que décrite pour SfType=0.

SfType=3 prolonge chaque cycle de supertrame par un nombre randomisé d'intervalles de temps dans la plage de 0 à dlmo.Superframe[ ].RndSlots. Il convient que le point de départ initial du cycle de supertrame soit également randomisé lorsque SfType=3, et la séquence de saut de voie doit être telle que décrite pour SfType=0.

9.4.3.5.4 Saut de voie lent

Le saut de voie lent est défini comme étant une supertrame où dlmo.Superframe[ ].ChRate>1, ce qui conduit à un ensemble de liaisons contiguës sur la même voie. La fréquence de saut de voie, ChRate, peut être configurée comme étant égale à la période de supertrame, SfPeriod, auquel cas chaque période de saut de voie peut raisonnablement être configurée comme étant une plage de liaisons utilisant dlmo.Link[ ].Schedule=2.

Il convient que le côté réception d'une configuration de saut de voie lent utilise le modèle de récepteur de transaction par défaut pour le balayage conformément au Tableau 167, ou un modèle similaire. Il convient que ce modèle, lorsqu'il est appliqué à des intervalles de temps contigus sur la même voie, actionne son récepteur sans interruption, et il peut exécuter une transaction jusqu'à son parachèvement même si cette transaction traverse la frontière d'un intervalle de temps. Une liaison de réception utilisant ce modèle peut se répéter fréquemment ou sans interruption dans une supertrame, habituellement avec une priorité basse pour donner la préséance aux opérations de saut de voie discrétisé.

Un ensemble de liaisons de réception de saut de voie lent sur une voie donnée, utilisant le modèle de récepteur de transaction par défaut pour le balayage, peut être temporairement interrompu par des transactions de plus haute priorité, par exemple, comme représenté graphiquement à la Figure 66. En l'absence de telles transactions, il convient que le récepteur fonctionne sans interruption à travers les frontières d'intervalle de temps dans de telles configurations.

Il convient que le côté émission d'une configuration de saut de voie lent utilise un modèle approprié pour une transaction d'émission sur le sous-réseau D, tel que le modèle d'initiateur de transaction par défaut conformément au Tableau 166. Il convient que la configuration de liaison d'émission soit configurée pour rendre compte de la dérive d'horloge. Par exemple, dans un sous-réseau D avec des intervalles de temps de 10 ms, un appareil particulier dans une configuration de saut de voie lent pourrait être censé subir une dérive d'horloge pouvant atteindre 15 ms entre les mises à jour d'horloge. Dans cet exemple, il convient de ne pas indiquer les deux premiers et deux derniers intervalles de temps dans chaque période de saut de voie lent comme étant des liaisons d'émission, incorporant ainsi des temps de garde de 20 ms dans la configuration.

Le côté émission dans une configuration de saut de voie lent peut désigner des intervalles de temps spécifiques pour l'émission, ou en variante, il peut désigner une plage d'intervalles de temps. Lorsqu'une plage d'intervalle de temps est indiquée, il convient que la fréquence de saut de voie concorde avec la période de supertrame, et il convient que la liaison d'émission soit désignée comme étant une plage (dlmo.Link[].Schedule=2), représentée graphiquement à la Figure 72. Dans cette configuration, il convient que la DLE traite chaque plage comme une seule occasion d'émission et sélectionne la liaison d'émission au sein de la plage sur une base randomisée.

9.4.3.5.5 dlmo.SuperframeIdle

dlmo.SuperframeIdle fournit l'accès en lecture/écriture aux seuls champs de dlmo.Superframe qui sont relatifs à la supertrame inactive. Il est conceptuellement similaire à une vue SQL de dlmo.Superframe. Il peut être utilisé pour lire et écrire des champs spécifiques dans des OctetStrings indexés de supertrame, mais il ne peut pas être utilisé pour ajouter ou supprimer des entrées.

Le Tableau 176 spécifie les champs au sein de l'OctetString dlmo.SuperframeIdle.

Tableau 176 – Champs de dlmo.SuperframeIdle

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice)
Reserved (alignement d'octets)	Type: Unsigned7=0
IdleUsed (indique si la supertrame est inactive lorsque la valeur de IdleTimer est zéro)	Type: Boolean1
IdleTimer (temporisateur inactivité/éveil pour supertrame)	Type: Integer32 ou null

Le Tableau 177 montre la structure de dlmo.SuperframeIdle.

Tableau 177 – Structure de dlmo.SuperframeIdle

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	* Index							
1	Reserved = 0							IdleUsed
0 ou 4	IdleTimer							

Les champs sont exactement tels que spécifiés pour les champs de même nom dans l'attribut dlmo.Superframe, et les valeurs instantanées de ces champs sont identiques à celles contenues dans dlmo.Superframe.

9.4.3.6 dlmo.Graph

9.4.3.6.1 Généralités

dlmo.Graph est un ensemble OctetString indexé qui contient des graphes. Sur une DLE particulière, un graphe est simplement une liste de voisins qui peuvent être utilisés pour le prochain saut lorsqu'un graphe est spécifié dans le sous-en-tête DROUT.

Le gestionnaire de système insère, met à jour ou efface des entrées de dlmo.Graph en envoyant au DMAP un graphe, accompagné d'un indice unique et (si sélectionné) d'un temps TAI de basculement.

Graph ID = 0 ne doit pas être utilisé, car cette valeur est réservée comme un indicateur dans le sous-en-tête DROUT, tel que décrit en 9.3.3.6.

Les ID de graphe sont limités à une plage de valeurs de 12 bits, avec une plage de $1..2^{12}$. Dans le routage de source, ces ID de graphe de 12 bits sont codés sous la forme 0x 1010 gggg gggg gggg.

Comme décrit en 9.1.6.3, des voisins immédiats sont implicitement traités comme étant couverts par un graphe, indépendamment du fait que le voisin soit énuméré dans la structure de graphe ou non. Lorsque l'adresse de destination de la DPDU est dans une table de voisins d'une DLE, le graphe est automatiquement étendu pour couvrir le voisin en question. Ainsi, même si la structure de dlmo.Graph ne peut prendre en charge qu'un petit nombre de voisins, le graphe peut en traiter beaucoup plus par l'intermédiaire de ces extensions de graphe.

Il convient que les ID de graphe soient uniques au sein de la portée d'un sous-réseau D. Cependant, des ID de graphe en doublons ne sont pas interdits. Lorsque deux graphes avec le même ID de graphe se rencontrent dans une seule et même DLE, ils s'unissent pour devenir un seul graphe.

9.4.3.6.2 Sémantique

Le Tableau 178 spécifie les champs pour dlmo.Graph.

Tableau 178 – dlmo.Graph

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice) Plage valide: 1..4095
PreferredBranch (indique s'il faut traiter le premier voisin énuméré comme étant la branche préférentielle)	Type: Boolean1
NeighborCount	Type: Unsigned3 Plage valide: 0..4
Queue (alloue des tampons dans la file d'attente de messages pour les DPDU qui sont transmises à l'aide de ce graphe)	Type: Unsigned4
MaxLifetime	Type: ExtDLUint
Neighbors (indice dans dlmo.Neighbor; habituellement deux ou trois voisins dans la liste pour la diversité de prochain saut)	Type: SEQUENCE OF ExtDLUint (SIZE(NeighborCount))

Le Tableau 179 montre la structure de dlmo.Graph dans le cas où chaque ExtDLUint exigerait un octet.

Tableau 179 – Structure de dlmo.Graph

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1..2	* Index							
1	PreferredBranch	NeighborCount			Queue			
1..2	MaxLifetime							
1..2	$Neighbors_0$							
1..2	$Neighbors_1$							
...	...							
1..2	NeighborsNeighborCount-1							

Les éléments comprennent:

- dlmo.Graph[ ].PreferredBranch. Si cet indicateur est 1, traiter le premier voisin énuméré comme étant la branche préférentielle, et il convient que la DLE attende jusqu'à ce qu'il y ait une occasion pour essayer au moins une émission le long de la branche préférentielle avant de tenter d'autres solutions de remplacement. Si cet indicateur est 0, ne pas accorder un tel traitement préférentiel au premier voisin énuméré.
- dlmo.Queue permet au gestionnaire de système de réserver jusqu'à 15 tampons de la file d'attente de messages pour les DPDU qui suivent le graphe.
- dlmo.Graph[ ].MaxLifetime (unités ¼ s). Si cet élément est différent de zéro, la valeur de dlmo.MaxLifetime doit être neutralisée pour toutes les DPDU transmises en suivant ce graphe.
- Liste de voisins (communément, deux voisins pour la diversité de liaison de prochain saut).

9.4.3.7 dlmo.Link

9.4.3.7.1 Généralités

dlmo.Link est un ensemble OctetString indexé qui contient des liaisons. Chaque liaison se réfère à exactement une entrée de dlmo.Superframe.

Le gestionnaire de système insère, met à jour ou efface des liaisons en envoyant au DMAP une liaison, avec un indice unique et (si sélectionné) d'un temps TAI de basculement.

Quand un voisin est référencé dans une liaison d'émission, les DPDU qui se réfèrent à ce voisin sont considérées comme des candidats pour la liaison. Les DPDU qui se réfèrent au voisin via la première entrée dans le sous-en-tête DROUT, directement par l'adresse ou indirectement par l'intermédiaire d'un graphe, doivent être considérées comme étant des candidats pour la liaison. En outre, les DPDU qui désignent le voisin comme l'adresse de destination dans le sous-en-tête DADDR doivent également être considérées comme étant des candidats pour la liaison. L'exception est que certaines liaisons sont désignées exclusivement pour les DPDU suivant des graphes spécifiques, et seules les DPDU avec des GraphID concordants doivent être considérées comme étant des candidats pour de telles liaisons. Si plusieurs DPDU sur la file d'attente de messages sont des candidats pour une liaison donnée, la DPDU est sélectionnée par priorité comme décrit en 9.1.8.5.

9.4.3.7.2 Sémantique

Le Tableau 180 spécifie les champs pour dlmo.Link.

Tableau 180 – Champs de dlmo.Link

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice)
SuperframeIndex (référence à une entrée de dlmo.Superframe)	Type: ExtDLUint
Type (voir Tableau 182 et le texte associé)	Type: Unsigned8
Template1 (référence de dlmo.TsTemplate au modèle principal)	Type: ExtDLUint
Template2 (référence de dlmo.TsTemplate au modèle secondaire)	Type: ExtDLUint ou null
NeighborType	Type: Unsigned2 Plage valide: 0..2
GraphType	Type: Unsigned2 Plage valide: 0..2
SchedType	Type: Unsigned2
ChType	Type: Unsigned1
PriorityType	Type: Unsigned1
Neighbor (identifier le voisin ou le groupe)	Type: ExtDLUint ou null
GraphID (identité de 12 bits du graphe avec accès exclusif ou hiérarchisé par ordre de priorité à la liaison)	Type: ExtDLUint ou null
Schedule (programme de liaisons; voir Tableau 184)	Type: Voir Tableau 184
ChOffset (sélectionner la voie en fonction du décalage par rapport au modèle de saut de supertrames)	Type: Unsigned8 ou null
Priority (priorité de liaison)	Type: Unsigned8 ou null Plage valide: 0 x 0000 xxxx

Le Tableau 181 montre la structure de dlmo.Link. Les champs ExtDLUint y sont montrés comme étant des octets seuls.

Tableau 181 – Structure de dlmo.Link

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1..2	* Index							
1	SuperframeIndex (plage 1..127)							
1	Type							
1	Template1 (plage 1..127)							
0 ou 1	Template2 (plage 1..127)							
1	NeighborType		GraphType		SchedType		ChType	PriorityType
0..2	Neighbor							
0..2	GraphID							
1..4	Schedule (voir Tableau 184)							
0 ou 1	ChOffset							
0 ou 1	Priority							

Les éléments comprennent:

- dlmo.SuperframeIndex. Indique la référence de supertrame pour la liaison.
- dlmo.Link[ ].Type. Indique comment la liaison est configurée pour l'émission et/ou la réception, et/ou la découverte de voisins. Voir Tableau 182.
- dlmo.Link[ ].Template1. Modèle d'intervalle de temps principal. Voir 9.4.3.3 pour un débat relatif aux modèles.
- dlmo.Link[ ].Template2. Modèle d'intervalle de temps secondaire, pour des intervalles de temps d'émission/réception (T/R) uniquement, en combinaison avec d'autres sélections de liaisons. Utiliser Template2 comme modèle de récepteur de transaction, s'il n'y a aucune DPDU dans la file d'attente pour le modèle principal. Template2 n'est émis et n'a de sens que pour les liaisons TRx, c'est-à-dire les liaisons où les bits 6 et 7 Link[ ].Type ont tous les deux une valeur de 1. Voir 9.1.8.5.
- dlmo.Link[ ].NeighborType et dlmo.Link[ ].Neighbor. Un voisin est désigné pour des liaisons d'émission, et peut être désigné pour des liaisons de réception en duodiffusion/diffusion N. Voir 9.4.3.4 pour un débat relatif aux voisins. Lorsqu'un voisin est désigné dans une liaison, il peut référencer soit un indice dlmo.Neighbor, soit un groupe (dlmo.Neighbor[ ].GroupCode).
  - Si dlmo.Link[ ].NeighborType=0, l'attribut dlmo.Link[ ].Neighbor est null (vide) et n'est pas émis.
  - Si dlmo.Link[ ].NeighborType=1, l'attribut dlmo.Link[ ].Neighbor désigne un indice dans l'attribut dlmo.Neighbor.
  - Si dlmo.Link[ ].NeighborType=2, l'attribut dlmo.Link[ ].Neighbor désigne un groupe.
- dlmo.Link[ ].GraphType, dlmo.Link[ ].GraphID. Les DPDU suivant un graphe particulier peuvent recevoir un accès exclusif ou prioritaire à certaines liaisons d'émission. Ces champs, lorsqu'ils ont été configurés comme tels, limitent l'accès des liaisons à certains graphes, reliant donc la liaison à un flux particulier de communication à travers le sous-réseau D. Lorsque GraphType est laissé vide, la liaison d'émission est disponible à toute DPDU qui est acheminée par l'intermédiaire du voisin désigné de la liaison. Lorsque GraphType est utilisé, un graphe particulier reçoit un accès exclusif ou prioritaire à la liaison.
  - Si GraphType=0, l'élément GraphID est null et n'est pas émis.
  - Si GraphType=1, la liaison est désignée pour un usage exclusif par un graphe particulier. L'accès à la liaison doit être limité aux DPDU suivant le graphe en question.
  - Si GraphType=2, les DPDU avec un ID de graphe concordant reçoivent un accès prioritaire. Il convient que les DPDU suivant le graphe en question reçoivent une priorité sur les autres DPDU lorsque la liaison est utilisée.
- dlmo.Link[ ].SchedType, dlmo.Link[ ].Schedule. Indique la (les) position(s) d'intervalle de temps de la liaison au sein de chaque cycle de supertrame. Le programme peut désigner un décalage fixe, un ensemble répétitif avec un intervalle fixe, une plage, ou une carte de bits, comme suit:

  0: décalage uniquement;

  1: décalage et intervalle;

  2: plage;

  3: carte de bits;
- dlmo.Link[ ].ChType, dlmo.Link[ ].ChOffset. Indique comment la voie de la liaison est sélectionnée.
  - Si dlmo.Link[ ].ChType=0, l'attribut dlmo.Link[ ].ChOffset est null et n'est pas émis. Suivre simplement le modèle de saut de voie de ligne de base de la trame.
  - Si dlmo.Link[ ].ChType=1, ajouter dlmo.Link[ ].ChOffset au courant dlmo.Superframe[ ].ChOffset, modulo de la taille effective du modèle de saut de voie (après avoir rendu compte des voies exclues) des supertrames, et sélectionner la voie en conséquence.

- dlmo.Link[ ].PriorityType, dlmo.Link[ ].Priority. Indique comment la priorité des liaisons est établie. Les priorités de liaison sont décrites fonctionnellement en 9.1.8.5.
  - Si dlmo.Link[ ].PriorityType=false, l'attribut dlmo.Link[ ].Priority est null et n'est pas émis. Pour les liaisons d'émission, utiliser la priorité dlmo.LinkPriorityXmit. Pour les liaisons de réception, utiliser la priorité dlmo.LinkPriorityRcv.
  - Si dlmo.Link[ ].PriorityType=true, utiliser l'attribut dlmo.Link[ ].Priority. Si la liaison est à la fois une liaison d'émission et une liaison de réception, utiliser dlmo.Link[ ].Priority pour l'émission et dlmo.LinkPriorityRcv pour la réception.

Le Tableau 182 montre la structure du champ dlmo.Link[ ].Type.

Tableau 182 – Structure de dlmo.Link[ ].Type

Octet	Bits							
	7	6	5	4	3	2	1	0
1	Transmit	Receive	Exponential backoff	Idle	Discovery: Valeurs nommées: 0: aucune 1: annonce 2: réservé 3: sollicitation		JoinResponse: liaison utilisée pour envoyer une réponse de rattachement à un voisin	SelectiveAllowed

Les types de liaison sont définis comme suit:

- bit 7: Transmit (T=true). Indique l'émission de charge utile;
- bit 6: Receive (R=true);
- bit 5: Exponential backoff (B=true). Indique s'il convient que l'initiateur de la transaction applique les règles de repli exponentiel pour les répétitions de tentative (partagé), versus l'utilisation de l'intervalle de temps sans égard pour le repli exponentiel (non partagé). Voir 9.1.8.2;
- bit 4: Idle (I=true). Lorsque la valeur est "true", la liaison doit être inactive à moins qu'elle ne soit temporairement activée conjointement avec l'émission d'un sous-en-tête DAUX d'activation; voir 9.3.5.4. Lorsque la valeur est "false", l'activation de liaison ne s'applique pas à la liaison. Un intervalle de temps désigné comme étant inactif peut inclure une référence de voisin. Même sans référence de voisin, il a besoin de Booleans d'émission et de réception positionnés selon les besoins pour se référer au modèle d'intervalle de temps dont il aura besoin lorsqu'il sera activé;
- bits 3..2: Discovery (DD). Configuration d'annonce ou de sollicitation. DD='01' spécifie une seule annonce émise avec la temporisation telle que définie dans le modèle d'intervalle de temps. Si DD='01', il convient que la liaison soit utilisée pour émettre une annonce ou une sollicitation, même s'il n'y a pas de charge utile d'ordre supérieur qui a besoin d'être envoyée. DD='11' distingue une sollicitation issue d'une annonce. DD='10' doit être ignoré.

NOTE DD='10' était utilisé par ISA 100.11a pour une autre forme d'annonce, et n'est ainsi pas disponible pour une affectation future. Son utilisation n'est pas prise en charge par la présente norme;

- bit 1: JoinResponse (J=true). Lorsqu'un routeur est un proxy pour une demande de rattachement pour un voisin immédiat, il recevra finalement un message issu du gestionnaire de système à transmettre à la DLE qui se rattache. Le routeur transmet ces messages en utilisant les liaisons qui sont marquées avec JoinResponse=true. Une réponse de rattachement dans la file d'attente de messages peut être identifiée par un en-tête de DPDU avec une adresse de destination EUI64Address. Un intervalle de temps désigné comme prenant en charge une réponse de rattachement peut inclure une référence de voisin, permettant ainsi que la liaison soit également utilisée pour le trafic de sous-réseau D régulier. Même sans référence de voisin, il a besoin que le boolean d'émission soit mis;

- bit 0: SelectiveAllowed (S=true). La DLE peut, sans instruction du gestionnaire de système, traiter de façon autonome et sélective les liaisons d'émission comme étant inactives si elles se produisent sur certaines voies radio avec des antécédents de connectivité médiocre. Il s'agit d'une forme d'utilisation de voie sélective, qui est décrite en 9.1.7.2.4. La DLE peut sauter les liaisons se produisant sur des voies qu'elle juge de façon autonome comme étant problématiques en raison d'antécédents de connectivité médiocre, potentiellement avec la granularité d'une voie spécifique utilisée pour la communication avec un voisin spécifique. De cette manière, la DLE peut économiser l'énergie et réduire les interférences inutiles avec d'autres utilisateurs du spectre. Cependant, la DLE ne doit pas sauter les liaisons de cette façon lorsque la liaison est marquée avec SelectiveAllowed=0.

Le Tableau 183 montre des combinaisons autorisées de bits dans la représentation de dlmo.Link[ ].Type. Les bits montrés comme étant X indiquent qu'une valeur "false" (0) ou "true" (1) est autorisée. Par exemple, plusieurs combinaisons impliquant Transmit=true présentent un X pour le repli exponentiel ("Exponential backoff"), indiquant que de telles liaisons pourraient être configurées comme étant partagées ou non.

Tableau 183 – Combinaisons autorisées de dlmo.Link[ ].Type

Combinaison TRBI DDJS	Description
1X10 001X	Réponse de rattachement
10XX 000X	Emission, pas d'annonce
11XX 000X	Emission/réception, pas d'annonce
10X0 010X	Emission, annonce
0000 0100	Annonce dédiée
0000 1100	Sollicitation
010X 0000	Réception

Une combinaison de liaisons d'émission/réception est essentiellement une représentation compressée d'une liaison d'émission et d'une liaison de réception distincte. Si au moins une DPDU sortante dans la file d'attente concorde avec la liaison, elle doit être traitée comme étant une liaison d'émission en utilisant le modèle d'intervalle de temps principal. Autrement, elle doit être traitée comme étant une liaison de réception en utilisant le modèle d'intervalle de temps secondaire, avec la priorité dlmo.LinkPriorityRcv.

Des modèles de saut de voie, des périodes de supertrame et des intervalles de liaison peuvent être configurés afin que seules certaines voies radio dans la séquence de saut de voie soient réellement utilisées. Par exemple, si une liaison se répète tous les 20 intervalles de temps, et le modèle de saut de voie inclut 15 voies, alors seules trois voies seront réellement utilisées par la liaison. Pour éviter de tels scénarios, l'intervalle de liaison et le modèle de saut de voie peuvent être configurés de façon à disposer d'un plus grand commun diviseur (PGCD) égal à un (1).

Le Tableau 184 spécifie les différents types de programmes pour une liaison donnée. Les liaisons dans une supertrame sont indexées en fonction du décalage d'intervalle de temps dans chaque cycle, le premier intervalle de temps dans chaque cycle ayant un décalage zéro.

Tableau 184 – Valeurs pour dlmo.Link[ ].Schedule

Valeur pour dlmo.Link[ ].Schedule	Codage d'élément	Description
0 = décalage uniquement	ExtDLUint (décalage)	La liaison se produit une fois à une position d'intervalle de temps fixe dans chaque cycle de supertrame
1 = décalage et intervalle	ExtDLUint, ExtDLUint (décalage, intervalle)	La liaison se produit plusieurs fois dans chaque cycle, d'abord au décalage donné puis en se répétant à un certain intervalle jusqu'à la fin du cycle. Les valeurs sont spécifiées en nombre d'intervalles de temps
2 = plage	ExtDLUint, ExtDLUint (premier, dernier)	La liaison se produit à une plage d'intervalles de temps dans chaque cycle de supertrame, en commençant par le décalage donné par la première valeur et en continuant jusqu'au décalage donné par la seconde valeur
3 = carte de bits	BooleanArray32	La carte de bits couvre les 32 premiers intervalles de temps dans chaque cycle de supertrame. La liaison se produit dans des intervalles de temps avec une valeur "true" correspondante dans la matrice. En suivant les conventions LSB, la matrice est émise dans des messages de DMAP avec les indices 7..0 émis les premiers et les indices 31..24 émis les derniers

9.4.3.8 dlmo.Route

9.4.3.8.1 Généralités

L'attribut dlmo.Route est un ensemble OctetString indexé qui contient des chemins. L'attribut dlmo.Route décrit les chemins disponibles pour les DPDU. Lorsqu'une DSDU descend la pile de protocoles issue de la NL, elle reçoit une adresse de destination finale, accompagnée d'un ID de contrat et d'une classe de priorités. La DLE met en correspondance l'ID de contrat et l'adresse de destination avec un chemin, en se basant sur des consultations de table. La classe de priorités issue de la NL est simplement copiée dans l'en-tête de la DPDU sans être prise en considération dans la sélection du chemin.

Le gestionnaire de système insère, met à jour ou supprime des chemins en envoyant au DMAP un chemin, accompagné d'un indice unique et (si sélectionné) d'un temps TAI de basculement.

Pour une description de cette sélection de chemin, voir 9.1.6.5.

9.4.3.8.2 Sémantique

Le Tableau 185 spécifie les champs pour dlmo.Route.

Tableau 185 – Champs de dlmo.Route

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (utilisé comme un indice)
Size [taille (nombre d'entrées) de l'attribut Route]	Type: Unsigned4 Plage valide: 1..15
Alternative	Type: Unsigned2
Reserved (alignement d'octets)	Type: Unsigned2=0
ForwardLimit (valeur d'initialisation pour la limite de transmission en DPDU qui utilisent ce chemin)	Type: Unsigned8
Route (série de destinations de routage; si le bit de poids fort d'entrée est 0, cela représente une adresse de monodiffusion; si les bits de poids fort d'entrée sont 0x 1010, cela représente un graphe)	Type: SEQUENCE OF Unsigned16 (SIZE (size))
Selector (voir texte)	Type: Unsigned16 ou null
SrcAddr (voir texte)	Type: ExtDLUint ou null

Le Tableau 186 montre la structure de dlmo.Route.

Tableau 186 – Structure de dlmo.Route

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1..2	* Index							
1	Size				Alternative		Reserved = 0	
1	ForwardLimit							
2	$Route_0$							
...	...							
2	$Route_{Size-1}$							
0 ou 2	Selector							
0..2	SrcAddr							

L'attribut dlmo.Route[ ].Selector dépend de la valeur de réglage de dlmo.Route[ ].Alternative:

- lorsque dlmo.Route[ ].Alternative=0, sélectionner ce chemin si dlmo.Route[ ].Selector concorde avec le ContractID et dlmo.Route[ ].SrcAddr concorde avec le champ SrcAddr (adresse source) dans le sous-en-tête DADDR. Cette alternative ne doit pas être utilisée, sauf si la DLE est un routeur dorsal. Si dlmo.Route[ ].Alternative<>0, l'attribut dlmo.Route[ ].SrcAddr est null (vide) et ne doit pas être émis;
- lorsque dlmo.Route[ ].Alternative=1, sélectionner ce chemin si dlmo.Route[ ].Selector concorde avec ContractID;
- lorsque dlmo.Route[ ].Alternative=2, sélectionner ce chemin si dlmo.Route[ ].Selector concorde avec l'adresse de destination;
- lorsque dlmo.Route[ ].Alternative=3, utiliser ce chemin comme valeur par défaut. L'attribut dlmo.Route[ ].Selector est null (vide) et ne doit pas être émis.

L'attribut dlmo.Route[ ].Alternative doit être appliqué dans l'ordre, en donnant aux alternatives ayant les bas numéros la préséance sur les alternatives ayant les numéros plus élevés. Il convient qu'il n'y ait pas plus d'une entrée dlmo.Route par combinaison de ContractID/SrcAddr (Alternative=0), pas plus d'une entrée par ContractID (Alternative=1), pas plus d'une entrée par adresse de destination (Alternative=2), et pas plus d'une valeur par

défaut (Alternative=3). S'il y a des doublons, l'entrée concordante ayant l'indice le plus faible doit être sélectionnée.

9.4.3.9 dlmo.NeighborDiag

9.4.3.9.1 Généralités

L'attribut dlmo.NeighborDiag est un ensemble OctetString indexé qui contient les diagnostics pour un jeu de voisins. L'attribut est en lecture seule, avec des rangées créées selon les besoins par la DLE.

Chaque entrée de NeighborDiag comporte une matrice d'un ou deux OctetString, chaque entrée correspondant à un voisin différent.

Les entrées de NeighborDiag sont instanciées par le gestionnaire de système, en mettant les bits de dlmo.Neighbor[ ].DiagLevel à des valeurs différentes de zéro. Si et seulement si Bit0=1, les diagnostics de résumés doivent être recueillis pour le voisin, consolidés à travers toutes les voies. Si et seulement si Bit1=1, les diagnostics d'horloge détaillés doivent être recueillis pour le voisin, consolidés à travers toutes les voies radioélectriques.

NOTE Les diagnostics de voie individuels sont recueillis par l'intermédiaire de l'attribut dlmo.ChannelDiag.

Les diagnostics incluent des compteurs et des niveaux, qui sont accumulés selon la description en 9.1.15.3. En général, les compteurs sont incrémentés de 1 au cours des transactions réussies ou non réussies, alors que RSSI (intensité de signal) et RSQI (qualité de signal) sont des niveaux qui sont accumulés sous la forme de moyennes mobiles exponentielles.

NeighborDiag est rapporté de trois manières générales:

- par l'intermédiaire du HRCO, le gestionnaire de système peut configurer la DLE pour rapporter périodiquement NeighborDiag, par exemple toutes les 30 min. Après chaque rapport de ce type, sur une base par entrée, les comptes de NeighborDiag doivent être réinitialisés à zéro. Les niveaux doivent utiliser la valeur courante comme un point de départ pour la prochaine période;
- le gestionnaire de système peut lire (interroger) NeighborDiag comme un attribut en lecture seule sur une base entrée par entrée. Comme dans un rapport de HRCO, les comptes doivent être réinitialisés à zéro après une lecture;
- la DLE peut en outre être configurée, par l'intermédiaire de l'attribut dlmo.AlertPolicy, pour rapporter des informations de NeighborDiag lorsque des valeurs de diagnostics dépassent un seuil. Seule la rangée déclenchant l'alerte est rapportée. Aucune valeur n'est réinitialisée à zéro.

En général, dans la présente norme, la capacité des métadonnées d'un OctetString indexé est rapportée comme étant le nombre de rangées. Sachant que les rangées dans NeighborDiag peuvent avoir des tailles substantiellement variables, les métadonnées pour NeighborDiag (DiagMeta) doivent être rapportées en capacité mémoire en octets pour les OctetString, avec la convention selon laquelle chaque champ ExtDLUint est supposé consommer deux octets. Une DLE doit avoir la capacité pour des diagnostics de résumés (dlmo.NeighborDiag[ ].Summary) pour au moins la moitié de sa capacité de voisins telle qu'indiquée par dlmo.NeighborMeta.Capacity ou pour au moins deux voisins, la valeur la plus grande étant retenue.

9.4.3.9.2 Sémantique

Chaque entrée de NeighborDiag inclut trois OctetString, un chacun pour les diagnostics Summary et ClockDetail. Un OctetString de longueur zéro indique que le diagnostic n'est pas accumulé. Le Tableau 187 spécifie les champs pour dlmo.NeighborDiag.

Tableau 187 – Champs de dlmo.NeighborDiag

Nom de champ	Codage de champ
* Index	Type: ExtDLUint (adresse de voisin, utilisée comme un indice)
Summary	Type: OctetString
ClockDetail	Type: OctetString

Le Tableau 188 spécifie les champs au sein de l'OctetString "Summary" de diagnostic.

Tableau 188 – Champs de l'OctetString "Summary" de diagnostic

Nom de champ	Codage de champ
RSSI (niveau)	Type: Integer8
RSQI (niveau)	Type: Unsigned8
RxDPDU (compte)	Type: ExtDLUint
TxSuccessful (compte)	Type: ExtDLUint
TxFailed (compte)	Type: ExtDLUint
TxCCA_Backoff (compte)	Type: ExtDLUint
TxNAK (compte)	Type: ExtDLUint
ClockSigma (niveau)	Type: Integer16

Le Tableau 189 spécifie la structure des OctetString "Summary" de diagnostic.

Tableau 189 – Structure de l'OctetString "Summary" de diagnostic

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	RSSI							
1	RSQI							
1 ou 2	RxDPDU							
1 ou 2	TxSuccessful							
1 ou 2	TxFailed							
1 ou 2	TxCCA_Backoff							
1 ou 2	TxNAK							
2	ClockSigma							

Les champs comprennent:

- RSSI (intensité de signal): voir 9.1.15.2 pour un débat relatif aux unités de RSSI. RSSI est cumulé sous la forme d'une moyenne mobile exponentielle; voir 9.1.15.3;
- RSQI (qualité de signal): voir 9.3.5.5 et 9.1.15.2 pour un débat relatif aux unités de RSQI. RSQI est cumulé sous la forme d'une moyenne mobile exponentielle; voir 9.1.15.3;
- RxDPDU: compte des DPDU Data valides reçues en provenance du voisin, à l'exclusion des DPDU sans charge utile de DSDU (mais également des DPDU ACK/NAK);
- TxSuccessful: compte des émissions en monodiffusion réussies vers le voisin, où un DPDU ACK a été reçu en réponse;

- TxFailed: compte des émissions en monodiffusion de DPDU, où un DPDU ACK/NAK était attendu mais n'a pas été reçu en réponse;
- TxCCA_Backoff: compte des émissions en monodiffusion qui ont été abandonnées en raison de la CCA. Ces émissions abandonnées ne sont pas incluses dans TxFailed;
- TxNAK: compte des NAK reçus, non inclus dans TxFailed;
- ClockSigma: estimation grossière, au sein d'un écart type, des récentes corrections d'horloge, en unités de 2^{-20} s. Une valeur de 1 sigma rend compte d'approximativement 68 % des corrections d'horloge. ClockSigma est réinitialisé à zéro chaque fois que les compteurs sont réinitialisés.

NOTE 1 Voir 9.1.15.3 pour le comportement des compteurs.

Si la DLE traite de façon autonome une liaison d'émission comme étant inactive, telle que décrite en 9.1.7.2.4, de telles liaisons sautées ne doivent pas être comptées dans les diagnostics de voisin. Cependant, ces liaisons sautées sont reflétées dans le diagnostic de voie, tel que décrit en 9.4.2.27.

Le Tableau 190 spécifie les champs au sein de l'OctetString ClockDetail de diagnostic.

Tableau 190 – Champs de l'OctetString ClockDetail de diagnostic

Nom de champ	Codage de champ
ClockBias (niveau, signé)	Type: Integer16
ClockCount (compte)	Type: ExtDLUint
ClockTimeout (compte)	Type: ExtDLUint
ClockOutliers (compte)	Type: ExtDLUint

Le Tableau 191 spécifie la structure de l'OctetString ClockDetail de diagnostic, avec les champs ExtDLUint montrés sous forme d'un seul octet.

Tableau 191 – Structure de l'OctetString ClockDetail de diagnostic

Octets	Bits							
	7	6	5	4	3	2	1	0
2	ClockBias							
1 ou 2	ClockCount							
1 ou 2	ClockTimeout							
1 ou 2	ClockOutliers							

Si le voisin est une source d'horloge de DL préférentielle, telle qu'indiquée par IncludeClock=1, il convient que la DLE soit configurée pour accumuler les champs de ClockDetail.

ClockSigma, ClockBias, et ClockOutliers se rapportent tous à des corrections d'horloge. Si le voisin est une source d'horloge de DL, ces valeurs se rapportent à des corrections d'horloge reçues en provenance de la source d'horloge de DL. Si le voisin n'est pas source d'horloge de DL, ces valeurs se relient aux corrections d'horloge envoyées vers le voisin de la DLE par l'intermédiaire de la DPDU ACK/NAK.

Les champs comprennent:

- ClockBias: une moyenne mobile exponentielle (EMA) de correction d'horloge, en unités de 2^{-20} s, y compris le signe, avec un facteur de lissage de 1 %. Voir 9.1.15.3 pour un débat relatif à l'EMA.

NOTE 2 Si cette valeur est sensiblement différente de zéro, elle indique que l'horloge est biaisée par rapport à la source d'horloge distante;

- ClockCount: compte des mises à jour d'horloge reçues en provenance du voisin ou émises vers celui-ci;
- ClockTimeout: compte des événements de temporisation d'horloge;
- ClockOutliers: compte estimé des corrections d'horloge de plus de trois écarts types selon ClockSigma.

9.5 Méthodes de DLE

9.5.1 Méthode pour le basculement synchronisé des attributs de DLE

Une méthode Scheduled_Write, avec MethodID=1, est fournie pour positionner un attribut à un temps TAI spécifique. Elle suit exactement le modèle donné dans le Tableau J.1.

9.5.2 Méthodes pour accéder aux attributs OctetString indexés

Les diverses méthodes dans la DLE se rapportent à l'écriture, à la lecture, et à la suppression d'attributs OctetString indexés. Ces méthodes sont généralement basées sur les modèles fournis en Annexe J.

Tous les attributs OctetString indexés dans la DL sont indexés par un seul nombre entier codé comme étant une ExtDLUint (voir 9.3.2.2). Suivant la convention des méthodes de modèle, ces indices sont dupliqués dans les arguments d'entrée. Par exemple, la méthode Write_Row inclut un indice comme argument d'entrée même si l'indice est également transporté au sein de l'OctetString qui constitue la nouvelle entrée.

Le Tableau 192 spécifie la méthode Read_Row.

Tableau 192 – Méthode Read_Row

Nom de méthode	ID de méthode	Description de la méthode			
Read_Row	2	Méthode pour lire la valeur d'une seule rangée d'un attribut OctetString indexé dont les données sont visualisées sous la forme d'un tableau d'informations			
	Arguments d'entrée				
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**	
	1	Attribute_ID	Unsigned16	L'ID d'attribut dans le DLMO auquel la présente méthode est appliquée	
	2	Index	Unsigned16	Le champ * Index dans l'attribut pour accéder à une rangée particulière	
	Arguments de sortie				
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**	
	1	Data_Value	OctetString	Une chaîne d'octets qui contient le contenu de la rangée. Si la rangée est vide, l'OctetString ne doit contenir que l'Index, codé comme ExtDLUint	

Le Tableau 193 spécifie la méthode Write_Row.

Tableau 193 – Méthode Write_Row

Nom de méthode	ID de méthode	Description de la méthode		
Write_Row	3	Méthode pour établir/modifier la valeur d'une seule rangée d'un attribut OctetString indexé dont les données sont visualisées sous la forme d'un tableau d'informations		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Attribute_ID	Unsigned16	L'ID d'attribut dans le DLMO auquel cette méthode est appliquée, tel que déterminé par l'index ordinal de l'attribut dans la définition du DLMO
	2	Scheduled_TAI_Time	Unsigned32	Temps TAI en secondes auquel il convient que la valeur soit écrite dans la rangée de l'attribut structuré. Si le temps se situe dans le passé, par rapport au sens du temps de l'appareil de réception, l'écriture doit être effectuée immédiatement
	3	Index	Unsigned16	Le champ * Index dans l'attribut pour accéder à une rangée particulière
	4	Data_Value	OctetString	Une chaîne d'octets qui contient le nouveau contenu de la rangée. Si la rangée de DLMO n'est pas peuplée, il est créé une nouvelle rangée contenant l'OctetString si de la mémoire est disponible. Si la rangée de DLMO existe déjà, son contenu est remplacé par l'OctetString. Si l'OctetString est null (vide), alors la rangée doit être supprimée
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	Aucun			

Le Tableau 194 spécifie la méthode Write_Row_Now. Elle est identique à la méthode Write_Row, sans l'argument Scheduled_TAI_Time. Elle a l'effet d'écrire une rangée OctetString indexé immédiatement à la réception.

Tableau 194 – Méthode Write_Row_Now

<table>
<tr><th>Nom de méthode</th><th>ID de méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="9">Write_Row_Now</td><td>4</td><td colspan="3">Méthode pour établir/modifier la valeur d'une seule rangée d'un attribut OctetString indexé dont les données sont visualisées sous la forme d'un tableau d'informations</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>Attribute_ID</td><td>Unsigned16</td><td>L'ID d'attribut dans le DLMO auquel cette méthode est appliquée, tel que déterminé par l'index ordinal de l'attribut dans la définition du DLMO</td></tr>
<tr><td>2</td><td>Index</td><td>Unsigned16</td><td>Le champ * Index dans l'attribut pour accéder à une rangée particulière</td></tr>
<tr><td>3</td><td>Data_Value</td><td>OctetString</td><td>Une chaîne d'octets qui contient le nouveau contenu de la rangée. Si la rangée de DLMO n'est pas peuplée, il est créé une nouvelle rangée contenant l'OctetString si de la mémoire est disponible. <tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td colspan="4">Aucun</td></tr>
</table>

9.6 Alertes de DL

9.6.1 Alerte DL_Connectivity

Les diagnostics des performances de DLE sont accumulés dans les attributs dlmo.NeighborDiag pour les diagnostics par voisin, et dlmo.ChannelDiag pour les diagnostics par voie. Normalement, le gestionnaire de système configure le HRCO pour rapporter ces diagnostics périodiquement, et la DLE réinitialise automatiquement les compteurs de diagnostics chaque fois que ces attributs sont ainsi rapportés. Entre de tels rapports, les diagnostics peuvent indiquer un problème qui a besoin d'être immédiatement rapporté au gestionnaire de système. L'alerte DL_Connectivity fournit le mécanisme permettant à la DLE de rapporter de tels problèmes, et l'attribut dlmo.AlertPolicy permet au gestionnaire de système d'établir des seuils pour la production de tels rapports.

L'attribut dlmo.AlertPolicy active/désactive l'alerte de DL_Connectivity et fournit des seuils pour commander si, oui ou non, des alertes sont rapportées. L'attribut dlmo.AlertPolicy est un OctetString contenant des champs tels que montrés dans le Tableau 195.

Tableau 195 – Champs de dlmo.AlertPolicy

Nom de champ	Codage de champ
Descriptor (active ou désactive l'alerte DL_Connectivity)	Type: Alert report descriptor Par défaut: Disabled=true Par défaut: Priority=0
NeiMinUnicast (nombre minimal de transactions en monodiffusion nécessaires pour un rapport de voisin)	Type: ExtDLUint
NeiErrThresh (rapporter le diagnostic de voisin si le taux d'erreur en pourcentage atteint ce seuil)	Type: Unsigned8
ChanMinUnicast (nombre minimal de transactions en monodiffusion sur une voie nécessaires comme condition préalable du déclenchement d'une alerte)	Type: ExtDLUint
NoAckThresh (rapporter ChannelDiag si une valeur NoAck est supérieure à ce seuil)	Type: Unsigned8
CCABackoffThresh (rapporter ChannelDiag si une valeur CCABackoff est supérieure à ce seuil)	Type: Unsigned8

Le Tableau 196 spécifie la structure de l'OctetString dlmo.AlertPolicy.

Tableau 196 – Structure de l'OctetString dlmo.AlertPolicy

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
2	Descriptor							
1 ou 2	NeiMinUnicast							
1	NeiErrThresh							
1 ou 2	ChanMinUnicast							
1	NoAckThresh							
1	CCABackoffThresh							

Les champs comprennent:

- l'attribut dlmo.AlertPolicy.Descriptor détermine si, oui ou non, l'alerte DL_Connectivity est activée. Par défaut, l'alerte DL_Connectivity est désactivée jusqu'à ce que le gestionnaire de système l'active en peuplant cet attribut avec les seuils appropriés. Lorsque Disabled=true, tous les autres champs de dlmo.AlertPolicy sont sans signification et sont ignorés;
- l'attribut dlmo.AlertPolicy.NeiMinUnicast établit un nombre minimal de transactions tentées en monodiffusion avant qu'un taux d'erreur soit considéré comme étant significatif. Le compte de transactions tentées en monodiffusion pour un voisin est la somme des champs de l'attribut dlmo.NeighborDiag

  TxSuccessful + TxFailed + TxCCA_Backoff + TxNAK.

  Si cette somme est inférieure à NeighborTxMinReport, ne pas envoyer d'alerte DL_Connectivity pour le voisin;
- l'attribut dlmo.AlertPolicy.NeiErrThresh établit le seuil pour rapporter une alerte DL_Connectivity pour un voisin. Le taux d'erreur en pourcentage est calculé comme étant:

  (TxFailed + TxCCA_Backoff + TxNAK) x 100 /
  (TxSuccessful + TxFailed + TxCCA_Backoff + TxNAK)

  Si cette valeur est supérieure à NeiErrThresh, il convient que les diagnostics pour le voisin soient rapportés en utilisant l'alerte DL_Connectivity, à moins qu'il n'y ait un nombre insuffisant de transactions en monodiffusion vers le voisin ou à moins que la même alerte n'ait été rapportée récemment;

- l'attribut dlmo.AlertPolicy.ChanMinUnicast est similaire à NeiMinUnicast. Les compteurs sous-tendant dlmo.ChannelDiag ne sont pas exposés, mais un compte des transactions tentées en monodiffusion est implicite dans les ratios rapportés;
- les attributs dlmo.AlertPolicy.NoAckThresh et dlmo.AlertPolicy.CCABackoffThresh fournissent des seuils pour la production de rapports. Sachant que les valeurs rapportées par dlmo.ChannelDiag sont des ratios, les valeurs rapportées sont simplement comparées aux seuils. Si la valeur excède les seuils, il convient que dlmo.ChannelDiag soit rapporté par l'intermédiaire de l'alerte DL_Connectivity, à moins que l'exigence relative à ChanMinUnicast ne soit pas respectée ou à moins que la même alerte n'ait été rapportée récemment.

Le gestionnaire de système peut répondre à l'alerte de connectivité de DL en recueillant les diagnostics afin de caractériser plus complètement la situation. En variante, en particulier si une topologie modifiée est facilement obtenue, le gestionnaire de système peut simplement reconfigurer la topologie du sous-réseau D.

Le Tableau 197 montre la structure de l'alerte DL_Connectivity.

Tableau 197 – Alerte DL_Connectivity

Nom du type d'objet normalisé: DL management object (DLMO, objet de gestion de DL)					
Identificateur du type d'objet normalisé: 124					
Description de l'alerte: connectivité médiocre de voisin					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alerte**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
Evénement	Comm	0 = DL_Connectivity	Medium	Type: DL16Address	Voir Tableau 187

Le format de l'OctetString émis avec l'alerte DL_Connectivity est montré dans le Tableau 198. Il s'agit simplement du numéro d'attribut pour dlmo.ChannelDiag (48) ou pour dlmo.NeighborDiag (46), suivi d'un OctetString contenant les données de diagnostic issues de l'attribut en question. Dans le cas de ChannelDiag, l'attribut entier est émis. Dans le cas de NeighborDiag, seule la rangée qui a déclenché l'alerte est émise, avec l'adresse de voisin spécifiée au sein de la rangée identifiant le voisin.

Tableau 198 – OctetString d'alerte DL_Connectivity

Octets	**Bits**							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**
1	AttributeNumber (Unsigned8)							
N	Attribute (OctetString)							

9.6.2 Alerte NeighborDiscovery

Comme décrit en 9.4.2.24, l'alerte NeighborDiscovery fournit un mécanisme permettant à la DLE de rapporter le contenu de l'OctetString dans l'attribut dlmo.Candidates.

Le Tableau 199 montre la structure de l'alerte NeighborDiscovery.

Tableau 199 – Alerte NeighborDiscovery

Nom du type d'objet normalisé: DL management object (DLMO, objet de gestion de DL)					
Identificateur du type d'objet normalisé: 124					
Description de l'alerte: alerte de découverte de voisin					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alerte**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
Evénement	Comm	1 = NeighborDiscovery	Medium	Type: OctetString	Une copie exacte de l'OctetString dans dlmo.Candidates; voir 9.4.2.24

10 Couche Réseau

10.1 Généralités

L'Article 10 donne une vue d'ensemble de la fonctionnalité de NL. Il décrit également les services conceptuels que la NL offre à la couche au-dessus d'elle (transport), l'objet de gestion de NL (NLMO) et la structure des NPDU.

NOTE Les formats d'en-tête de NPDU ont été conçus pour la compatibilité avec l'IETF RFC 6282.

Le NL suit la convention gros-boutiste; les champs à plusieurs octets sont documentés et émis avec l'octet de poids fort le premier (car ils sont traités comme une série d'octets par la couche inférieure). Au sein d'un octet, les bits sont documentés en commençant à partir du bit de poids fort (bit 7) à gauche et en continuant jusqu'au bit de poids faible (bit 0) à droite.

Des parties de l'Article 10 présentent des aspects hypothétiques de mise en œuvre comme s'ils étaient soumis à des essais de conformité. Lorsque de tels aspects ne sont pas observables extérieurement, ces spécifications sont strictement hypothétiques. Seuls les aspects observables pouvant être soumis à essai de l'Article 10 sont normatifs.

10.2 Vue d'ensemble des fonctionnalités de la NL

10.2.1 Généralités

La NL dans la présente norme accomplit les fonctions suivantes:

- adressage: une NLE détermine les informations appropriées relatives à l'adresse pour une NPDU;
- conversion d'adresses: la présente norme utilise principalement deux types d'adresses, les adresses DL16Addresses courtes et les adresses IPv6Addresses longues. Les adresses courtes DL16Addresses sont utilisées au sein d'un sous-réseau D pour conserver l'énergie et la largeur de bande. Les ALE, les TLE et les NLE sur des réseaux dorsaux utilisent de longues adresses IPv6Addresses. La NLE est responsable de la conversion entre les divers types d'adresses, par exemple, lorsqu'une NPDU se déplace d'un sous-réseau D vers un réseau dorsal (ou vice versa);
- formats de NPDU: la présente norme prévoit plus d'un format de NPDU pour prendre en charge la conservation de l'énergie et de la largeur de bande (qui favorise les en-têtes courts), une diversité de topologies de réseau, et l'interconnexion de réseaux avec des réseaux dorsaux. La NLE sélectionne un format approprié pour la NPDU en se basant sur des considérations telles que l'adressage, le routage, le niveau de service, etc.;

- fragmentation et réassemblage: la fragmentation et le réassemblage de NPDU se produisent au sein de la NLE. Une NPDU de taille supérieure à la taille maximale de DSDU est fragmentée par la NLE expéditrice au point d'entrée du sous-réseau D. Le réassemblage est accompli par la NLE réceptrice au point de sortie du sous-réseau D;
- routage: la présente norme accomplit le routage à deux niveaux: au sein du réseau dorsal et au sein du sous-réseau D de la maille. La responsabilité du routage au niveau des couches de protocole de NL et de DL incombe aux entités des couches respectives.

10.2.2 Adressage

Les ALE et les TLE dans la présente norme utilisent des adresses IPv6Addresses. Chaque NLE doit avoir une adresse IPv6Address. Si la NLE n'a pas une adresse IPv6Address avant le processus de rattachement de réseau, la NLE doit avoir une telle adresse IPv6Address qui lui est assignée par le gestionnaire de système au cours du processus de rattachement. La NL utilise ces adresses IPv6Addresses, mais ne leur associe aucune autre signification.

Chaque NLE conforme à la présente norme doit également avoir une adresse IPv6Address qui est autoconfigurée par la NLE comme partie intégrante de l'initialisation de sa couche de protocoles. Cette adresse IPv6Address est appelée adresse locale à une liaison de la NLE et est dérivée à partir de l'adresse EUI64Address de la DLE qui lui est associée. Le format de cette adresse IPv6Address est celui d'une adresse en monodiffusion locale à une liaison, telle que définie dans l'IETF RFC 4291:2006, 2.5.6. Le Tableau 200 montre la structure de cette adresse.

Tableau 200 – Structure d'adresse locale à une liaison

10 bits	54 bits	64 bits
11 1111 1010	0	EUI64Address

Lorsque les DPDU sont émises sur un sous-réseau D, l'acheminement des adresses IPv6Addresses consomme de précieuses ressources de largeur de bande et d'énergie d'appareil. Aussi, la présente norme définit-elle des pseudonymes D de 16 bits pour les adresses IPv6Addresses afin que de courts pseudonymes D soient utilisés sur le sous-réseau D. Pour chaque sous-réseau D, une adresse DL16Address unique doit être assignée à chaque DLE au sein du sous-réseau D en question, ainsi qu'à chaque DLE située à l'extérieur du sous-réseau D avec laquelle une DLE au sein du sous-réseau D a un contrat. Cela permet d'utiliser des adresses D courtes dans le sous-réseau D pour représenter toutes les NLE d'origine et de destination.

La portée d'une adresse DL16Address est le sous-réseau D au sein duquel elle a été définie. Ainsi, un appareil particulier peut avoir une adresse D dans le sous-réseau D auquel elle appartient et une adresse D différente dans un sous-réseau D étranger. Lorsqu'une adresse DL16Address est utilisée, elle est transportée dans l'en-tête de la DPDU.

Au cours du processus de rattachement, une NLE pourrait ne pas encore avoir une adresse IPv6Address et sa DLE associée pourrait ne pas avoir une adresse DL16Address. Dans ce cas, les TPDU entre l'appareil se rattachant et le routeur D d'annonce de D doivent utiliser les adresses IPv6Addresses locales à une liaison lorsqu'elles sont nécessaires (par exemple, pour le pseudo-en-tête de TPDU dans les TPDU de rattachement). L'appareil se rattachant et le routeur d'annonce doivent être identifiés en tant que tels en utilisant leurs adresses EUI64Addresses dans les en-têtes de DPDU qui acheminent les messages de rattachement.

Le gestionnaire de système assigne respectivement l'adresse DL16Address et l'adresse IPv6Address de chaque DLE et de chaque NLE, qui fonctionnent dans un WISN selon la présente norme. Ces adresses sont assignées au cours du processus de rattachement au sous-réseau. La NLE spécifiée par la présente norme ne prend en charge que l'adressage en monodiffusion.

NOTE 1 L'adressage en multidiffusion est un sujet pour une future normalisation.

NOTE 2 Les technologies de réseau dorsal et de réseau d'installation ne relèvent pas du domaine d'application de la présente norme. Par conséquent, la présente norme ne spécifie pas la représentation des adresses IPv6Addresses sur un réseau dorsal ou d'installation particulier.

10.2.3 Conversion d'adresse

Sachant que la présente norme utilise des adresses DL16Addresses au sein d'un sous-réseau D, lorsqu'une NPDU se déplace d'un sous-réseau D vers un réseau dorsal (ou vice versa), la NLE du routeur dorsal doit effectuer des conversions entre les adresses DL16Addresses et les adresses IPv6Addresses. La même sorte de conversion doit être accomplie par la NLE d'un point d'extrémité de sous-réseau D.

Tous les appareils dans la présente norme doivent maintenir une table de conversion d'adresses (ATT), telle que montrée dans le Tableau 201.

Tableau 201 – Table de conversion d'adresses (ATT)

Adresse D (DL16Address)	Adresse N (IPv6Address)
N1_16	N1_128
N2_16	N2_128
GW_16	GW_128
BBR_16	BBR_128
SM_16	SM_128

La table de conversion d'adresses est initialisée au cours du processus de rattachement au sous-réseau avec l'adresse DL16Address et avec l'adresse IPv6Address du gestionnaire de système. Ces informations sont une partie intégrante de la composante autre que de sécurité de la réponse de rattachement reçue en provenance du gestionnaire de système, telles que décrites en 6.3.9.2.

La table de conversion d'adresses doit être mise à jour par la NLE source chaque fois qu'une session de communication est établie avec une nouvelle NLE de destination. Les sessions de communication sont décrites en 6.3.11.2.5.2. L'adresse DL16Address et l'adresse IPv6Address de la destination NLE de destination et sa DLE associée sont stockées dans la table de conversion d'adresses à l'achèvement réussi du processus d'établissement de session. Le processus d'établissement de session est décrit en 7.5. S'il est mis fin à une session pour une raison quelconque, toute entrée associée à l'appareil de destination doit être supprimée.

Une NLE maintient des entrées dans sa table ATT pour d'autres NLE avec lesquelles elle communique; ces autres NLE pouvant soit appartenir au même sous-réseau D que la première NLE, soit avoir une adresse DL16Address dans le même sous-réseau D.

Au sein d'un sous-réseau D particulier, une NLE (qu'elle soit locale ou distante) doit avoir une seule adresse DL16Address. Ainsi, la table ATT peut être utilisée par la NLE pour la consultation dans le sens tant direct qu'inverse. Par exemple, une fonction ATT_lookup peut être définie, l'adresse étant ainsi consultée comme un paramètre:

- adresse IPv6Address déterminée par l'intermédiaire de la fonction ATT_lookup d'une adresse DL16Address;
- adresse DL16Address déterminée par l'intermédiaire de la fonction ATT_lookup d'une adresse IPv6Address.

Plusieurs NLE ou DLE peuvent être empaquetées dans un seul appareil physique pour prendre en charge le rattachement multiple. Bien qu'une telle opération ne soit pas spécifiée par la norme, elle n'est pas interdite.

Une adresse sans entrée dans la table ATT doit être convertie avec l'aide du gestionnaire de système. Pour chaque NLE rejoignant le réseau, le gestionnaire de système doit maintenir

l'adresse IPv6Address de la NLE et l'adresse DL16Address associée ou le pseudonyme D associé pour chaque sous-réseau D dans lequel la NLE a un tel pseudonyme. Par conséquent, la table ATT locale en une NLE doit être mise à jour par l'intermédiaire du gestionnaire de système.

La table ATT est une partie intégrante du NLMO et peut être directement mise à jour par le gestionnaire de système en utilisant les méthodes de manipulation de NLMO décrites dans le Tableau 210.

Si une consultation dans la table ATT ne donne pas de résultat, la fonction de consultation le notifie au NLMO. Le NLMO délivre une primitive de lecture vers l'objet de service d'annuaire (DSO) dans le gestionnaire de système pour obtenir la conversion appropriée. La fonction de consultation retourne une valeur null (vide) si le gestionnaire de système n'a également pas de mapping pour une adresse particulière ou si le gestionnaire de système n'est pas disponible. Toute nouvelle information provenant du gestionnaire de système est stockée dans la table ATT.

Ce processus est montré à la Figure 91.

10.2.4 En-têtes d'unités de données de protocoles de réseau

Trois formats sont utilisés pour les en-têtes de NPDU. La valeur du premier octet de l'en-tête fournit le moyen de distinguer entre ces formats:

- en-tête de base: ce format est destiné aux NPDU traversant un seul sous-réseau D et ne doit être utilisé que sur le sous-réseau D en question. Il est censé être le plus courant format en utilisation parce que son utilisation réduit au maximum le surdébit associé à l'émission d'en-têtes. L'en-tête de base est juste une abréviation pour une valeur fixe spécifique de l'en-tête compressé 6LoWPAN; cette valeur indique que les adresses de source et de destination sont élidées, au lieu d'être acheminées dans l'en-tête de DPDU, comme décrit en 10.5.2;
- en-tête activé par contrat: ce format également est utilisé seulement sur un seul sous-réseau D, lorsque l'appareil source a besoin d'inclure plus d'informations dans la NPDU, telles qu'un contractID. Ces informations complémentaires permettent à des routeurs dorsaux de sélectionner les ressources appropriées (par exemple, graphID, priorité) pour le routage de la NPDU, comme décrit en 10.5.3;
- en-tête complet: il s'agit d'un en-tête IPv6 complet, adapté à être utilisé sur la dorsale. Les NPDU contenant un en-tête de base ou l'en-tête activé par contrat doivent être allongées au format d'en-tête complet avant le routage sur la dorsale. En retour, les routeurs dorsaux convertissent les en-têtes complets en en-têtes de base ou en en-têtes activés par contrat pour l'émission sur un sous-réseau D, comme décrit en 10.5.4.

10.2.5 Fragmentation et réassemblage

Si la NPDU entière est plus petite que la taille de DSDU maximale, la NPDU ne doit pas être fragmentée et l'en-tête de réseau ne doit pas contenir un en-tête de fragmentation. Si la NPDU excède la taille maximale de DSDU, la NPDU doit être fragmentée en NPDU fragmentées qui ne dépassent pas la taille maximale de DSDU dans le sous-réseau D. La fragmentation doit être accomplie par la NLE au point d'entrée d'un sous-réseau D. Le réassemblage doit être accompli par la NLE au point de sortie d'un sous-réseau D.

NOTE L'émission par une TLE dans un appareil connecté à un sous-réseau D constitue “un point d'entrée” du sous-réseau D. De même, la livraison à une TLE dans un appareil connecté à un sous-réseau D constitue “un point de sortie” du sous-réseau D.

Le premier fragment doit contenir le premier en-tête de fragment tel que défini dans le Tableau 219. Le deuxième segment et les suivants (jusqu'au dernier segment compris) doivent contenir un en-tête de fragmentation, tel que définis dans le Tableau 220. Le décalage de ce fragment, appelé décalage de datagramme, doit être exprimé en unités de huit octets, de sorte que chaque fragment autre que le dernier soit constitué d'un multiple de huit octets.

Le champ Datagram_size doit être présent dans chaque fragment, pour simplifier les tâches de réassemblage lorsque les fragments arrivent dans le désordre à leur NLE de réassemblage. L'inclusion du champ Datagram_size dans chaque fragment permet au récepteur d'allouer la quantité appropriée de l'espace tampon lorsque le premier fragment est différé.

Tous les fragments (le premier et les fragments suivants) doivent avoir un champ Datagram_tag dans leur en-tête. La valeur de ce champ doit être assignée par l'appareil accomplissant la fragmentation et doit être la même pour tous les fragments de la NPDU, afin que l'appareil de réassemblage puisse reconnaître que les fragments appartiennent à la même NPDU. Dans la mesure du possible, la NLE accomplissant la fragmentation doit assigner une valeur de Datagram_tag différente à chaque NPDU distincte qu'elle fragmente. Pour ce faire, chaque NLE doit avoir un compteur qui est initialisé à une valeur aléatoire uniforme et est incrémenté pour chaque NPDU qui subit la fragmentation; la valeur de ce compteur doit être placée dans le champ Datagram_tag de chaque fragment de la NPDU.

Dans le cas extrêmement rare où deux NPDU allant de la même source vers la même destination seraient fragmentées par des routeurs intermédiaires différents qui prendraient par coïncidence le même Datagram_tag exactement, l'appareil accomplissant le réassemblage peut ne pas être capable de désambiguïser des fragments. Dans ce cas, le GraphID peut être utilisé pour désambiguïser de façon plus poussée; cependant, cela n'est pas spécifié comme étant obligatoire dans la présente norme. Les TPDU réassemblées par erreur à partir de plusieurs sources seront rejetées en raison d'erreurs de somme de contrôle puis retransmises. Les routeurs intermédiaires qui fragmentent des NPDU peuvent aussi coordonner leurs diagrammes d'états de fragmentation afin d'éviter les scénarios dans lesquels l'appareil accomplissant le réassemblage pourrait ne pas être capable de désambiguïser des fragments.

La Figure 92 montre le processus de fragmentation.

a) This is the size of the NwkHdr excluding any contained fragmentation subheader.	a) Il s'agit de la taille de l'en-tête de réseau en excluant tout sous-en-tête de fragmentation contenu

Figure 92 – Processus de fragmentation

Pour identifier tous les fragments qui appartiennent à la même NPDU, la NLE accomplissant le réassemblage doit utiliser:

- l'adresse IPv6Address source;
- l'adresse IPv6Address de destination;
- le datagram_tag et
- le datagram_size.

Autrement, la NLE doit commencer à reconstruire la NPDU non fragmentée initiale, dont la taille est Datagram_size, en utilisant le champ Datagram_offset pour déterminer l'emplacement relatif des différents fragments au sein de la NPDU non fragmentée initiale.

Lorsqu'une NLE reçoit d'abord un fragment avec un Datagram_tag donné qui nécessite une reconstruction, elle démarre un temporisateur de réassemblage. Si ce temporisateur expire avant que la NPDU entière n'ait été rassemblée, les fragments reçus doivent être rejetés. La temporisation du réassemblage doit être mise à une valeur définie dans NLMO.Frag_Reassembly_Timeout (identificateur d'attribut 11 dans le Tableau 206). Si un fragment qui recouvre partiellement un autre fragment est reçu, et il diffère par la taille ou par le Datagram_offset du fragment recouvert, le(s) fragments déjà accumulé(s) dans le tampon de réassemblage doit/doivent être rejeté(s).

Le texte précédant la Figure 92 fournit un exemple de la façon dont une telle fragmentation inconsistante peut se produire.

Un nouveau réassemblage débute avec un fragment contenant une étiquette pour laquelle aucun fragment n'est en cours. Il peut en résulter que des tampons sont alloués quand certains fragments arrivent après la temporisation du processus de réassemblage qui avait été précédemment initié pour la même étiquette (par essence, en tentant de réassembler la NPDU une nouvelle fois ou plus tard). En général, ce réassemblage répété échouera, entraînant l'éventuelle purge de nouveaux tampons à cause de NLMO.Frag_Reassembly_Timeout.

Le processus de réassemblage est achevé lorsque la NPDU est entièrement réassemblée ou lorsque le temporisateur expire. Si la NPDU excède la taille indiquée par NLMO.Max_NSDU_size, le processus de réassemblage peut être abandonné et la NPDU peut être rejetée. L'appareil peut envoyer une alerte PDU abandonnée/erreur de PDU avec la valeur 7 indiquant qu'il manque de mémoire. Les alertes PDU abandonnée/erreur de PDU sont montrées dans le Tableau 211.

Le processus de réassemblage de NPDU est montré à la Figure 93.

10.2.6 Routage

10.2.6.1 Généralités

Le routage dans un réseau conforme à la présente norme se produit à deux niveaux:

- un niveau comporte les points d'extrémité et les appareils dorsaux, s'il y en a; la NL est responsable du routage des PDU à ce niveau. Ce niveau ne traite pas le routage sur les liaisons de DL; la traversée d'un sous-réseau D apparaît comme un seul saut à une NLE;
- le deuxième niveau de routage se situe au sein d'un sous-réseau D. Ce niveau est de la responsabilité de la DL (une mise en œuvre de maille de couche 2).

Le routage entre sous-réseaux D et réseaux dorsaux est de la responsabilité de la NL, dont les NPDU sont conformes aux normes IETF IPv6 et 6LoWPAN La présente norme spécifie des exigences minimales pour le routage, avec des services de gestion hypothétiques pour ajouter, supprimer et maintenir des chemins.

10.2.6.2 Tables de routage

La NLE dans des appareils conformes à la présente norme doit maintenir une table de routage (RT) pour garder la trace du prochain saut pour une destination donnée. Cette table doit être maintenue en utilisant des adresses IPv6Addresses, car de telles adresses sont uniques à travers un réseau entier conforme à la présente norme (y compris tous les sous-réseaux D). Un exemple d'une table de routage est fourni dans le Tableau 202. La table de routage peut être mise à jour à l'appareil de source chaque fois qu'une session de communication est établie avec un appareil de destination.

Tableau 202 – Exemple de table de routage

DestinationAddress	NextHop	NWK_Hop_Limit	OutgoingInterface [a]
N1	BBR1	2	Dorsale
N2	BBR1	2	Dorsale
GW	GW	2	Dorsale
N3	N3	1	sous-réseau D
N4	N4	1	sous-réseau D
N5	N5	1	sous-réseau D
…	…	…	…

[a] Ce champ est mis au sous-réseau D pour toutes les destinations dans les routeurs et les appareils E/S.

NOTE Dans la présente norme, la table de routage et tous les objets de gestion de NL sont spécifiés pour prendre en charge un seul sous-réseau D actif à la fois. Toutes les adresses DL16Addresses sont uniques dans la portée du seul sous-réseau D en question. Cela n'est pas censé empêcher un appareil de participer simultanément à plusieurs sous-réseaux D. Plusieurs sous-réseaux D sont représentés par plusieurs NLE.

Les DLE qui ne sont pas à capacité de dorsale acheminent seulement des DPDU au sein du sous-réseau D. Le routage au sein du sous-réseau D est de la responsabilité de la DL (une mise en œuvre de maille de couche 2). Par conséquent, les DLE qui fonctionnent dans le sous-réseau D, mais qui ne sont pas à capacité de dorsale, peuvent maintenir une table de routage, mais elles ne sont pas tenues de le faire. Cela est également reflété dans le Tableau B.18 qui propose de façon normative les tailles minimales des tables de routage qui ont besoin d'être prises en charge par les appareils qui répondent à divers profils de rôles. Les tables de routage de NL fournissent l'indépendance de couche et permettent des mises en œuvre potentielles de route-over, où le routage dans le sous-réseau D est réalisé par l'intermédiaire du routage de NL.

La table de routage doit être également utilisée par les routeurs dorsaux pour décider d'acheminer une PDU sur une dorsale ou sur le sous-réseau D de la présente norme. Le champ OutgoingInterface indique si la PDU doit être envoyée sur la dorsale ou sur le sous-réseau D.

NextHop indique le prochain appareil dont la NLE doit traiter la NPDU destinée à la DestinationAddress. N'importe quel appareil joignable par l'intermédiaire de la maille de DL a NextHop égal à l'adresse de destination et le champ NWK_Hop_Limit mis à 1. De la perspective de la NLE, tout appareil qui est joignable par l'intermédiaire de la maille de DL est à un seul saut de réseau de distance.

10.2.6.3 Traitement d'une unité de données de service réseau reçue en provenance d'une TLE

Lorsqu'une NSDU est passée à une NLE par une TLE, la NLE détermine la destination finale pour la NSDU en question en se basant sur le ContractID. La table de contrat (voir Tableau 207) est utilisée pour obtenir l'adresse de destination. Les appareils avec une dorsale et une interface de DL conforme à la présente norme doivent rechercher l'adresse de destination dans la table de routage pour déterminer quelle interface réseau utiliser. Toutes les DLE autres que dorsales doivent toujours utiliser leur interface de DL.

La NLE doit utiliser la ContractTable pour obtenir la priorité à deux bits pour le contractID dans la N-Data.request. Cette priorité de contrat doit être combinée avec les deux bits de la priorité de message (également passée dans la N-Data.request) pour obtenir une priorité de NPDU à 4 bits qui est passée à la DLE; les deux bits de poids fort doivent être la priorité de contrat, et les deux bits de poids faible doivent être la priorité de message. Le champ Discard Eligible (DE) issu de la N-Data.request est également passé à la DLE. Si l'OutgoingInterface pour l'adresse de destination est la dorsale, alors la priorité de 4 bits et les bits éligibles de DE doivent être inclus dans le champ TrafficClass de l'en-tête IPv6.

La NLE doit utiliser la ContractTable pour vérifier si le ContractID a besoin d'être inclus dans la NPDU. Le fait d'inclure le ContractID dans la NPDU permet aux routeurs dorsaux intermédiaires de faire des choix appropriés de routage (niveau de service, graphID, etc.) sur la dorsale ou sur un sous-réseau D différent. Pour le routage sur l'interface de DL, si le ContractID n'a pas besoin d'être inclus, il convient alors qu'un en-tête de base de NPDU soit construit; autrement, il convient de construire un en-tête de NPDU activé par contrat.

La NLE doit aussi déterminer si, oui ou non, la fragmentation est nécessaire pour la NPDU et doit accomplir le processus de fragmentation s'il y a lieu. La fragmentation doit être exigée seulement pour les NPDU acheminées sur un sous-réseau D; l'attribut dlmo.MaxDSDUSize doit indiquer la charge utile maximale qui peut être transportée sur un sous-réseau D. Si la taille de DSDU est supérieure à cette valeur, la fragmentation est alors nécessaire.

Les mécanismes de mise en cache des BBR (routeurs dorsaux intermédiaires) ainsi que les protocoles de transmission et de réassemblage inter-BBR peuvent fournir les fonctionnalités nécessaires pour permettre aux fragments de NSDU qui arrivent (du sous-réseau D) de différer le réassemblage et la transmission des BBR par l'un de ces BBR.

NOTE Une édition future de la présente norme peut spécifier un tel mécanisme et protocole inter-BBR.

A moins que le gestionnaire de système de configuration ne sache que les BBR sélectionnés ont la capacité nécessaire, les NPDU exigeant une fragmentation ne doivent pas utiliser les chemins du sous-réseau D qui se terminent par plusieurs BBR, car les NPDU non initiales résultant d'une fragmentation 6LoWPAN ne transportent pas suffisamment d'informations pour qu'elles soient acheminées directement vers leur destination finale prévue sur le sous-réseau dorsal avant que le réassemblage n'ait lieu.

La Figure 94 montre le traitement d'une NSDU reçue en provenance d'une TLE.

Figure 94 – Traitement d'une NSDU reçue en provenance d'une TLE

10.2.6.4 Traitement d'une NPDU reçue

Une NPDU reçue (un paquet), qu'elle soit reçue en provenance de DL ou en provenance de l'interface de dorsale, doit être d'abord vérifiée pour déterminer si la destination finale est une TLE de l'appareil courant. Si oui, la NSDU qui est acheminée comme étant la charge utile de la NPDU (après une éventuelle défragmentation de NPDU exigée) doit être passée à la TLE

contiguë. Si la destination finale n'est pas l'appareil courant, l'appareil doit acheminer la NPDU de façon appropriée (par l'intermédiaire soit de la dorsale, soit de la DLE associée). Le processus global de décision est montré à la Figure 95. Tous les paquets reçus en provenance de la DLE n'auront pas une entrée d'adresse DL16Address correspondante dans la table ATT. Certains appareils fonctionnant sur la dorsale peuvent ne pas avoir une adresse DL16Address assignée, mais avoir uniquement une adresse IPv6Address. Dans ce cas, la NPDU sera livrée par la DLE locale après avoir été transmise à partir de la DLE distante expéditrice sur un chemin par défaut. Dans ce cas, l'appareil à capacité de dorsale recherchera directement le chemin associé à l'adresse IPv6Address de destination.

NOTE La coordination des BBR pour le réassemblage des paquets de NPDU fragmentées par 6LoWPAN pour l'émission à travers la capacité très limitée de charge utile du sous-réseau D est spécifique au fournisseur et ne relève pas du domaine d'application de la présente norme.

Figure 95 – Traitement d'une NPDU reçue

Les services hypothétiques DD-DATA.indication et DD-DATA.request de la DLE acheminent un paramètre LastHop (LH). Lorsque ce paramètre LH est mis, il indique que la PDU est entrée dans le sous-réseau D par un routeur dorsal, et qu'elle ne doit donc pas sortir du sous-réseau D par un routeur dorsal afin d'éviter les chemins circulaires au sein de la NL. Cette restriction permet à la NLE d'élider le champ Hop Limit d'une NPDU compressée qui utilise le format d'en-tête de base tout en empêchant toujours le routage circulaire.

Lorsque la NPDU est reçue en provenance de la DL à un appareil autre que la destination, si le paramètre LastHop (LH) est mis dans la primitive DD-DATA.indication, la NPDU a atteint l'appareil courant en erreur et doit être rejetée. Si la NPDU est reçue en provenance du sous-réseau D et n'est pas rejetée (voir Figure 95), le routeur intermédiaire doit d'abord étendre complètement l'en-tête du réseau de la NPDU. Comme partie intégrante de cette extension, la valeur de la notification d'encombrement explicite (ECN) fournie par la primitive DD-DATA.indication doit être incluse dans le champ approprié de l'en-tête étendu.

Après toute expansion d'en-tête, la DLE réceptrice doit vérifier pour voir si, oui ou non, le réassemblage (en raison d'une fragmentation antérieure) est nécessaire pour cette NPDU. Une fois que l'éventuel réassemblage nécessaire s'achève, la NPDU doit être préparée pour un routage sur la dorsale. Les adresses DL16Address d'origine (tout premier V) et de destination (destination finale F) dans la primitive DD-DATA.indication doivent être converties en adresses IPv6Addresses. Ensuite, la table de routage doit être utilisée pour déterminer le prochain saut de NL pour atteindre la destination finale. La NPDU doit être présentée à la NLE de l'interface de la dorsale pour le routage sur le réseau dorsal. La présente norme ne spécifie pas comment la dorsale traite et achemine la NPDU. La dorsale a la responsabilité de livrer la NPDU à la NLE du NextHop.

La présente norme utilise toujours ECN. Lorsque la notification d'encombrement est transportée dans un en-tête de DPDU, si les bits ECN sont différents de zéro dans l'en-tête de la NPDU, ils doivent être mis à zéro dans l'en-tête en question pour indiquer que la notification est transportée dans l'en-tête de la DPDU. Une NLE de routeur dorsal qui reçoit une NPDU potentiellement réassemblée provenant de sa DLE associée doit utiliser les informations ECN transportées dans l'en-tête de DPDU reçu pour remplir les bits ECN dans l'en-tête de NPDU étendu. Les NPDU provenant d'appareils de dorsale doivent avoir les bits ECN mis pour indiquer que la notification d'encombrement explicite est utilisée.

Si une NPDU est reçue en provenance de la dorsale, elle aura un en-tête étendu, et les adresses de destination finale et les toutes premières adresses (d'initiateur) seront déjà exprimées sous forme d'adresses IPv6Addresses. Si la NPDU a besoin d'être acheminée sur un sous-réseau D, les adresses DL16Addresses dans le sous-réseau D en question de la toute première DLE (initiatrice) et de la DLE de destination finale doivent être obtenues à partir de la table ATT et passées à la DLE dans la primitive DD-DATA.request. La NLE doit vérifier si le ContractID et la priorité sont respectivement inclus dans les champs FlowLabel et TrafficClass de l'en-tête étendu de la NPDU. Si tel est le cas, le ContractID et la priorité doivent également être passés à la DLE pour permettre la sélection des mécanismes appropriés de routage de DL (GraphID, etc.).

La présence ou l'absence d'encombrement est déterminée à partir du champ ECN de la NPDU reçue en provenance de la dorsale, qui est passée à la DLE locale dans une primitive DD-DATA.request. Lors du passage d'une NPDU avec un en-tête de base à une DLE locale, le paramètre LastHop (LH) doit être mis dans la primitive DD-DATA.request pour indiquer que la NPDU est entrée dans un sous-réseau D dont elle ne peut pas sortir. Si la taille de NPDU excède dlmo.MaxDsduSize pour ce sous-réseau D, la NPDU doit être fragmentée avant le transport sous la forme des DSDU. Ce processus est décrit sous la forme d'un organigramme à la Figure 96.

Figure 96 – Traitement d'une NPDU reçue par une NLE en provenance de la dorsale

Si la NLE réceptrice est la destination finale prévue, la NLE en question doit traiter la NPDU et doit passer à la TLE locale associée la NSDU acheminée, accompagné d'une indication disant si, oui ou non, un encombrement a eu lieu, tel qu'acheminé par les bits ECN de la NPDU. La NLE doit d'abord vérifier si elle a reçu un fragment; si tel est le cas, elle doit accomplir le processus de réassemblage (voir Figure 93). L'adresse IPv6Address source de la NPDU doit être convertie en une adresse IPv6Address, s'il y a lieu, et la NSDU doit être passée à la TLE associée. La Figure 97 décrit l'organigramme pour ce traitement.

Figure 99 – Diagramme de suites de protocoles pour le routage allant d'un appareil de terrain directement vers une passerelle connectée de terrain sans routage dorsal

A la Figure 99, la passerelle est montrée comme ayant un moyen de terrain; aucun réseau dorsal n'est donc impliqué dans cet exemple. Les pointillés bleus (à gauche) représentent le flux de messagerie sur le réseau sur l'interface inférieure (partie du terrain par exemple) de la passerelle, alors que les pointillés verts (à droite) représentent le flux de messagerie sur le réseau sur l'interface supérieure (partie de la gestion opérationnelle par exemple) de la passerelle.

Les opérations des NLE au niveau des appareils que la NPDU traverse (numérotés dans l'ordre) sont comme suit:

a) la NLE dans l'appareil de terrain d'origine utilise un en-tête de base de réseau; l'adresse DL16Address de la passerelle et l'adresse DL16Address de l'appareil lui-même sont obtenues à partir de la table ATT et sont passées à la DLE sous forme d'une DSDU pour acheminement vers la passerelle;

b) la NLE dans la passerelle reçoit la NPDU, vérifie que la NPDU est destinée à la passerelle, convertit l'adresse DL16Address de l'appareil d'origine (fournie par la primitive DD-DATA.indication) en adresse IPv6Address, puis passe la NSDU à la TLE.

10.2.7.2 Routage allant d'un appareil de terrain vers une passerelle en passant par un routeur dorsal

La Figure 100 montre le routage d'une PDU allant d'un appareil de terrain vers une passerelle en passant par un routeur dorsal.

Figure 100 – Routage d'une NPDU allant d'un appareil de terrain vers une passerelle en passant par un routeur dorsal

La Figure 101 montre le flux d'une NPDU allant d'un appareil de terrain vers une passerelle résidant sur le réseau dorsal.

La NPDU est d'abord acheminée vers un routeur dorsal sur le sous-réseau D, et de là vers la passerelle sur la dorsale. L'opération des NLE au niveau des appareils que la NPDU traverse (énumérés dans l'ordre) se présente comme suit:

a) la NLE de l'appareil E/S passe à sa DLE locale sa propre adresse DL16Address comme étant l'adresse source et l'adresse DL16Address de la passerelle comme étant l'adresse de destination finale. Si le ContractTable spécifie que le ContractID a besoin d'être inclus dans la NPDU, l'en-tête activé par contrat est utilisé; autrement, l'en-tête de base est utilisé si la compression utilisée par le transport le permet (voir 10.5.2.1). Si la taille de la NPDU est plus grande que la taille maxDSDU, la NPDU est fragmentée. La NPDU complète (ou l'ensemble de fragments des NPDU) est alors passée sous forme de(s) DSDU à la DLE associée;

b) la DLE achemine la DSDU vers le routeur dorsal. S'il y a eu fragmentation en a), l'ensemble de fragments est réassemblé en la NPDU au niveau du routeur dorsal. La NLE au routeur dorsal reçoit la NPDU et détermine que la NPDU n'est pas destinée au routeur dorsal, car l'adresse de destination finale dans la primitive DD-Data.indication est l'adresse DL16Address de la passerelle. Le routeur dorsal convertit cette adresse DL16Address en adresse IPv6Address de la passerelle désirée, utilise sa table de routage pour déterminer l'adresse de prochain saut pour atteindre la passerelle et crée un en-tête complet (format montré dans le Tableau 216);

c) la NPDU reconstituée avec l'en-tête de réseau étendu est présentée à l'interface de la dorsale. L'interface de la dorsale achemine la NPDU vers sa destination finale. Dans cet exemple, le prochain saut est la destination finale (la passerelle);

d) la NPDU arrive à la NLE de la passerelle sur la dorsale. La NLE à la passerelle détermine que l'adresse de destination finale est égale à l'adresse de la passerelle elle-même et passe la NSDU à sa TLE.

Figure 103 – Diagramme de suites de protocoles pour le routage allant d'un appareil E/S sur un sous-réseau D vers un autre appareil E/S sur un sous-réseau D différent

La NPDU est acheminée sur la dorsale à partir d'un sous-réseau D vers l'autre. Les opérations accomplies par les NLE des appareils à mesure que la NPDU se déplace de l'appareil E/S d'origine (E/S-1) situé dans le sous-réseau D DS-1 vers l'appareil E/S de destination (E/S-2) situé dans le sous-réseau D DS-2 sont comme suit:

a) la NLE au niveau de l'E/S-1 crée la NPDU en utilisant l'en-tête de réseau activé par contrat. La NLE passe la NPDU à la DLE associée comme une DSDU, accompagnée de l'adresse DL16Address de l'E/S-1 au sein de DS-1 comme étant l'adresse de source, et l'adresse DL16Address de l'E/S-2 au sein de DS-1 comme étant l'adresse de destination finale, par l'intermédiaire de la primitive hypothétique DD-DATA.request. Le ContractID est placé dans le champ FlowLabel de l'en-tête activé par contrat;

b) la(les) DPDU qui en résulte(nt) est(sont) acheminée(s) sur DS-1 et arrive(nt) à la DLE de BBR-1, à savoir, le routeur dorsal dans DS-1. Les charges utiles de DPDU sont utilisées pour régénérer la NPDU, qui est vérifiée pour voir si elle est destinée au BBR-1 lui-même. Comme elles ne sont pas destinées au BBR-1, les adresses DL16Addresses de l'E/S-1 et de l'E/S-2 dans la primitive hypothétique DD-DATA.indication sont converties en leurs adresses IPv6Addresses;

c) l'en-tête étendu (au format défini dans le Tableau 216) est créé et présenté à l'interface de la dorsale. Le prochain saut pour cette NPDU sur la dorsale est déterminé en recherchant l'adresse IPv6Address de la destination finale dans la table RT. La RT retourne l'adresse IPv6Address du BBR-2 (le routeur dorsal de DS-2) comme étant le prochain saut, car BBR-2 est le routeur dorsal desservant l'E/S -2. Le ContractID est placé dans le champ FlowLabel de l'en-tête étendu. La priorité de la PDU est placée dans le champ TrafficClass;

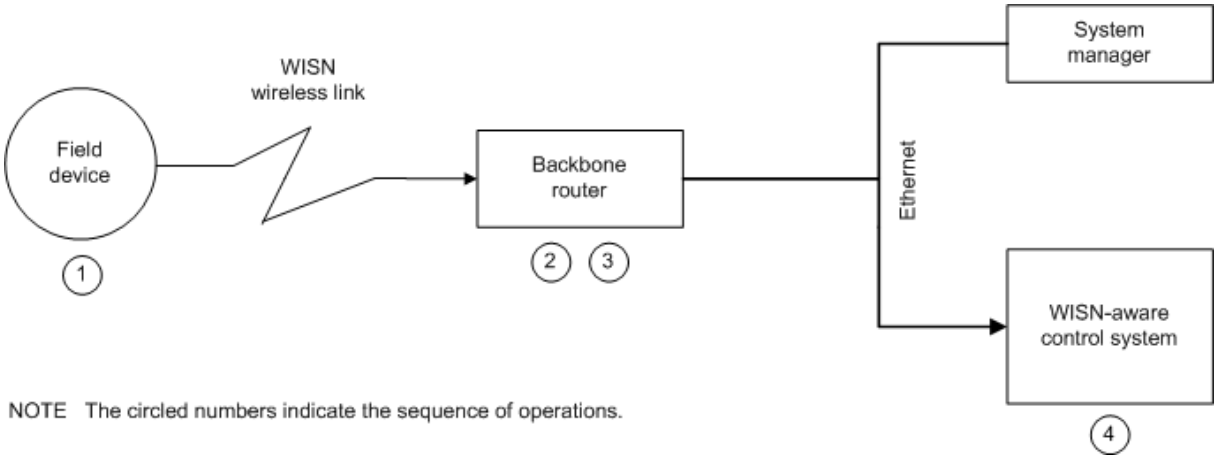
d) la NLE au niveau du BBR-2 reçoit la NPDU sur la dorsale. La NPDU indique que la destination finale est l'adresse IPv6Address de l'E/S-2. Cette NPDU est alors préparée pour le routage sur DS-2 pour atteindre l'E/S-2;

e) la NLE au niveau du BBR-2 crée un en-tête de base de NPDU. Dans la primitive hypothétique consécutive DD-DATA.request, l'adresse DL16Address de l'E/S -1 dans DS-2 est l'adresse d'origine et l'adresse DL16Address de l'E/S-2 dans DS-2 est la destination finale. Le ContractID, extrait du champ FlowLabel de l'en-tête étendu, et la priorité, extraite de TrafficClass, sont également passés à la DL pour permettre la sélection des ressources appropriées de routage (GraphID, etc.);

f) la NPDU arrive à la NLE de l'E/S-2. Comme la destination finale indiquée dans la primitive hypothétique DD-DATA.indication est l'adresse DL16Address de l'E/S -2 dans DS-2, la NLE convertit les adresses en une adresse IPv6Address et passe la NSDU à la TL de l'E/S-2.

10.2.7.4 Exemple de routage sur un réseau dorsal Ethernet

La Figure 104 est un exemple de mise en œuvre du diagramme de suites de protocoles montrée à la Figure 103. Dans ce réseau, un appareil de terrain communique avec un système de commande qui est compatible avec le protocole natif de la présente norme; le réseau dorsal dans cet exemple est un réseau Ethernet transportant le trafic IPv6.



Légende

Figure 104 – Exemple de routage sur un réseau dorsal Ethernet

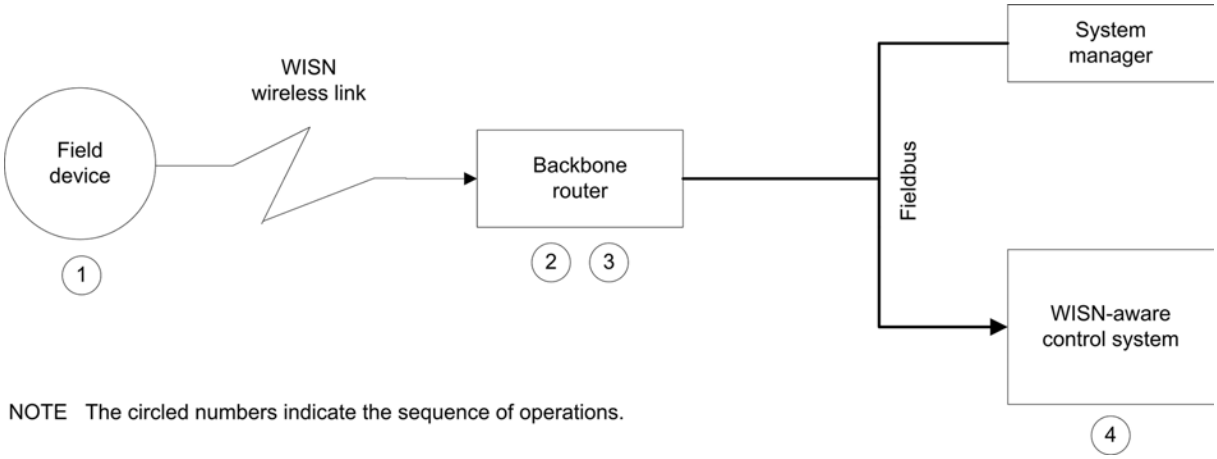
Les cercles numérotés à la Figure 104 indiquent les étapes du processus de routage et l'endroit où elles se produisent:

1) la NLE au niveau de l'appareil de terrain crée une NPDU et la remet à la DLE associée pour émission vers le prochain saut de NL (routeur dorsal). L'adresse de destination finale de la DPDU est l'adresse DL16Address pour le système de commande compatible avec le protocole natif. La maille de DL livre la NPDU à la NLE du routeur dorsal;
2) le routeur dorsal reçoit la NPDU, convertit les adresses DL16Addresses en adresses IPv6Addresses correspondantes et étend la NPDU en une NPDU IPv6 complète;
3) le routeur dorsal envoie la NPDU IPv6 sur l'interface d'Ethernet;
4) la NLE au niveau du système de commande reçoit la NPDU IPv6 issue de son interface d'Ethernet, accomplit le traitement de la NL et passe la NSDU à la TLE.

10.2.7.5 Exemple de routage sur un réseau dorsal

La Figure 105 est une variante de la Figure 104 qui substitue un bus de terrain générique au réseau dorsal Ethernet. Dans cette variante, la NPDU IPv6 est encapsulée à des fins de transport sur le réseau de bus de terrain via une ou plusieurs PDU de bus de terrain.

NOTE Il existe d'autres variantes de ce scénario de réseau dorsal de bus de terrain.



NOTE The circled numbers indicate the sequence of operations.

L'adresse de destination finale de la DPDU est l'adresse DL16Address pour le système de commande compatible avec le protocole natif. La maille de DL livre la NPDU à la NLE du routeur dorsal;
2) le routeur dorsal reçoit la NPDU, convertit les adresses DL16Addresses en adresses IPv6Addresses correspondantes et étend la NPDU en une NPDU IPv6 complète;
3) le routeur dorsal encapsule la NPDU entière dans une ou plusieurs PDU de bus de terrain adressées au système de commande;
4) le système de commande (passerelle) reçoit la (ou les) PDU de bus de terrain, extrait la NPDU, accomplit le traitement de la NL et livre la NSDU à la TLE associée.

10.3 Services de données de NLE

10.3.1 Généralités

La TLE utilise l'interface NDSAP de la NLE pour envoyer et recevoir des données. Cette interface est interne à un appareil conforme et est donc hypothétique et ne peut pas être soumise à essai. Les NSAP internes de l'appareil sont décrits à la Figure 16.

Toutes les interfaces entre la NLE et ses NME ou la TLE adjacente et la DLE sont des interfaces internes au sein de l'appareil, et sont donc inobservables. Par conséquent, elles ne sont pas soumises à une normalisation. Ainsi, toute cette description est hypothétique.

10.3.2 N-Data.request

10.3.2.1 Généralités

La primitive N-DATA.request est utilisée par une TLE pour demander à la NLE d'émettre une TSDU.

10.3.2.2 Sémantique

La sémantique de la primitive N-DATA.request se présente comme suit:

```
N-DATA.request   (
                 DestAddress,
                 ContractID,
                 Priority,
                 DE,
                 NSDU,
                 NSDUSize,
                 NSDUHandle,
                 ECN
                 )
```

Le Tableau 203 spécifie les éléments pour la primitive N-DATA.request.

Tableau 203 – Eléments pour la primitive N-Data.request

Nom du type de données normalisé: N-Data.request		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
DestAddress (l'adresse IPv6Address de la NLE de destination pour la NSDU)	1	Type: Adresse de l'appareil
ContractID (l'ID de contrat associé aux ressources devant être utilisées pour émettre cette NPDU; cet ID est passé directement à la DLE)	2	Type: Unsigned16 Valeurs nommées: 0 indique l'absence de contrat
Priority (priorité du message au sein du contrat) [a]	3	Type: Unsigned2
DE (indique si la PDU est éligible au rejet)	4	Type: Unsigned1
NSDU (le jeu d'octets formant la NSDU devant être émise par la NL, y compris les en-têtes de transport)	5	Type: OctetString
NSDUSize (le nombre d'octets dans la NSDU devant être émise)	6	Type: Unsigned16
NDSUHandle (le descripteur associé à la NSDU devant être émise)	7	Type: Unsigned16
ECN (notification d'encombrement explicite)	8	Type: Unsigned2
[a] La NLE doit combiner cette priorité avec la priorité de contrat à 2 bits pour coder la priorité D sous la forme d'un champ de 4 bits avant de la passer à la DLE.		

10.3.2.3 Utilisation appropriée

La TLE invoque N-DATA.request pour demander que la NLE émette une NSDU.

10.3.2.4 Effet à la réception

A la réception de N-DATA.request, la NLE construit les en-têtes de NL de NPDU, d'abord en élidant le premier octet du LoWPAN_NHC de la NSDU si l'en-tête de base est utilisé, puis en fragmentant la NPDU (s'il y a lieu), et en l'acheminant vers la DLE pour émission sur le sous-réseau D local. Si ContractID est égal à zéro, la NLE traite la NSDU comme étant une PDU relative au rattachement avec une adresse EUI64Address de destination associée, pour

laquelle l'adresse IPv6Address de destination exigée est dérivée de l'adresse locale à une liaison passée sous forme du paramètre DestAddress.

10.3.3 N-Data.confirm

10.3.3.1 Généralités

La primitive N-DATA.confirm est utilisée pour rapporter le résultat d'une primitive N-DATA.request.

10.3.3.2 Sémantique

La sémantique de la primitive N-DATA.confirm se présente comme suit:

```
N-Data.confirm    (
                  NSDUHandle,
                  status
                  )
```

Le Tableau 204 spécifie les éléments pour la primitive N-DATA.confirm.

Tableau 204 – Eléments pour la primitive N-Data.confirm

Nom de l'élément	Identificateur de l'élément	Type scalaire de l'élément
NSDUHandle (le descripteur de la NSDU dont le statut est rapporté)	1	Type: Unsigned16
Status (le résultat de la primitive N-DATA.request qui a acheminé la NSDU)	2	Type: Unsigned Valeurs nommées: 0: réussite

10.3.3.3 Moment de sa génération

La NLE génère une primitive N-DATA.confirm comme réponse différée à une primitive N-DATA.request. La primitive N-DATA.confirm retourne un statut vers la TLE qui indique soit SUCCESS (réussite), soit FAILURE (échec).

10.3.3.4 Utilisation appropriée

La primitive N-DATA.confirm notifie à la TLE le résultat de sa demande d'émission d'une NSDU.

10.3.4 N-Data.indication

10.3.4.1 Généralités

La primitive N-DATA.indication est utilisée par une NLE pour livrer à une TLE associée une TSDU reçue.

10.3.4.2 Sémantique

La sémantique de la primitive N-DATA.indication se présente comme suit:

```
N-Data.indication (
                  SrcAddress,
                  DestAddress,
                  NSDU,
                  NSDUSize,
                  ECN,
                  Priority
                  )
```

Le Tableau 205 spécifie les éléments pour la primitive N-DATA.indication.

Tableau 205 – Eléments pour la primitive N-Data.indication

Nom de l'élément	Identificateur de l'élément	Type scalaire de l'élément
SrcAddress (l'adresse IPv6Address de la source de la NSDU)	1	Type: Adresse de l'appareil
DestAddress (l'adresse IPv6Address de la destination de la NSDU, par exemple la propre adresse IPv6Address de l'appareil)	2	Type: Adresse de l'appareil
NSDU (la NSDU reçue, y compris les en-têtes de TL associés)	3	Type: Séquence d'octets
NSDUSize (le nombre d'octets dans la NSDU reçue)	4	Type: Unsigned16
ECN (informations relatives à la notification d'encombrement explicite issues de la NSDU reçue)	5	Type: BitArray4
Priority (priorité de NPDU de 4 bits telle que reçue)	6	Type: Unsigned4

10.3.4.3 Utilisation appropriée

La NLE invoque la primitive N-DATA.indication pour notifier à la TLE associée une NSDU reçue et les informations associées relatives à l'acheminement. Si la NPDU reçue contient un en-tête de base, alors, avant de passer la NSDU à la TLE, la NLE restaure (ajoute en préfixe) le premier octet de la NSDU comme LoWPAN_NHC (= 0x 1111 0111), qui avait été élidé lorsque l'en-tête de base avait été construit. Si l'adresse D source reçue en provenance de la DLE sous-jacente est une adresse EUI64Address, une adresse IPv6Address locale à une liaison est construite à partir de l'adresse EUI64Address et elle est passée comme paramètre SrcAddress de la primitive N-DATA.indication. Le paramètre DestAddress de la primitive N-DATA.indication est l'adresse IPv6Address locale à une liaison de l'appareil lorsqu'elle est utilisée pour les APDU relatives au rattachement, ou l'adresse IPv6Address globalement assignée pour le fonctionnement ultérieur au rattachement.

10.3.4.4 Effet à la réception

A la réception d'une primitive N-DATA.indication, la TLE peut traiter la NSDU rapportée.

10.4 Objet de gestion de NL

10.4.1 Base d'informations de gestion de NL

Le Tableau 206 spécifie les attributs de l'objet de gestion de NL (NLMO).

Tableau 206 – Attributs de NLMO *(1 de 4)*

Nom du type d'objet normalisé: NL management object (NLMO, objet de gestion de NL)				
Identificateur du type d'objet normalisé: 123				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Type d'attribut**	**Description du comportement de l'attribut**
Backbone_Capable	1	Indicateur booléen indiquant si l'appareil est à capacité de dorsale	Type: Boolean1 Classification: Static Accessibilité: Lecture seule	Valeur fixe basée sur les capacités de l'appareil et sur les détails de mise en œuvre. La capacité de dorsale peut être omise par un gestionnaire de système
DL_Capable	2	Indicateur booléen indiquant si l'appareil est capable de communiquer sur le support de Type A sans fil de la présente norme	Type: Boolean1 Classification: Static Accessibilité: Lecture seule	Valeur fixe basée sur les capacités de l'appareil et sur les détails de mise en œuvre. La capacité d'interface de DL peut être omise par un gestionnaire de système
DL16Address	3	L'adresse DL16Address de l'appareil	Type: DL16Address Classification: Static Accessibilité: Lecture/écriture Plage valide: 1.. 2^{15} -1	Une valeur fixe telle qu'assignée par le gestionnaire de système au moment du rattachement.[a] Cet attribut est un doublon des attributs correspondants dans le DMO et le DLMO
Long_Address	4	L'adresse IPv6Address de l'appareil	Type: IPv6Address Classification: Static Accessibilité: Lecture/écriture Plage valide: toutes les valeurs avec réglage sur bit de poids fort	Une valeur fixe telle qu'assignée par le gestionnaire de système au moment du rattachement.[a] Cet attribut est un doublon des attributs correspondants dans le DMO et le DLMO
Route_Table	5	La table de routage qui inclut les informations pour acheminer une NPDU	Type: Array of NLRouteTbl structures (voir NLRouteTbl) Classification: Static Accessibilité: Lecture/écriture Plage valide: Voir Tableau 208	La table de routage est constituée d'une adresse de destination, d'un prochain saut de réseau pour la destination en question et du nombre de sauts de réseau nécessaires. La structure de la table de routage et ses alertes et méthodes correspondantes sont débattues en 10.2.6.2. La taille de la table de routage présente dans des appareils qui fonctionnent seulement au sein du sous-réseau D et ne sont pas à capacité de dorsale est présentée dans le Tableau B.18
Enable_Default_Route	6	Une valeur booléenne mise pour indiquer si un routage par défaut est activé	Type: Boolean1 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: Désactivé	Permet un chemin par défaut

Tableau 206 *(2 de 4)*

Nom du type d'objet normalisé: NL management object (NLMO, objet de gestion de NL)				
Identificateur du type d'objet normalisé: 123				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Type d'attribut**	**Description du comportement de l'attribut**
Default_Route_Entry	7	Adresse de destination associée au chemin par défaut	Type: IPv6Address Classification: Static Accessibilité: Lecture/écriture	L'attribut peut être utilisé pour rechercher le chemin par défaut dans la table de routage. Des paquets qui incluent une adresse de destination sans l'entrée correspondante dans la table de routage doivent être transmis en utilisant le chemin par défaut. Les appareils de terrain peuvent utiliser le chemin par défaut pour envoyer des paquets vers des appareils fonctionnant sur la dorsale qui n'ont pas d'adresse assignée de 16 bits mais seulement des adresses IPv6Addresses
Contract_Table	8	Inclut des informations pour construire l'en-tête de réseau pour un flux de PDU particulier	Type: Array of NLContractTbl structures (voir NLContractTbl) Classification: Static Accessibilité: Lecture/écriture Plage valide: Voir Tableau 207	La table de contrat consiste en l'adresse de destination, priorité pour un flux particulier. La table inclut également des informations indiquant si, oui ou non, un ContractID a besoin d'être transporté dans la NPDU. La portée d'un ID de contrat est locale à un appareil, mais la combinaison d'une adresse de source (128 bits) et du ContractID est unique au niveau global. La structure de la table de contrat et ses alertes et méthodes correspondantes sont débattues ci-dessous
Address_Translation_Table	9	Inclut l'adresse IPv6Address et le pseudonyme DL16Address pour les adresses IPv6Addresses	Type: Array of NLATTbl structures (voir NLATTbl) Classification: Static Accessibilité: Lecture/écriture Plage valide: Voir Tableau 209	La table de conversion d'adresse dans un appareil est indexée par l'adresse IPv6Address et stocke le pseudonyme DL16Address correspondant dans le sous-réseau D auquel l'appareil appartient

Tableau 206 *(3 de 4)*

Nom du type d'objet normalisé: NL management object (NLMO, objet de gestion de NL)				
Identificateur du type d'objet normalisé: 123				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Type d'attribut**	**Description du comportement de l'attribut**
Max_NSDU_size	10	Taille maximale de l'unité de données de service prise en charge par la NL de l'appareil	Type: Unsigned16 Classification: Constant	Valeur fixe basée sur les capacités mémoire de l'appareil et sur les détails de mise en œuvre. La valeur 1 280 est issue de l'IETF RFC 4944. Voir 6.2.8 concernant la façon dont cette valeur peut nécessiter une fragmentation au niveau de l'AL. Les NSDU qui dépassent la valeur maximale peuvent être rejetées par l'appareil
			Accessibilité: Lecture seule	
			Valeur par défaut: 70	
			Plage valide: 70..1 280	
Frag_Reassembly_Timeout	11	Quantité de temps (en secondes) dont a besoin un tampon de réassemblage pour être maintenu ouvert afin que les fragments y pénètrent avant de rejeter la NPDU	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 60 Plage valide: 1..600	La valeur par défaut est 60 s, mais le gestionnaire de système peut changer cette valeur
Frag_Datagram_Tag	12	Numéro d'étiquette actuel pour la fragmentation au niveau de l'appareil	Type: Unsigned16 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: Aléatoire uniforme	Un nouveau numéro d'étiquette est utilisé pour chaque NPDU qui a besoin d'être fragmentée. Le numéro d'étiquette est incrémenté de 1 pour chaque NPDU devant être fragmentée. La valeur revient à zéro après 65 535
NLRouteTblMeta	13	Métadonnées pour l'attribut Route Table (attribut 5)	Type: Metadata_attribute Classification: Static Accessibilité: Lecture seule	Métadonnées contenant un compte du nombre d'entrées dans la table et la capacité (le nombre total de rangées autorisées) pour cette table. La taille de la table de routage présente dans des appareils qui fonctionnent seulement au sein du sous-réseau D et ne sont pas à capacité de dorsale est présentée dans le Tableau B.18

Identificateur du type d'objet normalisé: 123				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Type d'attribut**	**Description du comportement de l'attribut**
NLContractTblMeta	14	Métadonnées pour l'attribut Contract Table (attribut 8)	Type: Metadata_attribute Classification: Static Accessibilité: Lecture seule	Métadonnées contenant un compte du nombre d'entrées dans la table et la capacité (le nombre total de rangées autorisées) pour cette table.
NLATTblMeta	15	Métadonnées pour l'attribut Address Translation Table (attribut 9)	Type: Metadata_attribute Classification: Static Accessibilité: Lecture seule	Métadonnées contenant un compte du nombre d'entrées dans la table et la capacité (le nombre total de rangées autorisées) pour cette table.
DroppedNPDUAlertDescriptor	16	Décrit comment une alerte NPDU abandonnée est rapportée sur le réseau	Type: Alert report descriptor Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: [true, 7]	-

[a] L'attribut doit rester inchangé au cours du fonctionnement normal; seul un gestionnaire de système peut le modifier. L'assignation d'une nouvelle adresse DL16Address doit déclencher un Join_Command = 3, restartAsProvisioned, à la suite de quoi l'appareil doit effectuer un nouveau rattachement au réseau sans fil.

10.4.2 Bases d'informations de gestion structurées

Le NLMO définit trois bases d'informations de gestion structurées (SMIB) sous forme de tables. Ce sont la table de contrat, la table de routage (RT) et la table de conversion d'adresse (ATT).

Le Tableau 207 spécifie les éléments pour la table de contrat. Les appareils qui ne sont pas à capacité de dorsale peuvent élider le champ Source_Address.

10.4.3 Méthodes de l'objet de gestion de NL

Les méthodes normalisées telles que la lecture (read) et l'écriture (write) peuvent être utilisées pour les MIB scalaires ou structurées dans leur intégralité. Ces méthodes sont utilisées pour manipuler des tables. Elles permettent l'accès à une rangée particulière d'une MIB structurée en fonction d'un champ indice unique. Tous les appareils doivent être capables de manipuler immédiatement les attributs de NLMO. Les appareils prennent en charge la manipulation différée de ces attributs en utilisant des méthodes de basculement, mais ne sont pas tenus de le faire.

Il est supposé que les tables ont un champ indice unique, qui peut être soit un seul élément, soit la concaténation de plusieurs éléments. Le champ indice est supposé être le(s) (quelque(s)) premier(s) élément(s) de la table ou la concaténation des quelques premiers éléments de la table. Par exemple, le champ indice de la table de contrat est la concaténation du Contract_ID et Source_Address.

Ces méthodes ne spécifient pas l'interface entre la NME et le NLMO, car cette interface est interne à un appareil particulier. L'entité de gestion peut garder des copies locales des MIB.

Le Tableau 210 décrit les méthodes pour la manipulation des MIB structurées. Ces méthodes sont basées sur les modèles Read_Row, Write_Row, et Delete_Row définis en Annexe J.

Tableau 210 – Méthodes de manipulation des MIB structurées du NLMO

Nom du type d'objet normalisé: NL management object (NLMO, objet de gestion de NL)		
Identificateur du type d'objet normalisé: 123		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Set_row_RT	1	Méthode pour établir (soit ajouter, soit modifier) la valeur d'une seule rangée de la table de routage. La méthode utilise le modèle de méthode Write_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 5 (table de routage) Index 1: 1 (Destination_address)
Get_row_RT	2	Méthode pour obtenir la valeur d'une seule rangée de la table de routage. La méthode utilise le modèle de méthode Read_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 5 (table de routage) Index 1: 1 (Destination_address)
Delete_row_RT	3	Méthode pour supprimer une seule rangée de la table de contrat. La méthode utilise le modèle de méthode Delete_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 5 (table de routage) Index 1: 1 (Destination_address)
Set_row_ContractTable	4	Méthode pour établir (soit écrire, soit modifier) la valeur d'une seule rangée de la table de contrat. La méthode utilise le modèle de méthode Write_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 8 (table de contrat) Index 1: 1 (ContractID) Index 2: 2 (Source Address)
Get_row_ContractTable	5	Méthode pour obtenir la valeur d'une seule rangée de la table de contrat. La méthode utilise le modèle de méthode Read_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 8 (table de contrat) Index 1: 1 (ContractID) Index 2: 2 (Source Address)
Delete_row_ContractTable	6	Méthode pour supprimer la valeur d'une seule rangée de la table de contrat. La méthode utilise le modèle de méthode Delete_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 8 (table de contrat) Index 1: 1 (ContractID) Index 2: 2 (Source Address)
Set_row_ATT	7	Méthode pour établir (soit ajouter, soit modifier) la valeur d'une seule rangée de la table de conversion d'adresse. La méthode utilise le modèle de méthode Write_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 9 (table de conversion d'adresse) Index 1: 1 (Long Address)
Get_row_ATT	8	Méthode pour obtenir la valeur d'une seule rangée de la table de conversion d'adresse. La méthode utilise le modèle de méthode Read_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 9 (table de conversion d'adresse) Index 1: 1 (Long Address)

Nom du type d'objet normalisé: NL management object (NLMO, objet de gestion de NL)

Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Delete_row_ATT	9	Méthode pour supprimer une seule rangée de la table de conversion d'adresse. La méthode utilise le modèle de méthode Delete_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID: 9 (table de conversion d'adresse) Index 1: 1 (Long Address)

Le Tableau 211 décrit l'alerte pour indiquer une PDU abandonnée/erreur de PDU.

Tableau 211 – Alerte pour indiquer une PDU abandonnée/erreur de PDU

Nom du type d'objet normalisé: NL management object (NLMO, objet de gestion de NL)					
Identificateur du type d'objet normalisé: 123					
Description de l'alerte: Alerte pour indiquer une PDU abandonnée/erreur de PDU					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: haut, moyen, faible, journal seulement)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = Event	1 = Comm. diagnostic	0 = NL_Dropped_PDU	7 =Medium	Type: OctetString	La valeur est une chaîne d'octets constituée d'au moins deux octets. Le premier octet (Unsigned8) spécifie la taille du champ valeur inclus avec l'alerte en octets. Le second octet (Unsigned8) achemine la classe de diagnostic. Valeurs nommées: 0: réservé; 1: destination inaccessible; 2: erreur de fragmentation; 3: temporisation de réassemblage; 4: limite de saut atteinte; 5: erreurs d'en-tête; 6: pas de chemin, prochain saut inaccessible; 7: mémoire insuffisante; 8: taille de NPDU trop large; 9..255: réservés. Les octets restants incluent l'en-tête de NPDU pour la PDU abandonnée

10.5 Formats de NPDU

10.5.1 Généralités

Chaque NPDU doit être constituée de deux composantes de base:

- Un en-tête de réseau comportant probablement l'adressage, la classe de service ((CoS), et les champs de fragmentation.
- Une charge utile de réseau de taille variable contenant les données qui ont besoin d'être émises.

La présente norme doit permettre trois formats différents d'en-tête de NPDU:

– l'en-tête de base;

– l'en-tête activé par contrat; et

– l'en-tête complet.

Les appareils conformes à la présente norme doivent utiliser des préfixes d'expédition (les 3 bits de poids faible du premier octet de la NPDU) pour distinguer entre ces formats d'en-tête (voir Figure 106). Le préfixe 000 doit indiquer que le format d'en-tête de NPDU est l'en-tête de base. Le préfixe d'en-tête de base se conforme au NALP dispatch de 6LoWPAN.

Le préfixe 011 doit indiquer l'en-tête activé par contrat. L'en-tête activé par contrat se conforme au LOWPAN_IPHC dispatch de 6LoWPAN.

Le préfixe 010 doit indiquer le format d'en-tête complet. Les appareils à ressources contraintes qui opèrent dans le sous-réseau D sans fil et sont à capacité de dorsale peuvent construire l'en-tête complet, mais ne sont pas tenus de le faire. Si un paquet qui est construit en utilisant l'en-tête complet est reçu par un appareil qui n'est pas à capacité de dorsale, l'appareil peut rejeter la NPDU et envoyer une alerte PDU abandonnée/erreur de PDU avec la valeur 5 indiquant une erreur d'en-tête.

Enfin, un préfixe de 110 ou de 111 doit indiquer que la PDU est un fragment d'une plus grande NPDU qui a besoin d'être réassemblée.

La présente norme utilise principalement des adresses de 16 bits pour la toute première destination (initiateur) et la destination finale dans les DPDU émises sur le réseau sans fil selon l'IEEE 802.15.4. Par conséquent, il convient que l'en-tête de réseau soit au format d'en-tête de base ou au format d'en-tête activé par contrat pour les NPDU émises sur les liaisons sans fil selon l'IEEE 802.15.4. Il convient, bien que cela ne soit pas interdit, de ne pas utiliser le format d'en-tête complet pour l'émission de NPDU sur le moyen de terrain.

Figure 106 – Distinction entre les formats d'en-tête de NPDU

Les profils des bits d'octet dispatch sont montrés dans le Tableau 212.

Tableau 212 – Profils d'en-tête communs

Profil de dispatch	Type d'en-tête
000xxxxx	NALP (NPDU Not A 6LoWPAN) – En-tête de base
010xxxxx	IPv6 (en-tête IPv6 décompressé) – En-tête complet
011xxxxx	LoWPAN_IPHC (en-tête IPv6 compressé) – En-tête activé par contrat
11xxxxxx	LoWPAN fragment

Les en-têtes de NL doivent suivre les formats définis dans le présent document.

10.5.2 Format d'en-tête de base pour NL

10.5.2.1 Usage prévu

La DL de la présente norme utilise une maille de niveau liaison. Dans le cas le plus commun, une PDU traversera un seul sous-réseau D, si bien que l'en-tête de base est optimisé pour réduire au maximum le surdébit de NPDU. Le chemin qui a besoin d'être pris par la PDU est connu de l'appareil d'entrée dans le sous-réseau D; cet appareil d'entrée prend toutes les décisions nécessaires relatives au routage de DL. Le ContractID n'est pas émis dans l'en-tête de réseau de base.

L'en-tête de base pour la NL doit être utilisé seulement si l'en-tête de protocole datagramme d'utilisateur (UDP) est complètement comprimé (à savoir, les numéros de port source et destination sont compressés à quatre (4) bits chacun et la somme de contrôle de l'UDP est élidée). Le NL peut déterminer si, oui ou non, l'en-tête d'UDP est complètement comprimé en regardant l'octet LOWPAN_NHC, qui est toujours le premier octet de la NSDU passée à la NL par la TL. Sachant que l'en-tête de base est utilisé seulement en cas d'en-tête UDP complètement comprimé (à savoir, la valeur fixe et connue de LOWPAN_NHC de l'UDP), l'octet LOWPAN_NHC de l'UDP doit être élidé par la NL d'origine et restauré par la NL de destination.

10.5.2.2 Format

Le Tableau 213 décrit le format d'en-tête de réseau de base.

Tableau 213 – Format d'en-tête de NL de base

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Dispatch							
(variable)	Charge utile de réseau							

L'en-tête de NL de base doit être constitué d'un seul champ Dispatch comme suit:

- Dispatch: le champ dispatch indique le format d'en-tête de NL. Pour l'en-tête de base, le champ dispatch doit avoir la valeur de 0x 0000 0001.

10.5.2.3 Relation à 6LoWPAN

Le format 6LoWPAN permet à tous les champs de l'en-tête IPv6 complet d'être élidés. Les octets dispatch et de codage pour ce faire sont:0x0111 1110 0111 0111, ce qui indique (lorsqu'analysés comme étant 011.11.1.10.0.1.11.0.1.11):

- Dispatch = 011;
- TF = 11 (classe de trafic et étiquette de flux toutes deux élidées);
- NH = 1 (prochain champ d'en-tête élidé);
- HLIM = 10 (HopLimit = 64);
- CID = 0 (absence d'extension d'identificateur de contexte);
- SAC = 1 (compression d'adresse source avec états; la table ATT fournit le contexte);
- SAM = 11 (adresse source complètement élidée);
- M = 0 (pas de multidiffusion);
- DAC = 1 (compression d'adresse de destination avec états; la table ATT fournit le contexte);
- DAM = 11 (adresse de destination complètement élidée).

Le format 6LoWPAN permet également à l'en-tête d'UDP d'être comprimé, si bien que les numéros de port source et destination sont de quatre (4) bits chacun et la somme de contrôle est élidée. Dans ce cas, le champ LOWPAN_NHC de l'UDP a la valeur 0x 1111 0111, ce qui indique (lorsqu'analysée comme étant 11110.1.11):

– protocole = 11 110 (UDP);
– compression de somme de contrôle = 1 (somme de contrôle élidée);
– compression de port = 11 (les ports source et destination sont compressés en quatre (4) bits chacun et leur préfixe implicite est 0xF0B).

L'en-tête de base est essentiellement une abréviation d'un seul octet pour les trois octets (deux octets d'en-tête IP complètement compressés et un octet de l'en-tête UDP complètement compressé) notés ci-dessus. Comme il s'agit d'une abréviation, elle est totalement compatible avec le format 6LoWPAN. Un appareil recevant une NPDU d'en-tête de base peut étendre l'octet dispatch d'en-tête de base aux trois octets susmentionnés et obtenir une PDU conforme à 6LoWPAN.

10.5.3 Format d'en-tête de réseau activé par contrat

10.5.3.1 Usage prévu

Tout comme l'en-tête de base, l'en-tête de réseau activé par contrat est prévu pour une utilisation au sein de sous-réseaux D. Le tout premier appareil (initiateur) d'une NPDU peut utiliser l'en-tête activé par contrat en lieu et place de l'en-tête de base s'il est souhaitable que les appareils autres que le tout premier appareil (initiateur) aient connaissance du flux de NPDU auquel la NPDU appartient. Par exemple, un routeur intermédiaire sur la dorsale peut avoir besoin de choisir:

- des ressources de dorsale appropriées à la sortie d'un sous-réseau D d'origine; ou
- des ressources de DL appropriées (ID de graphe, priorité, etc.) à l'entrée d'un sous-réseau D de destination.

Le contrat inclut un fanion pour indiquer à la NL d'origine si, oui ou non, l'en-tête de réseau exige l'inclusion du ContractID.

L'en-tête activé par contrat doit également être utilisé si le LOWPAN_NHC de l'UDP n'indique pas la complète compression de l'en-tête UDP. Les messages du processus de rattachement entre le nouvel appareil et le routeur d'annonce s'inscriront toujours dans cette catégorie, car ils n'élident pas la somme de contrôle UDP.

10.5.3.2 Format

Le Tableau 214 décrit le format d'en-tête activé par contrat.

Tableau 214 – Format d'en-tête de NL activé par contrat

<table>
<tr><th rowspan="2">Nombre d'octets</th><th colspan="8">Bits</th></tr>
<tr><th>7</th><th>6</th><th>5</th><th>4</th><th>3</th><th>2</th><th>1</th><th>0</th></tr>
<tr><td rowspan="2">2</td><td colspan="3">Dispatch LOWPAN_IPHC</td><td colspan="5">Codage de LOWPAN_IPHC (bits 8..12)</td></tr>
<tr><td colspan="8">Codage de LOWPAN_IPHC (bits 0..7)</td></tr>
<tr><td rowspan="3">0 ou 3</td><td colspan="4">Reserved</td><td colspan="4">FlowLabel (bits16..19)</td></tr>
<tr><td colspan="8">Flow Label (bits 8..15)</td></tr>
<tr><td colspan="8">Flow Label (bits 0..7)</td></tr>
<tr><td>0..1</td><td colspan="8">HopLimit</td></tr>
<tr><td>(variable)</td><td colspan="8">Charge utile de réseau</td></tr>
</table>

Les champs comprennent:

- Dispatch LOWPAN_IPHC: ce champ doit indiquer que le format d'en-tête est "contract-enabled" (activé par contrat) et que les bits de codage de compression d'en-tête LOWPAN_IPHC suivent. Le champ dispatch LOWPAN_IPHC doit être 011.
- Codage de LOWPAN_IPHC: ce champ a une longueur de 13 bits; sa valeur doit être codée comme étant 0x0 11HH 0111 0111 où les octets 3..5 sont présents pour transporter l'ID de contrat, ou comme étant 0x1 11HH 0111 0111 où les octets 3..5 sont élidés. Dans un cas comme dans l'autre, HH doit avoir la valeur 00 si HopLimit est transporté porté en ligne, 01 si la limite de saut est 1, 10 si la limite de saut est 64 et 11 si la limite de saut est 255.
- FlowLabel: les 16 bits de poids faible de FlowLabel doivent être mis à ContractID. Les 4 bits de poids fort doivent être tous des zéros. Ce champ doit être présent seulement si les octets 3 à 5 sont présents, comme l'indique le codage de LOWPAN_IPHC.
- HopLimit: ce champ doit indiquer le nombre de sauts de la couche 3 autorisés avant que la NPDU ne soit rejetée. Le champ HopLimit doit être mis à une valeur indiquée par la table de routage de l'appareil (RT; voir 10.2.6.2). La valeur par défaut du champ HopLimit doit être 64. Les appareils qui fonctionnent seulement au sein du sous-réseau D et ne sont pas à capacité de dorsale doivent mettre le champ HopLimit à 1. De la perspective de la NL, tout appareil joignable par l'intermédiaire de la maille de DL est à un seul saut de réseau de distance.

Pour les messages du processus de rattachement, le codage de LOWPAN_IPHC doit avoir la valeur 0x1 1101 0111 0111 pour indiquer que les octets 3 à 5 sont élidés (pas d'ID de contrat) et que la limite de saut est 1 (champ HopLimit élidé).

10.5.3.3 Relation à 6LoWPAN

Le Tableau 215 montre le format de codage de 6LoWPAN_IPHC.

Tableau 215 – Format de codage de 6LoWPAN_IPHC

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	0	1	1	TF		NH	HLIM	
1	CID	SAC	SAM		M	DAC	DAM	
…	Champs non compressés							

Le codage pour l'en-tête de NL activé par contrat est dérivé en utilisant les valeurs suivantes pour les champs de codage de 6LoWPAN_IPHC:

- TF = 01 ou 11. Dans un format 6LoWPAN, TF = 01 implique un champ en ligne de 3 octets qui est transporté dans les champs non compressés. Ce champ en ligne est constitué de 2 bits d'ECN, suivis d'un bourrage de 2 bits, suivi de 20 bits d'étiquette de flux. Sachant que dans la présente norme, l'ECN est toujours activée et l'indication d'encombrement est transportée par la couche inférieure, l'ECN et le bourrage de 2 bits doivent être des 0 partout. Dans un format 6LoWPAN, TF = 11 implique que ce champ de 3 octets est élidé;
- NextHeaderNH = 1 pour indiquer que le prochain en-tête peut être inféré à partir du préfixe de l'en-tête de transport. Dans la présente norme, le prochain en-tête est toujours UDP;
- HLIM = HH. Ces bits sont utilisés par la présente norme pour indiquer le plan de compression de limite de saut tel que prévu dans 6LoWPAN;
- CID = 0 pour indiquer qu'aucune extension d'identificateur de contexte de 8 bits supplémentaire n'est utilisée;
- SAC = 1 pour spécifier la compression avec états pour l'adresse de source;

- SAM = 11 pour indiquer que tous les 128 bits de l'adresse source sont élidés (car, dans la présente norme, le pseudonyme D de 16 bits est transporté par la couche inférieure et est indexé dans la table ATT, qui fournit le contexte de conversion);
- M = 0 pour indiquer que l'adresse de destination n'est pas en multidiffusion;
- DAC = 1 pour spécifier la compression avec états pour l'adresse de destination;
- DAM = 11 pour indiquer que tous les 128 bits de l'adresse source sont élidés (car, dans la présente norme, le pseudonyme D de 16 bits est transporté par la couche inférieure et est indexé dans la table ATT, qui fournit le contexte de conversion).

10.5.4 Format (IPv6) d'en-tête complet

10.5.4.1 Usage prévu

Le format d'en-tête complet est utilisé principalement sur le réseau dorsal. Un appareil de terrain peut également utiliser le format d'en-tête complet au lieu du format de base ou du format activé par contrat, mais il convient de ne pas s'en servir.

Lorsque la NPDU atteint un routeur dorsal intermédiaire sur la DL, le routeur dorsal doit totalement étendre l'en-tête pour inclure tous les champs tels que définis dans l'en-tête IPv6. Les adresses de NL du tout premier appareil (initiateur) et de l'appareil de destination finale doivent être étendues à 128 bits pour désambiguïser leurs adresses DL16Addresses lors du routage à l'extérieur du sous-réseau D.

10.5.4.2 Format

Le Tableau 216 décrit le format d'en-tête IPv6.

Tableau 216 – Format d'en-tête de NL IPv6

<table>
<tr><th rowspan="2">Nombre d'octets</th><th colspan="8">bits</th></tr>
<tr><th>7</th><th>6</th><th>5</th><th>4</th><th>3</th><th>2</th><th>1</th><th>0</th></tr>
<tr><td>1</td><td colspan="4">Version</td><td colspan="4">TrafficClass (bits 7..4)</td></tr>
<tr><td rowspan="3">3</td><td colspan="4">TrafficClass (bits 3..0)</td><td colspan="4">FlowLabel (bits 19..16)</td></tr>
<tr><td colspan="8">FlowLabel (bits 15..8)</td></tr>
<tr><td colspan="8">FlowLabel (bits 7..0)</td></tr>
<tr><td rowspan="2">2</td><td colspan="8">PayloadSize (bits 15..8)</td></tr>
<tr><td colspan="8">PayloadSize (bits 7..0)</td></tr>
<tr><td>1</td><td colspan="8">NextHeader</td></tr>
<tr><td>1</td><td colspan="8">HopLimit</td></tr>
<tr><td>16</td><td colspan="8">Adresse source</td></tr>
<tr><td>16</td><td colspan="8">Adresse de destination</td></tr>
<tr><td>(variable)</td><td colspan="8">Charge utile de réseau</td></tr>
</table>

Les champs comprennent:

- Version: le numéro de version IP de 4 bits doit être mis à 6;
- TrafficClass: les quatre bits de poids fort de ce champ de 8 bits doivent être utilisés pour transporter la priorité de 4 bits de la NPDU sur la dorsale. Le cinquième bit doit être 0 et le sixième bit doit être utilisé pour transporter le bit Discard Eligible (DE) de la NPDU sur la dorsale. Les deux bits de poids faible doivent transporter l'ECN;
- FlowLabel: la valeur de ce champ doit être telle que définie dans le format d'en-tête activé par contrat (voir 10.5.3.2). Ce champ doit être mis à zéro partout si l'ID de contrat n'est pas transporté comme partie intégrante du flux;

- PayloadSize: ce nombre entier non signé de 16 bits doit contenir la taille de la charge utile IPv6, c'est-à-dire, le reste de la NPDU suivant cet en-tête, en octets;
- NextHeader: ce champ de 8 bits doit être mis à 0x 0001 0001 (17 en décimale) identifiant l'en-tête suivant comme étant UDP;
- HopLimit: la valeur de ce champ de 8 bits doit être mise au nombre de sauts de NL (couche 3) nécessaires pour atteindre la destination. Si la NPDU est reçue sur un sous-réseau D avec l'en-tête de base, ce champ doit être mis à jour à la sortie du sous-réseau D par un routeur dorsal conformément à la table de routage du routeur. Ce champ est décrémenté de 1 par la NL de chaque appareil si la NL transmet la NPDU. La NPDU doit être rejetée si HopLimit est décrémenté à zéro;
- adresse source: ce champ doit contenir l'adresse N de 128 bits de l'initiateur de la NPDU.
- adresse de destination: ce champ doit contenir l'adresse IPv6Address de la destination finale (destinataire prévu) de la NPDU.

10.5.4.3 Relation à 6LoWPAN

Il convient de ne pas utiliser le format d'en-tête de NL complet dans une NPDU émise sur le sous-réseau D de la présente norme. Cependant, la norme n'exclut pas l'utilisation de l'en-tête complet sur des sous-réseaux D. Si elle est utilisée sur le sous-réseau D, la NPDU doit contenir le dispatch IPv6 conformément au Tableau 217.

10.5.5 Format d'en-tête de fragmentation

10.5.5.1 Usage prévu

Si une NPDU avec une taille supérieure à dlmo.maxDSDUSize a besoin d'être émise sur la DL, la NPDU doit être fragmentée. Lorsqu'une NPDU doit être fragmentée, l'en-tête de fragmentation doit être inséré.

10.5.5.2 Format

L'en-tête de fragmentation contient un type de fragmentation de 5 bits, suivi d'un en-tête de 27 bits pour le premier fragment et d'un en-tête de 35 bits pour les fragments suivants. Les champs des en-têtes de base, activés par contrat ou complets, à partir de l'octet dispatch,

doivent être placés dans le premier fragment seulement. Le Tableau 218 montre le format d'en-tête de NL pour les NPDU fragmentées.

Tableau 218 – Format d'en-tête de NL pour les NPDU fragmentées

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
4..5	Type de fragmentation					En-tête de fragmentation		
	Autres champs d'en-tête de fragmentation (voir Tableau 219 et Tableau 220)							
(variable)	En-tête de base / activé par contrat / complet (pour le premier fragment seulement)							
(variable)	Charge utile de réseau							

Les champs comprennent:

- type de fragmentation: ce champ de 5 bits doit être mis à 0x1 1000 pour le premier fragment et à 0x1 1100 pour le deuxième fragment et les suivants;
- En-tête de fragmentation:
  - premier fragment: le premier fragment doit contenir le premier en-tête de fragment tel que défini dans le Tableau 219 et le texte suivant.

Tableau 219 – Format d'en-tête du premier fragment

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
2	Type de fragmentation					Datagram_size (bits 10..8)		
	1	1	0	0	0			
	Datagram_size (bits 7..0)							
2	Datagram_tag							

  - Fragments suivants: le deuxième segment et les suivants (jusqu'au dernier segment compris) doivent contenir un en-tête de fragmentation, tel que défini dans le Tableau 220 et le texte suivant.

Tableau 220 – Format d'en-têtes du second fragment et des fragments suivants

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
2	Type de fragmentation					Datagram_size (bits 10..8)		
	1	1	1	0	0			
	Datagram_size (bits 7..0)							
2	Datagram_tag							
1	Datagram_offset							

Tous les en-têtes de fragment comprennent:

- Datagram_size: ce champ de 11 bits code la taille de la NSDU entière avant fragmentation plus la taille de l'en-tête de base, activé par contrat ou complet. La valeur de Datagram_size doit être la même pour tous les fragments de la NSDU;
- Datagram_tag: il fournit l'identification pour la NLE de réassemblage. La NLE d'origine doit incrémenter Datagram_tag pour les NPDU fragmentées successives.

La valeur incrémentée de Datagram_tag est tronquée à gauche à 16 bits (à savoir, modulo 2^{16}) pour l'inclusion dans la NPDU. Pour réduire au maximum sa prévisibilité à un assaillant, la valeur initiale pour Datagram_tag doit être sélectionnée dans une distribution aléatoire uniforme. La valeur de Datagram_tag doit être la même pour tous les fragments d'une NSDU.

Les en-têtes du second fragment et des fragments suivants comprennent également:

– Datagram_offset: ce champ doit être présent seulement dans le deuxième fragment et les fragments suivants et il doit spécifier le décalage, en unités de 8 octets, du fragment par rapport au commencement de la charge utile de NPDU. (Le premier fragment de la NSDU a un décalage de zéro; la valeur implicite de Datagram_offset dans le premier fragment est zéro.) Ce champ a une longueur de 8 bits.

10.5.5.3 Relation à 6LoWPAN

Les formats d'en-tête de fragmentation dans la présente norme sont basés entièrement sur le format de l'IETF RFC 4944, sans changement. Comme dans l'IETF RFC 4944, le champ de Datagram_size est transporté dans tous les fragments, et le Datagram_offset est exprimé en unités de 8 octets. La fragmentation et le réassemblage peuvent se produire au niveau d'appareils intermédiaires et ne sont pas nécessairement de bout en bout.

11 Transport layer (couche transport)

11.1 Généralités

Le modèle de référence dans la présente norme est composé compose de cinq couches de protocoles. Dans ce modèle, le transport est la quatrième couche, immédiatement subordonnée à l'AL. Une TLE répond aux demandes de service d'une ALE supérieure en un TSAP et émet des demandes de service vers une NLE inférieure en un NSAP.

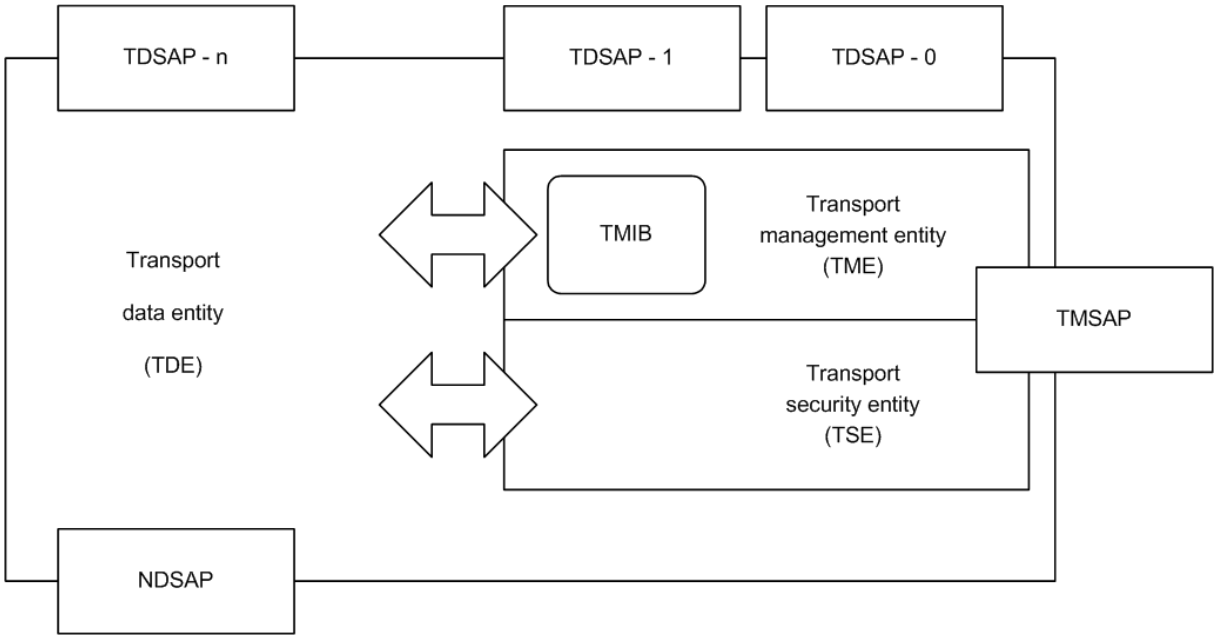
La TL est responsable de la communication de bout en bout et fonctionne seulement aux points d'extrémité de communication (par opposition aux appareils de routage).

Le TL fournit des services sans connexion, habituellement avec une sécurité fondée sur la cryptographie:

- le service sans connexion étend l'UDP sur l'IPv6, tel que défini dans l'IETF RFC 768 et l'IETF RFC 2460, en fournissant un contrôle d'intégrité de TDPU alternatif et plus sécurisé avec authentification cryptographique et, si configuré comme telle, avec la confidentialité;
- la sécurité est traitée d'une manière similaire à celle de la DL, mais de bout en bout plutôt que saut par saut;
- le service sans connexion étend également 6LoWPAN tel que défini par l'IETF RFC 6282. Lorsque la sécurité est activée, l'en-tête d'UDP peut être comprimé à un octet en élidant la somme de contrôle UDP et en s'appuyant sur le code d'intégrité des messages de transport (TMIC) qui est abouté et plus grand pour assurer l'intégrité de bout en bout.

11.2 Modèle de référence de TLE

Le modèle de référence de TLE d'état est représenté à la Figure 107.



Légende

Anglais	Français
Transport data entity (TDE)	Entité de données de transport (TDE)
Transport management entity (TME)	Entité de gestion de transport (TME)
Transport security entity (TSE)	Entité de sécurité de transport(TSE)

Figure 107 – Modèle de référence de TLE

La TLE inclut conceptuellement l'entité de gestion de transport (TME), l'entité de données de transport (TDE) et le composant de sécurité de transport (TSC).

La TDE a un TDSAP dédié pour le DMAP, à savoir TDE-0; un TDSAP qui est réservé pour SMAP, à savoir TDE-1; et un TDSAP pour chaque UAP, à savoir TDE-2 à TDE-n.

La TME configure et surveille les actions de la TLE. La base d'informations de gestion de transport (TMIB) (voir 11.6.2.5.2) maintient des informations abstraites pour la TME, qui sont accessibles au TMSAP comme partie intégrante du TLMO. Le TSC fournit les fonctions de sécurité de la TLE, basées sur les tables d'information de sécurité qui sont maintenues et surveillées par l'intermédiaire du TMSAP. La TDE utilise le TSC pour accomplir des opérations de sécurité sur les TPDU.

11.3 Entité de sécurité de transport

11.3.1 Généralités

Le TSC est conceptuellement un service compartimenté au sein de la TLE. La sécurité de TL peut protéger l'intégrité de l'unité de données de service de transport (TSDU) acheminée, de l'en-tête de transport et des adresses IPv6Addresses de points d'extrémité de transport. Si active, elle assure également la protection contre le retard excessif de TPDU et le rejet de TPDU, et peut chiffrer la TSDU pour la confidentialité.

11.3.2 Sécurisation de la TL

Le TSC et le DSC partagent la fonctionnalité. Le TSC est chargé de:

a) déterminer quel niveau de sécurité doit être appliqué à une session sécurisée en se basant sur les politiques;

b) à la réception d'une TPDU (comme tout ou partie d'une NSDU),

1) rejeter les TPDU non conformes;
2) rejeter les TPDUs qui échouent, selon la configuration d'association de T, soit
   i) au contrôle traditionnel d'intégrité d'UDP qui protège contre des erreurs non malveillantes, soit
   ii) aux contrôles d'authentification cryptographique qui protègent contre la modification tant accidentelle que délibérée de TPDU, contre le retard excessif de TPDU et le rejet de TPDU;
3) déchiffrer une TSDU protégée acheminée par la TPDU;

c) lors de la préparation d'une TPDU pour l'émission par l'intermédiaire d'une NLE,
   1) chiffrer les TSDU qui doivent avoir la protection de confidentialité pendant l'acheminement de TL; et
   2) selon la configuration de session, soit
      i) inclure la somme de contrôle d'intégrité d'UDP traditionnelle calculée pour protéger contre les erreurs non malveillantes, soit
      ii) inclure du support d'authentification cryptographique pour protéger contre la modification tant accidentelle que délibérée de TPDU, contre le retard excessif de TPDU et le rejet de TPDU.

La fonctionnalité du TSC est définie en 7.3.3.

Semblable à la sécurité de DL, la sécurité de TL utilise un chiffrement par blocs cryptographiques dans un mode de chiffrement par blocs de chiffrement authentifié générique, appelé le compteur avec CBC-MAC (CCM *), tel que défini par l'Annexe B de l'IEEE 802.15.4:2011. Le chiffrement par blocs par défaut est AES 128, mais d'autres chiffrements par blocs peuvent être utilisés lorsqu'exigés par la réglementation nationale.

CCM* permet l'authentification d'un message tout en chiffrant seulement une partie du message en question, laissant le reste du message (habituellement un en-tête) en texte clair. Lorsque cet appareil est activé pour une session particulière, la somme de contrôle d'UDP n'est pas utilisée et est élidée dans la forme comprimée de la TPDU, comme spécifié en 11.4.3.4. Elle est toujours présente dans la forme étendue de la TPDU, pour assurer la conformité à l'IETF RFC 2460 (UDP sur IPv6).

11.4 Entité de données de transport

11.4.1 Généralités

La TDE fournit des services sans connexion basés sur le protocole datagramme d'utilisateur (UDP, IETF RFC 768) sur IPv6 (IETF RFC 2460:1998), avec une compression telle que définie dans l'IETF RFC 6282:2011.

Les principales étapes de la construction de TPDU sont, dans l'ordre:

a) une TSDU est reçue en provenance d'une ALE locale par l'intermédiaire d'un TDSAP.

   NOTE Cette TSDU peut acheminer une seule APDU ou plusieurs APDU concaténées;

b) la TSDU est protégée et horodatée comme décrit en 7.3.3.2.1. La charge utile UDP résultante comprend un en-tête de sécurité de TL, la TSDU, et, lorsque la sécurité cryptographique est configurée, un TMIC. La TSDU est chiffrée pour la confidentialité si cela est ainsi indiqué par l'en-tête de sécurité de TL. La présence du TMIC, et sa taille, sont acheminées vers l'(les) appareil(s) de réception dans l'en-tête de sécurité de TL;

c) un en-tête d'UDP est ajouté en préfixe au début de la charge utile d'UDP. L'en-tête d'UDP peut être compressé. La compression implique d'élider la somme de contrôle UDP de l'en-tête d'UDP quand la charge utile d'UDP contient un autre contrôle d'intégrité. Un contrôle d'intégrité au sein de la charge utile d'UDP peut être un TMIC tel qu'indiqué dans l'en-tête de sécurité de TL et/ou un contrôle d'intégrité intégré dans une charge utile en tunnel.

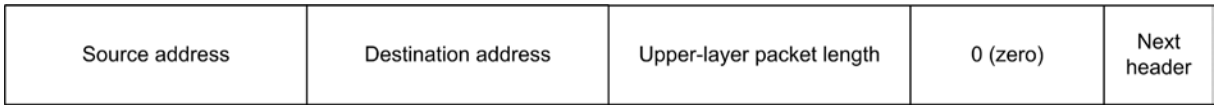
11.4.2 UDP sur IPv6

L'UDP (IETF RFC 768) fournit un mode sans connexion de communication d'ordinateurs dans l'environnement d'un ensemble interconnecté de réseaux d'ordinateurs.

L'UDP est essentiellement transparent au fonctionnement d'application, laissant à l'AL la commande et la responsabilité du fonctionnement correct du réseau. Des approches éprouvées, basées sur des normes, existent dans ce but. Les questions pertinentes sont documentées plus profondément en 11.4.4.

L'IETF RFC 768 suppose que l'IPv4 est utilisé comme protocole sous-jacent et définit le calcul d'une somme de contrôle d'UDP, utilisée pour la détection d'erreurs, qui couvre un pseudo-en-tête d'UDP d'information issu de l'en-tête de réseau IPv4, l'en-tête d'UDP, et la charge utile d'UDP. Si ce calcul donne un résultat de zéro, il est changé en 0xFFFF pour le placement dans l'en-tête d'UDP et la valeur de zéro est réservée pour indiquer qu'il n'y a aucun calcul de somme de contrôle.

L'IETF RFC 2460 spécifie les changements apportés à l'IETF RFC 768 pour adapter l'UDP à l'IPv6. Les changements apportés à l'UDP sont mineurs et se rapportent au calcul de la somme de contrôle d'UDP, qui devient obligatoire et inclut un pseudo-en-tête d'UDP modifié adapté pour l'IPv6, conformément à la Figure 108. Selon l'IETF RFC 2460, les récepteurs IPv6 rejettent les paquets UDP contenant une somme de contrôle de 0x0000 et consignent dans un journal cet événement comme étant une erreur.



Légende

Anglais	Français
Source address	Adresse source
Destination address	Adresse de destination
Upper-layer packet length	Longueur de paquet de couche supérieure
0 (zero)	0 (zéro)
Next header	Prochain en-tête

Figure 108 – Pseudo-en-tête UDP pour l'IPv6

Dans le pseudo-en-tête, la valeur dans le champ appelé "Next header" (prochain en-tête) est mise à 17 pour indiquer l'UDP et la valeur dans le champ appelé "Upper-layer packet length" (longueur de paquet de couche supérieure) est le même que le champ "Length" dans l'en-tête d'UDP et rend compte de la taille de la TPDU entière, y compris l'en-tête UDP.

Un pseudo-en-tête différent, soit le pseudo-en-tête TSS, est utilisé dans le traitement de la sécurité de TL, comme décrit en 7.3.3.2.1.

NOTE Voir l'IETF RFC 768, l'IETF RFC 2460, et les 4.5.2.1 et 7.3.3.2.1 pour comprendre les objectifs des présents pseudo-en-têtes.

11.4.3 Emission et compression d'en-tête UDP

11.4.3.1 Généralités

La TL prend en charge l'UDP non compressé pour l'émission et la réception d'une TPDU. Un appareil qui met en œuvre la TL de la présente norme doit prendre en charge l'UDP non compressé, mais il convient qu'il comprime l'en-tête UDP pour l'émission sur le réseau sans fil.

Le Tableau 221 décrit le codage d'en-tête UDP.

Tableau 221 – Codage d'en-tête UDP

Nombre d'octets	Bits (présentés dans la convention IEC, qui est différente de la convention IETF)						
	7	6	5	4	3	2	1..0
2	Source port: qui est en correspondance univoque (un à un) avec le TDAP de l'appareil de source						
2	Destination port: qui est en correspondance univoque (un à un) avec le TDAP de l'appareil de destination						
2	Size: la taille en octets de ce datagramme utilisateur, y compris cet en-tête et l'APDU						
2	Checksum: le complément à un de 16 bits de la somme de complément à un a) du pseudo-en-tête UDP de la Figure 108, dérivé de l'en-tête IP; b) de l'en-tête UDP, et c) de la TSDU éventuellement chiffrée, complétée d'octets zéro à la fin (s'il y a lieu) pour obtenir un multiple de deux octets. Au cours du calcul de la somme de contrôle, le champ "checksum" du TPDU de l'UDP est d'abord mis à zéro.						

La TL est également conforme à 6LoWPAN, qui spécifie une méthode pour comprimer l'UDP en utilisant un format Next Header Compression (LoWPAN_NHC) et oblige à utiliser la compression d'UDP sur le sous-réseau D local. Un appareil qui met en œuvre la TL de la présente norme doit ainsi prendre en charge toutes les combinaisons offertes par le LOWPAN_NHC pour la compression et l'extension de l'en-tête UDP.

La taille maximale d'une TSDU dépend d'une diversité de facteurs, tels que la capacité tampon à chaque TLE de point d'extrémité de session, le niveau sélectionné de sécurité de TL, et les caractéristiques de réseau. Le gestionnaire de système configure la taille maximale de TSDU sur une base de contrat pour rendre compte de ces considérations pertinentes et d'autres encore, par l'intermédiaire de la valeur de l'élément Assigned_Max_TSDU_Size, tel que décrit dans le Tableau 30.

11.4.3.2 Compression et restauration des numéros de port UDP

La compression pour les numéros de port d'UDP est décrite dans l'IETF RFC 6282:2011, 4.3. Il convient que ces numéros de port qui sont optimisés par le processus de compression soient assignés à des ports (AE) avec une plus grande fréquence d'utilisation. La compression optimale est obtenue lorsque les numéros de port tant source que destination commencent à un numéro de base P et sont exprimés comme étant P + short_port, où:

- P est le port de base, $61\,616_{10}$, à savoir, 0xF0B0;
- short_port est un nombre entier positif qui est $15 \leq$ (à savoir, 0x0F).

Dans un tel cas, la paire des ports de source et de destination est compressée en un seul octet qui a spécifié les valeurs de source et de destination comme short_ports, ce qui réduit la taille du champ de TPDU exigé pour acheminer des numéros de port UDP de quatre octets en un octet.

Lorsque les deux ports ne peuvent pas se trouver au sein de la plage 0xF0B0..0xF0BF, la taille de la TPDU peut encore être réduite d'un octet si le port source ou destination est dans la plage 0xF000..0xF0FF; dans ce cas l'octet de poids fort correspondant de 0xF0 est élidé. Il convient ainsi que les applications de serveur se mettent à l'écoute d'un port dans la plage 0xF000..0xF0FF. Par exemple, un appareil de terrain type a un DMAP à 0xF0B0 (codé comme short_port 0) et peut avoir son seul UAP à 0xF0B2 (codé comme short_port 2), car 0xF0B1 (codé comme short_port 1) est réservé pour le SMAP local.

11.4.3.3 Elision et restauration du champ UDP Size (taille d'UDP)

Si l'en-tête d'UDP n'est pas compressé, la taille de NSDU est égale à la taille de TPDU qui est placée dans l'en-tête d'UDP.

Si l'en-tête d'UDP est compressé, le champ UDP Size est toujours élidé en émission et il est inféré à la réception à partir de la taille de NSDU passée par la NLE de réception. Dans ce cas, la taille de TPDU est égale à la taille de NSDU plus la différence calculable entre les tailles d'un en-tête UDP complet et de l'en-tête UDP réel tel que compressé.

Même si aucun des autres champs dans l'en-tête d'UDP n'est compressé ou élidé, le fait de compresser le champ UDP Size réduit d'un octet la taille de la TPDU et permet l'utilisation de l'en-tête de base à la NL.

Par exemple, dans le cas optimal décrit dans le Tableau 223, l'en-tête UDP compressé requiert 2 octets, économisant ainsi 6 octets en comparaison avec l'en-tête UDP complètement étendu. La taille de TDPU pour l'en-tête UDP étendu est ainsi NSDU_Size + 6.

11.4.3.4 Elision et restauration de la somme de contrôle UDP

La TL est conforme aux règles 6LoWPAN et aux opérations définies dans l'IETF RFC 6282:2011, 4.3.2, comme suit:

- L'autorisation d'élider la somme de contrôle UDP pourrait venir de l'ALE ou TSC. Le TSC sous-entend la présence ou l'absence de cette somme de contrôle en spécifiant si le TMIC est présent ou non.
- Une ALE peut élider la somme de contrôle UDP dans les cas suivants:
  - tunnellisation: l'ALE source met en tunnel une PDU (de type non spécifié) qui possède son propre mécanisme d'intégrité qui assure au moins autant de protection que la somme de contrôle UDP de 16 bits;
  - MIC d'application: l'ALE source applique un contrôle d'intégrité de message de bout en bout d'au moins 16 bits (par exemple, comme partie intégrante d'un échange de clé).
- Si la NLE locale est un routeur dorsal, alors le routeur doit recalculer la somme de contrôle élidée en se basant sur le paquet reçu comme spécifié dans l'IETF RFC 2460 et doit placer le résultat de ce calcul dans l'en-tête UDP reformé avant émission sur un réseau dorsal IPv6.
- Si la NLE est la destination du paquet et a connaissance de la présence du TMIC dans la TPDU, elle peut complètement omettre l'opération de somme de contrôle UDP (ni recalculer ni vérifier la somme de contrôle).
- Un routeur dorsal qui transmet un paquet IPv6 dans le sous-réseau D utilise le champ contrôle de sécurité dans l'en-tête de sécurité de TPDU pour déterminer si un TMIC est présent ou pas. Lors de l'accomplissement de la compression UDP, il convient que le routeur dorsal élide la somme de contrôle UDP si le TMIC est présent, mais il ne doit pas élider la somme de contrôle UDP si le TMIC n'est pas présent. Réciproquement, le fait que la somme de contrôle ne soit pas compressée n'est pas une indication qu'il n'y a pas de TMIC dans la TPDU.

6LoWPAN permet la compression de somme de contrôle UDP seulement lorsque la protection alternative au sein de la TPDU assure une protection d'intégrité au moins aussi grande que la somme de contrôle UDP, y compris la protection de bout en bout pour tous champs que la somme de contrôle UDP protégerait. Pour satisfaire à cette exigence, la présente norme définit un pseudo-en-tête TSC qui est inclus dans le calcul de TMIC, comme décrit en 7.3.3.2.1. Comparé au pseudo-en-tête UDP normalisé selon l'IETF RFC 2460, le pseudo-en-tête de TSC inclut les ports UDP, mais n'inclut pas la taille de charge utile, car cela est implicitement protégé par le TMIC. La structure du pseudo-en-tête de TSC est définie au Tableau 47.

Dans le cas d'une TPDU préparée pour l'émission, les adresses IPv6Addresses source et destination sont obtenues à partir des informations de contrat; l'ID de contrat lui-même est passé par l'ALE comme un paramètre associé à la TSDU. Le champ Next header du pseudo-en-tête est mis à 17 (UDP). Le port source est obtenu à partir du contexte de TL associé au TSAP, alors que le port de destination est un autre paramètre associé à la TSDU. Le pseudo-en-tête de TSC a été modélisé comme s'il était construit par la TDE et passé avec la TSDU au TSC pour le traitement de sécurité.

Le TSC utilise le pseudo-en-tête de TSC dans le calcul du TMIC en l'ajoutant en préfixe au début de la TSDU, mais le pseudo-en-tête de TSC n'est pas chiffré quand le chiffrement doit être accompli sur la TSDU. Une fois que le processus cryptographique est achevé, le TSC doit enlever de la TSDU traitée le pseudo-en-tête de TSS, ajouter ses propres en-têtes et en-queues, et retourner à la TDE la charge utile UDP protégée. Le TDE doit compléter la TPDU en ajoutant en préfixe, et habituellement en compressant l'en-tête UDP pour former la NSDU qui est passée à la NL.

Dans le cas d'une TPDU reçue, les adresses IPv6Addresses source et destination et les bits de priorité sont passés par la NL comme paramètres associés à la NSDU, et les ports sont obtenus à partir de l'en-tête UDP dans la TPDU une fois que l'en-tête UDP a été étendu. Le TDE doit remplir le pseudo-en-tête, retirer de la NSDU l'en-tête UDP et passer à la TSC la charge utile UDP protégée obtenue accompagnée du pseudo-en-tête et des bits de priorité pour le traitement de sécurité.

Sachant qu'une NPDU pourrait être reçue hors séquence, peut-être en raison de ses valeurs de réglage de sécurité (voir Tableau 205), le TSC peut utiliser ces informations relatives à la priorité pour partitionner son cache parallèle, optimisant potentiellement sa capacité, dans le cadre des ressources mémoire limitées, à valider des TPDU qui avaient encouru un retard de transit substantiel. Les informations relatives à la priorité sont acheminées avec la NSDU dans la primitive N-DATA.indication reçue par la TLE en provenance d'une NLE locale; la TLE transmet ces informations et la TPDU au TSC.

Le TSC de réception enlève de la TSDU protégée les en-têtes et les en-queues de sécurité de TL, ajoute en préfixe le pseudo-en-tête de TSC, les ports UDP, et les en-têtes de sécurité (voir Figure 41), et ensuite accomplit les vérifications de sécurité. Si un contrôle d'intégrité est appliqué, la TLE peut vérifier si des parties critiques des informations de la NL et de la TL ont été modifiées pendant le transport de bout en bout.

Si le champ somme de contrôle de couche supérieure UDP est élidé, il appartient à l'appareil de réception sur le sous-réseau D sans fil de recalculer la somme de contrôle UDP comme partie intégrante du processus d'inversion de la compression 6LoWPAN, s'il y a lieu, avant la transmission plus avant de la NPDU d'acheminement vers une destination à l'extérieur du sous-réseau D sans fil. Cette étape d'inversion de compression est nécessaire en particulier pour un appareil intermédiaire, tel qu'un routeur de frontière de BBR, qui transmet la NPDU non compressée sur un réseau différent.

NOTE Il est inutile pour la TLE de destination adressée de reconstituer ainsi la TPDU non compressée.

Si la somme de contrôle UDP n'est pas élidée, alors la somme de contrôle UDP doit être calculée en émission après que l'opération de sécurité a été complète et les champs de sécurité ont été préréglés pour le calcul. La charge utile UDP qui est utilisée pour la somme de contrôle UDP doit inclure toutes les données depuis l'en-tête d'UDP jusqu'à la fin de la TPDU, y compris les champs de sécurité, les données d'application, et les champs de MIC, indépendamment du fait que les données d'application soient chiffrées ou pas. En réception, elle doit être vérifiée par la TDE avant l'opération de TSC, à moins que la TDE ne sache que le TSC vérifie le MIC, auquel cas la somme de contrôle peut être ignorée.

11.4.4 TSAP et ports UDP

L'appareil autoconfigure une adresse IPv6Address locale à une liaison IPv6 en se basant sur son adresse EUI64Address. Une fois que le processus de rattachement au sous-réseau est

achevé, un appareil possède également au moins une adresse IPv6Address globale. La présente norme autorise, mais n'exige pas, qu'un appareil prenne en charge plus d'une adresse IPv6Address globale. Pour une adresse IPv6Address donnée, un port UDP doit être associé avec un UAP maximum.

Le port est utilisé comme le port local pour toutes les émissions depuis/vers l'UAP en question en utilisant cette adresse IPv6Address. Un multiplexage plus poussé entre les objets UAP est de la responsabilité de l'ALE, se fait au sein des TSDU et est donc transparent à la TLE. En conséquence, seul un nombre limité de ports est réellement utilisé dans le système, et il n'y a aucune allocation dynamique de port après la phase d'initialisation (ou de réinitialisation) des applications.

Chaque UAP doit être responsable de connaître son numéro de port UDP et de l'enregistrer auprès de la TLE. A cet instant, un TLSAP doit être mis en correspondance sur une base univoque (1:1) avec l'UAP et le port local pour l'adresse IPv6Address. Une adresse de processus d'application doit être constituée d'une adresse d'appareil concaténée avec son identificateur de TLSAP.

11.4.5 Bonne citoyenneté de réseau

Les SDU (N) sont échangées avec les couches supérieures et inférieures par l'intermédiaire de primitives DATA (N). Une mise en œuvre peut rapporter l'encombrement transitoire dans une couche inférieure par l'intermédiaire d'un code d'achèvement spécifique dans une primitive (N)-DATA.confirm qui est acheminée en montant tout le chemin vers la suite de protocoles. A la réception d'un code d'achèvement indiquant un encombrement transitoire, il convient qu'une ALE diffère la réémission de la SDU (N) d'une quantité de repli exponentiel ou abandonne simplement la SDU (N).

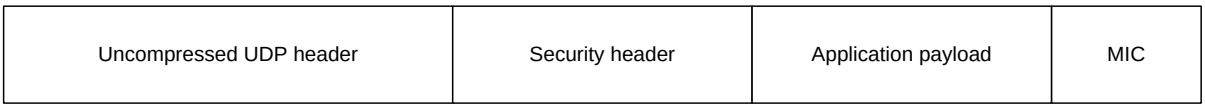
Sachant que la TL est basée sur l'UDP, il est souhaitable que les UAP prennent en charge le contrôle de flux compatible TCP ou le contrôle de débit compatible TCP (TFRC, IETF RFC 5348), en fonction de la nature du flux, afin de protéger les futures utilisations du réseau et partager équitablement le réseau dorsal.

Cela est habituellement réalisé en mettant en œuvre un protocole de blocage au niveau de l'AL qui applique un temps de propagation aller-retour (RTT) entre les TPDU ou utilise le RTT pour calculer un temporisateur de récupération sur perte. Dans le cas des échantillons périodiques, cela peut être réalisé en réservant la largeur de bande ou en gardant la période d'échantillonnage au-dessus de la valeur initiale de RTT pour TCP de 3 s (voir IETF RFC 6298). Des fréquences d'échantillonnage plus élevées peuvent être utilisées dans certaines applications.

11.5 Codage de TPDU

11.5.1 Généralités

Une TPDU échangée entre les deux TLE d'une communication doit être composée d'un en-tête UDP sous sa forme non compressée, d'un en-tête d'informations de sécurité, de la TSDU, et d'un TMIC, conformément à la Figure 109.



Légende

Anglais	Français
Uncompressed UDP header	En-tête UDP décompressé
Security header	En-tête de sécurité
Application payload	Charge utile d'application

Figure 109 – Structure de TPDU

Les données de NSDU passées par la TLE expéditrice à une NLE locale par l'intermédiaire d'un NSAP incluent toute compression d'en-tête UDP qui a été appliquée à la TPDU. Si la compression a été appliquée, l'octet 6LoWPAN _NHC-for-UDP est le premier octet de la NSDU.

La paire d'adresses IPv6Addresses, le type de transport (UDP=17) et la taille de la NSDU ne sont pas présents dans la NSDU, aussi sont-ils passés comme paramètres associés. Le fait de savoir si, oui ou non, la compression 6LoWPAN_NHC a eu lieu est également passé comme paramètre.

11.5.2 Compression d'en-tête – Codage de protocole datagramme d'utilisateur

Lorsque l'en-tête UDP n'est pas compressé, la NSDU est identique à la TPDU et l'en-tête UDP doit être présent au complet sans un octet de codage 6LoWPAN_NHC-for-UDP.

Si l'un quelconque des champs d'en-tête UDP est compressé, un octet de codage 6LoWPAN_NHC-for-UDP doit être ajouté en préfixe afin de décrire la compression. La NSDU doit être formée en remplaçant l'en-tête d'UDP au début de la TPDU par l'octet de codage 6LoWPAN_NHC-for-UDP suivi des données compressées. L'octet de codage 6LoWPAN_NHC-for-UDP est structuré conformément au Tableau 222.

Tableau 222 – Octet de codage 6LoWPAN_NHC-for-UDP

Nombre d'octets	Bits (présentés dans la convention IEC, qui est différente de la convention IETF)							
	7	6	5	4	3	2	1	0
1	1	1	1	1	0	C	P	

Les champs C (compression de somme de contrôle) et P (compression de ports) sont définis comme suit:

Champ C (1 bit):

0: La somme de contrôle de 16 bits de la TPDU est acheminée dans la TPDU;

1: La somme de contrôle de 16 bits de la TPDU est élidée de la TPDU.

Champ P (2 bits):

00: la TPDU achemine les ports source et destination sous forme de valeurs de 16 bits;

01: la TPDU achemine le port source sous forme d'une valeur de 16 bits alors que seuls les 8 bits de poids faible du port destination, qui se situe dans la plage 0xF000..0xF0FF, sont acheminés dans la TPDU;

10: la TPDU achemine le port destination sous forme d'une valeur de 16 bits alors que seuls les 8 bits de poids faible du port source, qui se situe dans la plage 0xF000..0xF0FF, sont acheminés dans la TPDU;

11: TPDU achemine seulement les 4 bits de poids faible des ports source et destination, qui se situent dans la plage 0xF0B0..0xF0BF.

Les champs compressés apparaissent dans le même ordre qu'ils le font dans le format d'en-tête UDP spécifié dans l'IETF RFC 768.

Lorsque le plus haut degré de compression est réalisé, seuls les numéros de port short_port compressés sont transportés après l'octet de codage 6LoWPAN_NHC-for-UDP conformément au Tableau 223.

Tableau 223 –Codage optimal d'en-tête UDP

Nombre d'octets	Bits (présentés dans la convention IEC, qui est différente de la convention IETF)						
	7	6	5	4	3	2	1..0
1	1	1	1	1	0	1 (la somme de contrôle est élidée)	11 (les ports source et destination sont compressés)
2	source short_port				destination short_port		

Les valeurs étendues pour le port source et les ports de destination compressés doivent être calculées en utilisant la formule:

UDP_port_number = P + short_port

où short_port est le numéro de port compressé de 4 bits et P est la valeur 0xF0B0 (61 616_{10}). En d'autres termes, short_port achemine les 4 bits de poids faible du numéro de port UDP.

Au moment du processus de rattachement au sous-réseau, l'appareil de terrain n'a pas le support cryptographique pertinent pour calculer un TMIC. Sachant que cette situation exige que le TMIC soit omis, l'appareil doit calculer la somme de contrôle UDP telle qu'exigée par l'IETF RFC 768 et l'IETF RFC 2460 et doit utiliser les adresses IPv6Addresses locales à une liaison pour calculer et envoyer la somme de contrôle et émettre. Dans ce cas, si les ports UDP peuvent être compressés, l'en-tête UDP codé est formaté tel que présenté dans le Tableau 224.

Tableau 224 – Codage d'en-tête UDP avec somme de contrôle et numéros de port compressés

Nombre d'octets	Bits						
	7	6	5	4	3	2	1..0
1	1	1	1	1	0	0 (la somme de contrôle est présente)	11 (les ports source et destination sont compressés)
2	source short_port				destination short_port		
3	Somme de contrôle UDP						
4							

11.5.3 En-tête de sécurité de TPDU

Pour des informations relatives à l'en-tête de sécurité d'une TPDU, le codage et le décodage, voir 7.3.3.6.

11.6 Modèle de TL

11.6.1 Généralités

Une TLE fournit deux interfaces:

- un TDSAP de TDE pour chaque UAP et un pour le DMAP;
- un TMSAP de TME pour le DMAP.

Ces interfaces sont illustrées dans le modèle de référence de protocole de la présente norme, montré à la Figure 16.

Toutes les interfaces entre la TLE et les entités de couche ou entités de gestion adjacentes sont des interfaces internes au sein de l'appareil, et sont donc inobservables. Par conséquent, elles ne sont pas soumises à une normalisation.

Les couches supérieures utilisent le TDSAP pour échanger des données communiquées par l'intermédiaire de la TLE. Il y a une instance de TDSAP distincte pour chaque UAP, plus une instance pour le DMAP.

Le TDSAP inclut une fonction de multiplexeur qui adapte l'espace de noms d'adresse de l'ALE à l'espace natif de noms d'adresse de la TLE. Le DMAP utilise le TMSAP pour configurer la TLE et surveiller son fonctionnement.

La TLE communique avec une NLE locale en utilisant un NDSAP.

11.6.2 Services de données

11.6.2.1 Généralités

Pour des besoins d'illustration, un exemple de jeu de primitives est fourni dans la présente norme. La TL offre un service non connecté basé sur le modèle UDP.

Une TLE utilise l'interface fournie par le TDSAP pour émettre et recevoir des unités de données de protocole avec l'ALE.

Le TDSAP transfère la TSDU, avec des paramètres d'information de commande et de statut.

11.6.2.2 T-DATA.request

11.6.2.2.1 Généralités

La primitive T-DATA.request ordonne à la TL d'émettre une unité de données de protocole.

11.6.2.2.2 Sémantique de la primitive de service

La sémantique de la primitive T-DATA.request se présente comme suit:

```
T-DATA.request   (
                 ContractId
                 TSDU_size
                 TSDU
                 Priority
                 DE
                 TDSAP
                 \Destination_Port)
```

Le Tableau 225 spécifie les éléments pour la primitive T-DATA.request.

Tableau 225 – Eléments pour la primitive T-DATA.request

Nom de l'élément	Identificateur de l'élément	Type scalaire de l'élément
ContractId (identifie les ressources TL contractuelles associées à l'unité de données de protocole)	1	Unsigned16 Valeurs nommées: 0: aucun contrat
TSDU_size (taille en octets de l'unité de données de protocole passée à partir de l'ASL)	2	Unsigned16
TSDU (la TSDU devant être émise)	3	OctetString
N-priority (identifie la priorité au sein de la NL de cette TSDU)	4	Unsigned2
DE (identifie le Discard Eligibility de cette TSDU)	5	Unsigned1
TDSAP (ID du TDSAP qui accorde le service UDP sur SourcePort)	6	Unsigned16
Destination_Port [port (distant) de destination UDP pour la TSDU]	7	Unsigned16

La TLE maintient une table indexée par TDSAP qui contient (implicitement ou explicitement) l'adresse IPv6Address locale et (explicitement) le port local pour l'émission. Cette table est accessible pour obtenir l'adresse IPv6Address source et le port pour l'émission sur un TDSAP donné. L'adresse IPv6Address de destination est obtenue à partir du champ Destination_Address dans les informations de contrat, indexé par l'ID de contrat.

La TLE ne retient pas les informations d'état relatives au port distant; ainsi, les informations qui sont passées par l'UAP sont passées dans le TPDU sans vérification.

Le paramètre N-priority communique la priorité N qui doit être utilisée par la NL. Les valeurs de réglage de N-priority ne sont pas utilisées dans la TL, mais elles sont passées par la NL à la DL, où elles sont utilisées pour choisir la classe de priorité dans l'en-tête de DL.

11.6.2.2.3 Utilisation appropriée

Une ALE invoque la primitive T-DATA.request pour passer une TSDU à une TLE locale pour émission sur le réseau.

11.6.2.2.4 Effet à la réception

A la réception de la primitive T-DATA.request, la TLE recherche le niveau de sécurité T dans le KeyDescriptor pour déterminer le traitement exigé par le TSC local, construit l'en-tête de TPDU, forme la TPDU, et génère la primitive N-DATA.request pour une NLE locale au niveau d'un NSAP.

11.6.2.3 T-DATA.confirm

11.6.2.3.1 Généralités

La primitive T-DATA.confirm est utilisée par la TLE pour répondre à une primitive T-DATA.request. La confirmation est immédiate et dit à l'ALE demandeuse soit que la demande a été couronnée de succès, soit qu'une erreur a été détectée. Les conditions d'erreur incluent des questions telles qu'un ID de contrat non reconnu, une taille de TSDU qui est incorrecte ou excessive, ou une erreur transitoire interne telle qu'un encombrement de réseau au-delà de la capacité du TSC et de ses agents pour les traiter.

11.6.2.3.2 Sémantique de la primitive de service

La sémantique de T-DATA.confirm se présente comme suit:

T-DATA.confirm (
ContractId
TDSAP
status
)

Le Tableau 226 spécifie les éléments pour T-DATA.confirm.

Tableau 226 – Eléments pour la primitive T-DATA.confirm

Nom de l'élément	Identificateur de l'élément	Type scalaire de l'élément
ContractId (identifie les ressources TL contractuelles associées à la TPDU)	1	Type: Unsigned16 Valeurs nommées: 0: aucun contrat
TDSAP (ID du TDSAP qui accorde le service UDP sur SourcePort)	2	Type: Unsigned16
Status (le résultat de la primitive T-DATA.request)	3	Type: Unsigned Plage valide: (voir Tableau 227)

Le Tableau 227 fournit les codes de statut pour la primitive T-DATA.confirm.

Tableau 227 – Codes de statut de la primitive T-Data.confirm

Nom	Description
SUCCESS	TSDU acceptée
TRANSIENT_FAILURE	La TSDU est rejetée, mais peut être tentée de nouveau après une brève période de temps
FAILURE	Echec générique: TSDU rejetée sans raison explicite
INVALID_CONTRACT	Echec spécifique: ID de contrat non reconnu; TSDU rejetée
INVALID_LENGTH	Echec spécifique: La TSDU est plus grande que l'Assigned_Max_TSDU_Size; rejetée
PORT_ERROR	Echec spécifique: SourcePort n'est pas enregistré pour le TDSAP; TSDU rejetée
SAP_ERROR	Echec spécifique: TDSAP inconnu; TSDU rejetée

11.6.2.3.3 Moment de sa génération

Une TLE génère une primitive T-DATA.confirm en réponse à une primitive T-DATA.request locale. La primitive T-DATA.confirm retourne de façon synchrone soit un statut de succès, soit un code d'erreur approprié.

11.6.2.3.4 Utilisation appropriée

La primitive T-DATA.confirm notifie à l'ALE le résultat de sa demande d'émettre une TSDU.

11.6.2.4 T-DATA.indication

11.6.2.4.1 Généralités

La primitive T-DATA.indication est utilisée pour transférer une TSDU vers l'ALE. Elle est générée lorsqu'une TPDU a été reçue avec succès en provenance d'une NLE locale et a été traitée par la TLE.

Une TPDU reçue qui échoue au traitement de sécurité T ou qui spécifie un port de destination non enregistré est rejetée à la réception. De telles erreurs sont journalisées dans la PIB de la TLE.

11.6.2.4.2 Sémantique de la primitive de service

La sémantique de la primitive T-DATA.indication se présente comme suit:

```
T-DATA.indication (
                SrcAddr
                SrcPort
                TSDU_size
                TSDU
                ECN
                TDSAP
                transportTime
                )
```

Le Tableau 228 spécifie les éléments pour la primitive T-DATA.indication.

Tableau 228 – Eléments pour la primitive T-Data.indication.

Nom de l'élément	Identificateur de l'élément	Type scalaire de l'élément
SourceNetworkAddress (adresse IP de l'extrémité distante)	1	Type: IPv6Address
SourcePort (port source UDP dans la TPDU entrante)	2	Type: Unsigned16
TSDU_size (taille en octets dans la TSDU d'accompagnement)	3	Type: Unsigned16
TSDU (le contenu reçu de couche supérieure de la TPDU)	4	Type: OctetStringN
ECN (bits de notification d'encombrement explicite)	5	Type: Unsigned2
TDSAP (ID du TDSAP qui accorde le service UDP et concorde avec un port local)	6	Type: Unsigned8
TransportTime (temps de transit de bout en bout du TSC d'origine au TSC de réception)	7	Type:Unsigned16
NOTE TransportTime est relatif à tpduMaxAge.		

Une TLE maintient une table qui contient le TDSAP, qui est indexée (implicitement ou explicitement) par l'adresse locale et (explicitement) par le port local pour la réception. La table en question est accessible pour trouver le TDSAP utilisé pour passer la TSDU à l'UAP.

11.6.2.4.3 Utilisation appropriée

Une TLE invoque la primitive T-DATA.indication pour notifier à l'ALE adressée une TSDU reçue.

11.6.2.4.4 Effet à la réception

A la réception de la primitive T-DATA.indication, l'ALE traite la TSDU reçue.

11.6.2.5 Services de gestion

11.6.2.5.1 Généralités

Le service de la gestion de la TLE est commandé par l'objet de gestion de TL (TLMO) dans le DMAP. Le TLMO commande les fonctionnalités de la TLE en:

- mesurant la latence de la TL et en réalisant les adaptations connexes pour se conformer dynamiquement aux exigences de latence; et
- en recueillant des paramètres opérationnels.

Le TLMO utilise son interface de TMSAP pour configurer et commander le fonctionnement de la TLE. La TME de la TLE fournit une TMIB qui maintient les informations d'état nécessaires pour mettre en œuvre la fonctionnalité de TMSAP.

11.6.2.5.2 Attributs

Le Tableau 229 spécifie les attributs du TLMO.

Tableau 229 – Attributs de TLMO *(1 de 2)*

Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)				
Identificateur du type d'objet normalisé: 122				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Reserved:	1	Réservé par la norme	-	-
MaxNbOfPorts	2	Nombre de ports actifs	Type: Unsigned8 Classification: Constant Accessibilité: Lecture seule Valeur par défaut: Dépendant de l'appareil Plage valide: 2..255	La valeur minimale couvre un appareil type avec un seul DMAP et un seul TDSAP UAP
TPDUin	3	Compteur rapportant le nombre de TPDU reçues	Type: Unsigned32 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0	Incrémenté avec chaque TPDU reçue en provenance d'une TLE distante
TPDUinRejected	4	Compteur rapportant le nombre de TPDU rejetées	Type: Unsigned32 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0	Incrémenté avec chaque unité de données reçue en provenance d'une TLE distante qui avait été rejetée (pour des raisons de sécurité, par exemple). Noter qu'il n'existe pas de tel compteur au sein du DSMO

Tableau 229 *(2 de 2)*

Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)				
Identificateur du type d'objet normalisé: 122				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
TSDUout	5	Compteur rapportant le nombre de TSDU passées à l'ALE locale	Type: Unsigned32 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0	Incrémenté avec chaque TPDU reçue en provenance d'une TLE distante qui a entraîné l'acheminement d'une TSDU contenue vers une ALE locale
TSDUin	6	Compteur rapportant le nombre de TSDU reçues	Type: Unsigned32 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0	Incrémenté avec chaque TSDU reçue en provenance d'une ALE locale
TSDUinRejected	7	Compteur rapportant le nombre de TSDU rejetées	Type: Unsigned32 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0	Incrémenté avec chaque TSDU reçue en provenance d'une ALE locale qui est rejetée
TPDUout	8	Compteur rapportant le nombre de TPDU passées à la NL	Type: Unsigned32 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0	Incrémenté avec chaque TSDU reçue en provenance d'une ALE locale qui est acheminée et acceptée par une NLE locale
IllegalUseOfPortAlertDescriptor	9	Utilisé pour changer la priorité d'alerte IllegalUseOfPort; cette alerte peut également être activée ou désactivée	Type: Alert report descriptor Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: [true, 8] -- medium	-
TPDUonUnregisteredPortAlertDescriptor	10	Utilisé pour changer la priorité d'alerte TPDUonUnregisteredPort ; cette alerte peut également être activée ou désactivée	Type: Alert report descriptor Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: [true, 4] -- low	-

Pour chaque attribut, le TLMO fournit des méthodes lecture et écriture disponibles au DMAP. Ces méthodes sont mises en œuvre en demandant des services TME au travers du TMSAP.

11.6.2.5.3 Méthodes

En plus des services lecture et écriture pour les attributs, des méthodes de TLMO complémentaires fournissent l'accès à des services de TME au travers du TMSAP.

Le Tableau 230 décrit la méthode "Reset".

Tableau 230 – Méthodes de l'objet de gestion de TL – Reset

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 122</th></tr>
<tr><th>Nom de méthode</th><th>ID de méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="8">Reset</td><td>1</td><td colspan="3">Réinitialise le transport aux états initiaux</td></tr>

	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Status	Unsigned8	0 = réussite, > 0 échec
	2	NbActivePorts	Unsigned16	Nombre de ports actifs
	3	FirstActivePort	Unsigned16	Premier port actif
	4	LastActivePort	Unsigned16	Dernier port actif

Le Tableau 233 décrit la méthode GetPortInfo.

Tableau 233 – Méthodes de l'objet de gestion de TL – GetPortInfo

Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)				
Identificateur du type d'objet normalisé: 122				
Nom de méthode	**ID de méthode**	**Description de la méthode**		
GetPortInfo	4	Rapporte les informations relatives au port UDP pour un port UDP donné ou le premier port UDP actif		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	DeviceAddress	IPv6Address	L'adresse IPv6Address de cet appareil
	2	PortNumber	Unsigned16	Le port dont les infos sont demandées (0 = le plus bas)
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Status	Unsigned8	0 = réussite, > 0 échec
	2	PortNumber	Unsigned16	Ce numéro de port
	3	UID	Unsigned32	ID d'application du propriétaire
	4	Compressed	Boolean	La compression s'applique à ce port
	5	TPDUsInOK	Unsigned32	Nombre de TPDU acceptées sur le port
	6	TPDUsInKO	Unsigned32	Nombre de TPDU rejetées sur le port
	7	TPDUsOutOK	Unsigned32	Nombre de TPDU envoyées sur le port
	8	TPDUsOutKO	Unsigned32	Nombre d'échecs d'émission de TPDU

Le Tableau 234 décrit la méthode GetNextPortInfo.

Tableau 234 – Méthodes de l'objet de gestion de TL – GetNextPortInfo

Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)				
Identificateur du type d'objet normalisé: 122				
Nom de méthode	**ID de méthode**	**Description de la méthode**		
GetNextPortInfo	5	Rapporte les informations relatives au port UDP pour un port UDP donné ou le premier port UDP actif		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	DeviceAddress	IPv6Address	L'adresse IPv6Address de cet appareil
	2	PortNumber	Unsigned16	Le précédent port à partir duquel des infos sont demandées
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Status	Unsigned8	0 = réussite, > 0 échec
	2	PortNumber	Unsigned16	Le port pour lequel des infos sont rapportées
	3	UID	Unsigned32	ID d'application du propriétaire
	4	Compressed	Boolean	Si, oui ou non, la compression s'applique à ce port
	5	TPDUsInOK	Unsigned32	Nombre de TPDU acceptées sur le port
	6	TPDUsInKO	Unsigned32	Nombre de TPDU rejetées sur le port
	7	TPDUsOutOK	Unsigned32	Nombre de TPDU envoyées sur le port
	8	TPDUsOutKO	Unsigned32	Nombre d'échecs d'émission de TPDU

11.6.2.5.4 Alertes

Le Tableau 235 décrit l'alerte pour indiquer une utilisation illégitime d'un port par une application.

Tableau 235 – Types d'alertes de l'objet de gestion de TL – Utilisation illégitime de port

Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)					
Identificateur du type d'objet normalisé: 122					
Description de l'alerte: alerte pour indiquer une utilisation illégitime d'un port par une application					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: haut, moyen, faible, journal seulement)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = Event	1= Communication diagnostic	0 =IllegalUseOfPort	8 = Medium	Type: Unsigned16	Numéro de port de 16 bits

Le Tableau 236 décrit l'alerte pour notifier une TPDU reçue qui adresse un port non enregistré.

Tableau 236 – Types d'alertes de l'objet de gestion de TL – TPDU reçue sur un port non enregistré

Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)					
Identificateur du type d'objet normalisé: 122					
Description de l'alerte: alerte pour notifier une TPDU reçue sur un port non enregistré					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: haut, moyen, faible, journal seulement)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = Event	1= Communication diagnostic	1=TPDUonUnregisteredPort	4 = Low	Type: OctetString	40 premiers octets de la TPDU

Le Tableau 237 décrit l'alerte pour notifier une TPDU reçue qui ne satisfait pas aux politiques de sécurité locales.

Tableau 237 – Types d'alertes de l'objet de gestion de TL – La TPDU ne concorde pas aux politiques de sécurité

Nom du type d'objet normalisé: TL management object (TLMO, objet de gestion de TL)					
Identificateur du type d'objet normalisé:					
Description de l'alerte: alerte pour notifier une TPDU qui ne satisfait pas aux politiques de sécurité locales					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: haut, moyen, faible, journal seulement)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = Event	1= Communication diagnostic	2=TPDUoutOfSecurityPolicies	2 = Journal	Type: OctetString	40 premiers octets de la TPDU

12 Couche d'application

12.1 Généralités

La couche d'application (AL) définit des objets logiciels pour modéliser des objets du monde réel et définit également les services de communication nécessaires pour permettre la communication d'objet à objet entre les applications distribuées dans un environnement d'application ouvert et interopérable conforme à, et fonction de, la présente norme. La présente norme ne définit pas le fonctionnement des applications distribuées elles-mêmes; à savoir, ni le fonctionnement local de l'application elle-même, tel que la façon dont une application acquiert les valeurs des attributs d'objet qu'elle prend en charge pour l'accès ni les instructions concernant comment et quand une application applique les modèles et/ou les services définis dans le présent document ne sont adressés par la présente norme.

NOTE 1 Par exemple, une entrée analogique du monde réel est modélisée comme étant un objet AnalogInput. L'objet AnalogInput communique souvent sa variable de processus à une partie correspondante en utilisant le service d'édition fourni par l'AL.

L'AL prend en charge les appareils sans fil sur le terrain, ainsi que les passerelles qui intègrent un réseau sans fil conforme à la présente norme et ses appareils avec un système de commande d'hôte.[10]

Le modèle d'application dans la présente norme est spécifiquement conçu pour satisfaire aux contraintes d'environnements de communication sans fil.

NOTE 2 Une approche AL orientée objet est utilisée pour les raisons principales énoncées ci-après.

Les protocoles basés sur des commandes peuvent être conçus pour se conformer au modèle d'objet défini par la présente norme en décrivant les commandes comme étant des méthodes d'objet distinctes. A savoir, une application basée sur des commandes peut être modélisée en utilisant le modèle d'objet dans la présente norme.

Le modèle d'objet prend en charge des principes architecturaux bien admis de séparation logique des informations. Par exemple, les informations de gestion sont logiquement séparées des données de fonctionnement. Les informations opérationnelles pour des variables indépendantes sont logiquement séparées. Afin de maintenir la séparation d'informations, le protocole doit identifier l'objet correspondant. Cela ajoute un surdébit d'octets pour identifier l'objet, ce qui avait été jugé comme étant une approche plus que raisonnable pour la séparation architecturale d'informations.

12.2 Considérations relatives à l'énergie

Le besoin de prolonger la vie de batterie rend extrêmement importante la messagerie à haut rendement énergétique. L'utilisation de l'alimentation par batterie ou des techniques de récupération d'énergie pour les appareils de terrain connectés exige des considérations complémentaires dans la conception de la couche de communication, en comparaison à l'approche adoptée pour les appareils câblés. Non seulement chaque couche en communication a besoin de considérer la disponibilité des ressources d'appareil, mais également elle a besoin de considérer la réduction au maximum de la consommation d'énergie (dans des limites de contraintes d'architecture appropriées, naturellement) afin de prolonger la vie de la batterie ou de fonctionner dans les limites du budget de récupération.

Sachant que l'énergie est consommée par le traitement des messages, ainsi que par l'opération de commande fondamentale de l'appareil, l'efficacité des communications doit être équilibrée avec l'utilisation de principes architecturaux éprouvés et bien acceptés de séparation des informations ainsi qu'avec l'efficacité de traitement de message. Le modèle d'application native dans la présente norme est défini pour répondre à ces besoins.

12.3 Considérations de système de commande hérité

Des réseaux sans fil conformes à la présente norme peuvent être connectés à des systèmes de commande hérités.

NOTE 1 Un modèle qui s'intègre à des systèmes existants permet la réutilisation d'outils et d'interfaces existants et éprouvés et réduit également le temps global de développement et d'essai, ce qui produit des mises en œuvre robuste plus précoces.

Un processus d'application dans un appareil natif communique sur le réseau en utilisant seulement des services et des charges utiles définis par l'ASL. Un processus d'application dans un appareil non natif exige la communication de constructions qui ne sont pas définies par les charges utiles de service de l'ASL. Cette communication à partir de l'appareil non natif sur le réseau défini par la présente norme est accomplie en utilisant le sous-ensemble de

[10] Voir 5.2.6.5 pour un débat plus complet relatif aux rôles pris en charge par la présente norme.

services normalisés définis dans la présente norme qui prend en charge la communication de charges utiles qui ne sont pas explicitement et entièrement définies par la présente norme.

L'AL native définit des objets et services spéciaux pour soutenir la tunnellisation de protocoles non natifs pour répondre aux besoins d'intégration de systèmes.

Le jeu d'objets d'application définis qui prend en charge des charges utiles définies non natives est constitué de l'objet tunnel et l'objet d'interface. Le jeu de services d'application définis par une norme qui prennent en charge les charges utiles au-delà de celles définies dans la présente norme est constitué du service tunnel, qui est utilisé pour la communication apériodique, et du service édition utilisant le mode non natif, qui est utilisé pour des communications périodiques. Par exemple, la charge utile du service tunnel pour la messagerie apériodique afin d'encapsuler des données construites par un système hérité n'est pas définie dans le WISN.

NOTE 2 Une manière de réaliser une synthèse avec des systèmes existants est de créer une version à optimum d'énergie et à optimum de ressources d'une approche héritée existante orientée fils en établissant un mapping du modèle hérité au modèle de la présente norme et en utilisant directement l'AL native. De tels mappings doivent habituellement être définis par des consortiums de protocoles individuels, tels que la HART Communication Foundation (HCF), la Fieldbus Foundation (FF), PROFIBUS Nutzerorganisation (PNO), ODVA, qui prend en charge des protocoles gérés tels que CIP [Common Industrial Protocol (Protocole industriel commun)], et d'autres.[11] Une autre manière de réaliser la synthèse est d'utiliser un tunnel de protocoles à travers l'AL native. Pour les deux approches, les implications en termes d'énergie et de ressource sont des considérations importantes.

NOTE 3 Quelle que soit la méthode choisie, le système de plus haut niveau communique toujours avec les appareils sans fil au sein d'un réseau conforme à la présente norme.

NOTE 4 Des fichiers de description d'appareil électronique sont souvent utilisés pour satisfaire à cette exigence. Pour la présente norme, le langage de description d'appareil (DDL) ou le langage de description électronique de produit (EDDL) décrivent les appareils natifs.

NOTE 5 Voir Annexe R pour plus de détails concernant l'interface de système hôte.

12.4 Vue d'ensemble de la modélisation orientée objet

12.4.1 Généralités

Un modèle d'objet est un moyen neutre vis-à-vis de tout protocole, de toute plateforme et de tout langage de décrire et de distinguer les composants (éléments de système) qui ont une identité unique. Les objets séparent le monde en des morceaux sensés et gérables. Les définitions d'objet favorisent non seulement la modularité, mais aussi la réutilisabilité de composants. Un objet peut représenter toute chose qui a un état et un comportement; les objets exposent des attributs pour représenter l'état, et fournissent des méthodes qui opèrent sur l'état de l'objet pour effectuer des comportements particuliers. Par exemple, les méthodes spécifiques à un appareil qui peuvent être prises en charge par un DMAP peuvent inclure des méthodes d'autotest spécifiques à un appareil ou des méthodes de réinitialisation d'appareils spécifiques à un appareil.

12.4.2 Concept de communication d'objet à objet

Du point de vue de l'utilisateur, la communication d'AL se produit à partir d'un objet dans un processus d'application vers un autre objet dans un processus d'application. Les concepts de polymorphisme permettent aux mêmes techniques de communication d'être appliquées aux objets d'application utilisateur indépendants vis-à-vis de l'industrie selon la présente norme comme aux objets dépendants vis-à-vis d'une industrie selon la présente norme, ainsi qu'aux objets de gestion selon la présente norme.

---

[11] HART, FF-H1, PROFIBUS, et ODVA sont les marques commerciales de diverses organisations commerciales. Cette information est donnée à l'intention des utilisateurs de la présente norme et ne signifie nullement l'approbation ou la recommandation du propriétaire de la marque ou des produits associés. La conformité au présent document n'exige pas l'utilisation de l'appellation commerciale. L'utilisation des appellations commerciales requiert la permission du détenteur de l'appellation concernée.

En accord avec ce principe, le modèle d'application définit un modèle d'objet et un modèle d'interaction de communication (service et protocole). Le modèle d'application prend également en charge plusieurs processus d'application au sein d'un appareil, qui peuvent contenir chacun plusieurs objets normalisés. Cela permet à la présente norme de répondre aux besoins spécifiques du marché, tels que ceux pour les industries de transformation ou l'automation en usine, ainsi que de permettre la prise en charge pour les architectures d'appareils tant simple processeur que multiprocesseur.

L'objet d'application peut, par exemple utiliser les services de l'AL pour:

- lire la valeur d'un attribut d'un objet distant;
- écrire la valeur d'un attribut d'un objet distant;
- demander l'exécution d'une méthode spécifique à un objet d'un objet distant;
- rapporter une alerte relative à un objet distant;
- acquitter une alerte rapportée par un objet distant;
- éditer des données pour un objet distant en utilisant la largeur de bande de communication programmée;
- tunnelliser un message d'application natif non WISN vers un objet distant.

Le codage pour ces services peut être trouvé en 12.23.1.4.

12.4.3 Structure de la couche AL

L'AL est divisée en deux sous-couches, l'AL supérieure (UAL) et la sous-couche d'application (ASL), telle que montrée à la Figure 16. Il y a un rapport univoque (1:1) entre un ASLDE-SAP et un TLDE-SAP.

L'UAL contient les processus d'application pour l'appareil. Ces processus peuvent être représentés comme un UAP ou comme un processus de gestion (MP), comme le DMAP ou toute autre application de gestion logique telle qu'une application de gestion de sécurité.

Les UAP peuvent être utilisés, par exemple, pour:

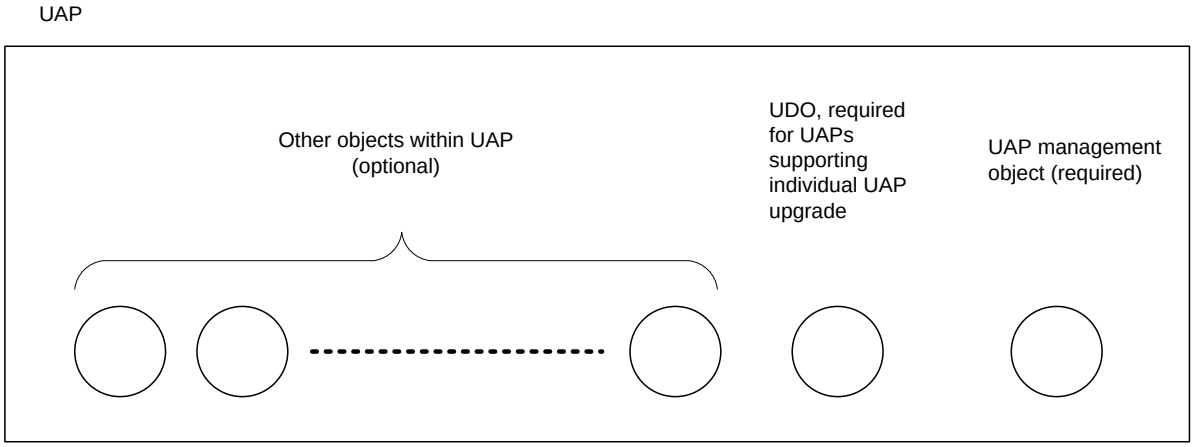
- traiter les matériels d'entrée et/ou de sortie;
- distribuer des communications vers un jeu d'UAP corésidents au sein d'un appareil (fonction proxy);
- prendre en charge la tunnellisation d'un protocole non natif (par exemple, hérité d'un système de commande) compatible avec l'environnement réseau de la présente norme; et/ou
- accomplir une fonction de calcul.

Un UAP peut accomplir une fonction individuelle ou n'importe quelle combinaison des fonctions. La manière dont un UAP accomplit ces fonctions en interne ne relève pas du domaine d'application de la présente norme. L'AL est concernée par le contenu de message spécifique à une application, le comportement visible de l'extérieur des objets normalisés contenus au sein de l'UAP, et les interfaces logiques à l'ASL qui représentent la communication d'UAP vers/depuis la suite inférieure de protocoles de communication de la présente norme. Les processus d'UAL peuvent contenir un ou plusieurs objets qui communiquent les uns avec les autres sur le réseau décrit dans la présente norme, en utilisant les services normalisés fournis par l'ASL.

NOTE La manière dont l'ASL met en œuvre son routage de messages interne ou sa communication entre applications au sein d'un appareil (au sein d'un UAP, au travers de plusieurs UAP dans un processeur commun, au travers de plusieurs UAP dans des processeurs physiques différents du même appareil, ou entre un UAP et un MP) relève d'une initiative locale et ne relève donc pas du domaine d'application de la présente norme.

12.4.4 Structure d'UAP

La Figure 110 décrit la structure globale d'un UAP tel que défini par la présente norme.



Légende

Anglais	Français
Other objects within UAP (optional)	Autres objets au sein de l'UAP (facultatif)
UDO, required for UAPs supporting individual UAP upgrade	UDO, requis pour les UAP prenant en charge la mise à niveau d'UAP individuel
UAP management object (required)	Objet de gestion d'UAP (requis)

Figure 110 – Objets d'application utilisateur dans un UAP

La représentation des applications et de leurs fonctions par des définitions normalisées d'objets permet la gestion et la construction uniformes d'applications distribuées. L'objet de gestion d'UAP identifie l'UAP auprès du réseau conforme à la norme et permet d'avoir une visibilité et/ou un contrôle sur certains aspects opérationnels de l'UAP en son ensemble. Cet objet de gestion d'UAP a un identificateur d'objet réservé de 1 (un). Si un UAP prend en charge la mise à niveau individuelle, l'UAP doit également contenir un objet UploadDownload (UDO) normalisé pour prendre en charge la mise à niveau d'UAP. Cet UDO a un identificateur d'objet réservé de 2 (deux). Si un UAP ne prend pas en charge la mise à niveau d'UAP individuelle, l'UAP ne doit pas contenir une instance d'objet avec l'identificateur d'objet de 2 (deux). Des objets complémentaires peuvent également être contenus au sein d'un UAP afin de fournir à l'UAP une fonctionnalité spécifique à une application.

NOTE 1 L'UAPMO est suffisant pour représenter l'UAP au système de communication.

NOTE 2 D'autres objets sont statiquement ou dynamiquement instanciés au sein de l'UAP.

NOTE 3 Il ne relève pas du domaine d'application de la présente norme de définir ce qui arrive aux données contenues au sein d'un UAP lorsque l'UAP est mis à niveau.

Le modèle d'interaction décrit la communication entre objets, y compris la classification de messages et les formats de messagerie. L'ASL contient les services qui prennent en charge la communication orientée objet et le routage vers l'objet de destination approprié au sein d'un UAP, à travers le réseau. Cette interaction réalise un mapping de l'ASL aux services fournis par la couche de suite inférieure de protocole de communication (voir Tableau 281 et Tableau 282 indiquant l'utilisation par l'AL des services de TL et les qualités de service). Entre l'UAL et l'ASL, il y a un SAP d'entité de données d'ASL (SAP d'ASLDE-n).

La gestion spécifique à l'ASL est également prise en charge localement par l'intermédiaire d'un SAP de gestion distinct.

12.5 Modèle d'objet

L'AL définie par la présente norme tire profit des concepts de modélisation orientés objet pour prendre en charge la tunnellisation tant de protocoles natifs que de protocoles (hérités) non natifs au sein d'applications. La tunnellisation de protocoles non natifs est réalisée par un UAP spécialisé qui inclut un ou plusieurs objets tunnel (TUN) et moyens de conversion de protocole. Cet UAP est constitué d'exactement un objet de gestion d'UAP pour permettre à la gestion uniforme de système et de réseau de l'UAP, plus un ou plusieurs TUN d'envoyer/recevoir des messages encapsulés tunnellisés vers l'UAP. D'autres objets natifs définis par la présente norme peuvent également être utilisés au sein d'un UAP de tunnellisation. Par exemple, la tunnellisation peut être utilisée pour la communication d'appareil sans fil à appareil sans fil, ainsi que la communication appareil sans fil à passerelle.

NOTE 1 Les constructions d'adressage autres que celles-ci ne relèvent pas du domaine d'application de la norme. Des constructions d'APDU de protocoles hérités (par opposition à des APDU natives) sont préservées au moyen d'encapsulation lorsque la tunnellisation d'application telle que définie par la présente norme est utilisée.

Une approche orientée objet est utilisée pour encapsuler les données (attributs) et la fonctionnalité (méthodes et état interne) pour la réutilisation et la cohérence. Les objets sont individuellement adressables en utilisant un identificateur d'objet qui est unique au sein de l'application. Cet identificateur unique permet à l'AL d'acheminer des messages vers la destination d'objet appropriée. Chaque message est interprété et traité par l'objet de destination en fonction du contexte et du contenu du message. Le fonctionnement d'objet est décrit en termes de fonctionnement, visible du réseau, de l'objet de destination qui est la cible du service d'AL.

La présente norme définit les identificateurs d'objet normalisés.

NOTE 2 Le complément des identificateurs normalisés pris en charge par un appareil est indiqué par la version de la présente norme qui est prise en charge. La version prise en charge est disponible auprès du DMAP. Voir Article 6 pour de plus amples détails.

Une instance d'objet qui est accessible au sein d'un processus d'application est distinguée d'une autre instance de la même classe d'objets dans le même processus d'application par son identificateur d'objet. Des instances d'objet différentes peuvent également avoir des valeurs d'attribut différentes et/ou des attributs conditionnels contenus dans son jeu d'attributs pris en charge.

A titre d'exemple, un processus d'application peut contenir deux instances de l'objet AnalogInput. Les instances d'objet au sein du processus d'application peuvent être distinguées par leur identificateur d'objet. Chaque objet peut prendre en charge différentes valeurs pour la mise à l'échelle et peut également exiger un différent complément d'alarmes devant être rapportées. Par conséquent, les instances peuvent avoir un complément différent d'attributs descriptor analogiques pris en charge par chaque instance.

Les objets définis dans les UAP et dans les MP de la présente norme adhèrent aux concepts traditionnels de modélisation d'objets; plus précisément, ces objets contiennent des attributs, et des méthodes appropriées spécifiques à un objet, si applicable, sont définies. L'AL définit des objets normalisés pour fournir l'interopérabilité (dans son domaine d'application) par l'intermédiaire de l'accès à des attributs normalisés et par l'intermédiaire de l'invocation de méthodes normalisées.

Des objets normalisés peuvent être classés dans des profils d'utilisation pour répondre aux besoins d'industries particulières.

Les objets de gestion normalisés sont censés être toujours disponibles. Des objets utilisateur d'application peuvent être instanciés de manière statique ou ils peuvent être instanciés de manière dynamique comme résultat d'une opération de téléchargement. Les objets normalisés sont extensibles selon les manières suivantes:

- Des types d'objets normalisés spécifiques à une industrie peuvent être ajoutés.
- Des types d'objet spécifiques à un fournisseur peuvent être ajoutés.
- Des attributs spécifiques à une industrie peuvent être ajoutés aux objets normalisés.
- Des attributs spécifiques à un fournisseur peuvent être ajoutés aux objets normalisés.
- Des méthodes spécifiques à une industrie peuvent être ajoutées à des objets par l'intermédiaire de profils spécifiques à une industrie.
- Des méthodes spécifiques à un fournisseur peuvent être ajoutées à des objets.
- Des profils spécifiques à une industrie de types d'objets peuvent être définis, tels qu'un profil d'industrie de transformation, un profil d'industrie d'automation en usine, et autres profils.

12.6 Modèle d'attribut d'objet

12.6.1 Généralités

Les objets définis par la présente norme prennent en charge deux sortes d'attributs, les attributs-clés d'objet et les attributs nommés.

Dans la présente norme, une ressource est représentée comme étant un objet et elle est identifiée par un attribut-clé d'objet, qui est une valeur numérique.

NOTE 1 La prise en charge d'un attribut-clé d'objet en utilisant une représentation alphanumérique de la ressource et celle des services d'annuaire correspondants pour localiser la ressource et résoudre la forme de nom alphanumérique externe en une forme numérique interne sont l'objet d'une normalisation future.

Un attribut spécifie un élément accessible représentant une propriété ou une caractéristique d'une ressource. Dans la présente norme, un attribut est représenté par une valeur numérique unique qui identifie de manière univoque l'attribut relativement à l'objet contenant. La plage prise en charge des valeurs valides pour un identificateur d'attribut est 0..4 095.

La présente norme définit les attributs d'objet normalisés. Des attributs normalisés complémentaires peuvent être définis à l'avenir.

NOTE 2 Le complément des attributs normalisés pris en charge est établi par la version de la présente norme qui est prise en charge. La version de la norme qui est prise en charge est disponible auprès du DMAP.

Le fait d'exposer les éléments de ressource comme étant des attributs d'un objet permet à l'état de l'objet d'être déterminé et permet également au comportement de l'objet d'être modifié. Un attribut de ressource est défini par:

- son influence sur le comportement d'objet;
- l'ensemble de valeurs qu'il peut prendre (telles que contraintes par la définition d'objet contenant l'attribut);
- les essais valides (par exemple, concordance d'ensemble de valeur valide) réalisables qu'il peut subir; et
- l'ensemble spécifique de conditions d'erreur qui peut découler d'un échec défini de l'objet en raison de l'accomplissement d'une opération orientée attribut.

Les attributs eux-mêmes n'ont pas de propriétés ou de sous-types accessibles. Des valeurs d'attribut peuvent être explicitement établies par des moyens externes ou par des moyens internes (par exemple, dérivées par calcul en utilisant les valeurs d'autres attributs).

Les attributs doivent avoir un type de données qui est un type scalaire normalisé défini par la présente norme. Les attributs peuvent avoir un type de données qui est une structure de données normalisée définie par la présente norme. Jusqu'à deux indices sont disponibles pour adresser les constructions avec des types normalisés définis par la présente norme. La plage valide pour un indice est 0..32 767.

NOTE 3 Par exemple, l'accès à un élément individuel d'une matrice unidimensionnelle de types scalaires normalisés est pris en charge. Comme autre exemple, l'accès à un élément individuel d'une structure de données contenue dans une matrice unidimensionnelle de telles structures est pris en charge.

Pour un attribut construit comme une matrice, la taille de la matrice doit être fixe et tous les éléments d'une matrice doivent être dimensionnés de façon homogène. Par exemple, une matrice de chaînes d'octets doit avoir la même taille de chaîne d'octets pour chaque élément de la matrice. Lorsque la dimension courante et la dimension maximale d'une matrice doivent être indiquées, il convient d'utiliser des informations de métadonnées. Ces informations de métadonnées sont décrites par le type de données de code 406 (structure de données Metadata_attribute) qui est défini en 6.2.6.3.

12.6.2 Attributs d'objets normalisés

Pour chaque objet normalisé, des attributs normalisés sont définis. Chaque attribut normalisé a un identificateur d'attribut normalisé qui est utilisé pour adresser l'attribut.

Les attributs d'objets normalisés peuvent être étendus selon les manières suivantes:

- Des attributs spécifiques à une industrie peuvent être ajoutés aux objets normalisés.
- Des attributs spécifiques à un fournisseur peuvent être ajoutés aux objets normalisés.

Des extensions aux attributs normalisés ont besoin d'être coordonnées pour s'assurer que les identificateurs d'attribut restent uniques au sein d'un type d'objet. Les mécanismes utilisés par des industries et des fournisseurs pour étendre les attributs de l'objet normalisé ne relèvent pas du domaine d'application de la présente norme.

12.6.3 Classification d'attributs

Les attributs sont classés pour fournir un guide relatif à leur fréquence de changement prévue. Ces informations sont utiles, par exemple, aux appareils passerelles qui placent des informations dans un cache. La fréquence à laquelle les valeurs d'attribut changent est caractérisée comme étant:

- "constant" (constante);
- "static" (statique);
- "static-volatile" (statique volatile);
- "dynamic" (dynamique); ou
- "non-cacheable" (non plaçable en cache).

Un attribut constant est invariable tout le temps. Un exemple d'un attribut constant est le numéro de série d'un appareil sans fil. Toutes les valeurs par défaut dans la présente norme sont des attributs constants. Les valeurs de ces attributs doivent être préservées lorsqu'un appareil subit un redémarrage à chaud/une panne de courant, lorsqu'un appareil se réinitialise aux valeurs d'usine par défaut ou lorsqu'une commande de réinitialisation donnée à l'attribut ou à l'objet de gestion pertinent est reçue.

L'information constante peut être:

- une information fixe qui ne change jamais, telle qu'une information pour indiquer un fabricant ou un numéro de série; et
- une information qui ne change pas pendant l'exploitation normale du système, mais qui peut changer, par exemple, lorsqu'un téléchargement de firmware se produit.

Un attribut "static" change rarement sa valeur. Habituellement, les données statiques sont changées comme résultat d'un message, d'une demande, ou d'un événement externe. Certaines informations statiques peuvent, par exemple, être seulement changées par un outil de configuration. Les plages de fonctionnement, les unités, les points d'extrémité de communication, les alarmes, et les valeurs d'entrée constantes sont des exemples

d'informations statiques. Les attributs stockant de l'information relative à la mise en service, ainsi que les informations de configuration fournies à un appareil, sont des attributs statiques. Les valeurs de ces attributs doivent être préservées lorsqu'un appareil subit un redémarrage à chaud/une panne de courant ou lorsqu'une commande de réinitialisation à un attribut ou objet de gestion sans rapport est reçue.

Un attribut " static-volatile" change rarement sa valeur. Habituellement, les données statiques volatiles sont changées comme résultat d'un message, d'une demande, ou d'un événement externe. Certaines informations statiques volatiles peuvent, par exemple, être seulement changées par un outil de configuration. Les valeurs de ces attributs peuvent ne pas être préservées lorsqu'un appareil subit un redémarrage à chaud/une panne de courant. Les valeurs de ces attributs doivent être préservées lorsqu'une commande de réinitialisation à un attribut ou objet de gestion sans rapport est reçue.

Un attribut "dynamic" peut être changé spontanément par l'appareil contenant l'objet et sans stimulation externe émanant du réseau sans fil. Des exemples d'attributs dynamiques sont les valeurs changeant fréquemment, telles que les variables de processus, les calculs et les temporisateurs. Des attributs dynamiques peuvent être traités différemment par un cache de passerelle changeant rarement des valeurs (statiques); cela appartient entièrement à la mise en œuvre interne de la passerelle. Un attribut dynamique n'est pas tenu de survivre lorsqu'un appareil subit un redémarrage à chaud/une panne de courant ou lorsqu'un appareil se réinitialise aux valeurs d'usine par défaut. Il peut être réinitialisé lorsqu'une commande de réinitialisation à un attribut ou objet de gestion pertinent est reçue.

Les informations "non-cacheable" ne sont jamais mises en tampon; par exemple, elles peuvent être utilisées pour l'information critique telle que l'information relative à la sécurité (dont l'utilisation peut ne pas relever du domaine d'application explicite de la présente norme), et pour les valeurs qui changent trop souvent pour faire du placement en cache une technique valide. Chaque fois que la valeur d'un attribut "non-cacheable" est demandée, elle doit être récupérée dans l'appareil final qui possède l'objet et l'attribut.

Si le placement en cache local d'appareil est nécessaire, cela relève de la responsabilité locale de l'application.

12.6.4 Accessibilité d'attribut

Les attributs accessibles du réseau peuvent être:

- accessibles pour être lus seulement; ou
- accessibles pour être tant lus qu'écrits.

12.7 Modèle de méthode

Les méthodes représentent le jeu d'interfaces (fonctions) spécifiques à un type d'objet qui peuvent être utilisées pour accéder à une instance d'objet. Par exemple, l'objet UploadDownload prend en charge une méthode StartUpload.

Les méthodes d'objets normalisés doivent toujours être disponibles, et ne doivent pas être renforcées au-delà de la définition donnée par la présente norme.

Les méthodes ne doivent pas être définies si le résultat équivalent peut être obtenu en utilisant un service d'AL (indépendant vis-à-vis de tout type d'objet) normalisé (le service lecture fourni par l'ASL, par exemple). La définition d'une méthode peut être justifiée, par exemple, pour remplacer une séquence de transactions de communication afin d'économiser de l'énergie. La définition d'une méthode peut également être justifiée lorsque des questions de synchronisation peuvent résulter si des actions individuelles sont utilisées plutôt qu'un ensemble de transactions atomiques.

Des méthodes d'objets normalisés peuvent être ajoutées à l'avenir par la présente norme.

Le déclenchement à base de temps des activités de processus d'application n'est pas une responsabilité de sous-système de communication. Si un tel déclenchement à base de temps est nécessaire, il est permis d'utiliser soit un paramètre d'une méthode, soit un attribut dédié d'un objet. Si la coordination à travers des objets est exigée, un objet d'application peut être défini avec un attribut représentant l'action coordonnée, agissant comme un proxy pour la coordination.

12.8 Modèle d'alerte

Le terme alerte est utilisé pour décrire un message d'application qui conseille ou avertit le destinataire de la présence d'une situation d'intérêt imminente ou existante. Le modèle d'alerte décrit des alertes rapportées par les objets résidents de processus d'application et le mécanisme pour les rapporter.

Deux types d'alertes sont pris en charge, à savoir les alarmes ("alarm") et les événements ("event"). L'événement est le terme utilisé pour représenter une condition sans état (c'est-à-dire, pour indiquer qu'une situation s'est produite). Les événements rapportent simplement que quelque chose s'est produit. Une alarme est un état avec état d'une situation existante, par exemple, qu'une alarme est passée à un état anormal, ou est revenue à la normale à partir d'un état anormal. La condition d'alarme reste true jusqu'à ce que la condition d'alarme soit éliminée. Alert est le terme utilisé pour décrire la messagerie relative à une condition d'événement ou une condition d'alarme. Les alarmes et les événements sont rapportés par l'intermédiaire du mécanisme de rapports d'alerte défini dans la présente norme.

Une alarme est caractérisée par un état, et les alertes sont utilisées pour rapporter:

- l'occurrence d'une condition; et
- le retour à la normale de la condition précédemment rapportée.

Les événements et les alarmes pris en charge par la présente norme s'inscrivent dans l'une des catégories suivantes:

– relative à un appareil;
– relative à la communication;
– relative à la sécurité; ou
– relative au processus de commande.

Chaque alarme et événement définis pour un objet doivent avoir un attribut associé qui décrit comment il(elle) est rapporté(e). Cet attribut associé doit inclure:

- s'il est activé ou désactivé pour les rapports; et
- sa priorité (importance).

Pour toutes les alarmes, l'information descriptive doit également inclure, dans le cas où l'alerte est une alarme, si, oui ou non, la condition est en alarme ou hors alarme.

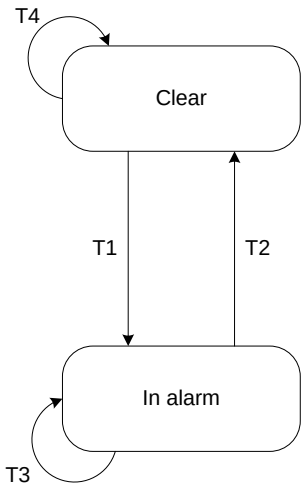
Une alarme analogique se produit lorsqu'une valeur atteint ou dépasse une limite établie. Pour les alarmes de valeur analogique, l'information descriptive doit inclure également l'information relative à la limite, le cas échéant, concernant le moment où la condition d'alarme est déclenchée.

12.9 Modèle d'état d'alarme

Le Tableau 238 et la Figure 111 représentent le modèle d'état d'alarme.

Tableau 238 – Table d'états pour des transitions d'alarme

Transition	Etat actuel	Evénement(s)	Action(s)	Etat suivant
T1	Clear	Alarme détectée	Rapporter l'alarme à l'ARMO dans le DMAP	In alarm
T2	In alarm	Clear est détecté	Rapporter alarm clear à l'ARMO dans le DMAP	Clear
T3	In alarm	Recovery requested	Rapporter l'alarme à l'ARMO dans le DMAP	In alarm
T4	Clear	Recovery requested	Ignorer	Clear
NOTE La récupération est habituellement demandée par un appareil distant.				



Légende

Anglais	Français
Clear	Sans
In alarm	En alarme

Figure 111 – Modèle d'états pour alarme

La détection d'alarme s'applique aux valeurs tant analogiques que discrètes. Les exemples d'alarmes analogiques incluent:

- alarmes de limite analogiques (par exemple, lorsqu'une valeur excède un seuil haut ou bas);
- alarmes d'écart analogiques (par exemple, la différence entre une variable de processus et un point de consigne);
- une alarme Boolean (par exemple, lorsque l'état du Boolean concorde avec le paramètre de limite discrète); et
- les diagnostics, tels que ceux définis dans la recommandation NAMUR NE107.

NOTE 1 Les alarmes qui dépendent de l'évaluation de conditions d'état spécifique à un appareil, spécifique entre objets ou spécifique au sein d'un objet sont considérées comme relevant d'une initiative locale et ne relèvent donc pas du domaine d'application de la présente norme.

NOTE 2 Des niveaux différents de conditions d'alarme sont indiqués par des alarmes différentes. Par exemple, pour une entrée analogique, une alarme High représente un niveau, et une alarme High-High représente un niveau supérieur.

12.10 Modèle d'état d'événement

12.10.1 Généralités

Le modèle d'état pour un événement est un sous-ensemble du modèle d'état pour une alarme.

12.10.2 Table et transitions d'états

Le Tableau 239 et la Figure 112 représentent respectivement la table d'état de l'événement et les transitions d'états de l'événement.

Tableau 239 – Table d'états pour des transitions d'événement

Transition	Etat actuel	Evénement(s)	Action(s)	Etat suivant
T1	Clear	Une condition d'événement est détectée	Déterminer les caractéristiques des rapports (la priorité, par exemple)	Detected
T2	Detected	Une condition d'événement est rapportée	Rapporter l'événement à l'ARMO dans le DMAP	Submitted
T3	Submitted	Présentation de la condition d'événement à l'ARMO comme achevée	Réinitialiser pour se préparer pour le prochain rapport d'événement	Clear

Figure 112 – Modèle d'événement

12.11 Rapports relatifs à l'alerte

12.11.1 Généralités

Des alertes sont rapportées promptement et exactement horodatées en utilisant une communication de rapports d'alerte unidirectionnelle placée en file d'attente. Les rapports relatifs aux alertes unidirectionnelles placées en file d'attente impliquent que l'appareil détectant l'alerte rapporte la condition en utilisant un flux de communication source/puits. Un acquittement d'alerte unidirectionnelle placée en file d'attente est reçu en retour.

NOTE 1 Dans un message édité, l'information de statut indique parfois qu'une alerte est disponible dans l'appareil rapporteur, accessible par l'intermédiaire du service lecture C/S. Cette méthode est parfois utilisée pour

l'automation en usine; d'autres systèmes d'automation en usine éditent une étiquette à un serveur qui génère des alarmes en soumettant à essai les valeurs limites dans le serveur.

NOTE 2 La communication source/puits est utilisée plutôt que client/serveur par anticipation d'une version future de la présente norme qui prend en charge des rapports alertes de multidiffusion.

12.11.2 Types d'alerte

L'objet de gestion de rapports d'alerte (ARMO) contenu dans le DMAP fournit l'encapsulation du rapport d'alerte, traite des temporisations et des répétitions de tentative, et étrangle les rapports d'alerte d'une façon commune pour toutes applications contenues au sein de l'appareil.

Il ne doit y avoir qu'un seul ARMO dans chaque appareil, dans le DMAP. Comme décrit en 6.2.7.2.3, le DMAP peut fournir un accès limité à des entités autres que le SMAP afin de prendre en charge des services relatifs aux alertes relatives à un processus et les alertes relatives à un appareil. Des acquittements d'alertes doivent être adressés à l'ARMO.

Les alertes de diagnostics sont spécifiques à l'appareil les rapportant. Par exemple, les alertes de diagnostics peuvent indiquer

- qu'une erreur s'est produite;
- qu'un symptôme a été détecté, qui peut indiquer qu'une erreur non diagnostiquée s'est produite;
- qu'un symptôme a été détecté, qui peut indiquer qu'une erreur peut se produire dans le futur;
- qu'une erreur se produira si une action préventive n'est pas entreprise.

Les alertes de diagnostics peuvent concerner un appareil dans son ensemble, un composant individuel, ou un jeu défini de composants d'un appareil. Les alertes de diagnostics peuvent être sans état ou orientées état. Les alertes de diagnostics peuvent être spécifiées par la présente norme, comme pour les alarmes relatives à une communication, ou peuvent être spécifiques à un fournisseur. Les alertes de diagnostics fournissent les informations qui peuvent être ultérieurement examinées pour établir des profils de comportement de systèmes de communication et/ou d'appareils.

Les alertes de processus sont spécifiques au processus commandé par l'appareil rapportant l'alarme de processus. Une alarme de processus indique une situation dans laquelle la variable signalée par une alarme a dépassé les limites opérationnelles établies. Par exemple, une alerte de processus peut être générée lorsqu'une condition de commande mesurable se situe hors des paramètres désirés de fonctionnement du système de commande.

Les alertes de processus fournissent des informations qui peuvent être ultérieurement examinées pour établir des profils de comportement de systèmes de commande, telles que:

– alertes qui se produisent souvent dans une séquence particulière;
– alertes qui se produisent souvent en étant proches dans le temps;
– alertes qui furent actives pendant des périodes de temps significatives;
– actions qui doivent résoudre une situation d'alerte;
– assistance pour déterminer les valeurs de réglages optimales du point de déclenchement et de l'hystérésis; ou
– l'information concernant les performances des systèmes de commande en termes de prévention et de résolution des alertes.

Les alertes de processus concernent un objet de commande particulier et une valeur d'attribut de l'objet en question (par exemple, le PV d'un objet d'entrée analogique). Les alertes de processus sont habituellement orientées état (c'est-à-dire des alarmes).

Un octet est utilisé pour coder les informations du type d'alerte. Pour tous les objets, trois plages normalisées sont identifiées pour les définitions disjointes du type d'alerte spécifique.

00..49: réservé pour et défini par la présente norme;

51..100: réservé pour des profils d'industrie d'une norme future;

101..255: attribuable au fournisseur pour les alertes spécifiques aux fournisseurs

12.11.3 Informations relatives aux rapports d'alerte

L'en-tête d'APDU indique l'application et l'objet qui ont initié la communication. Pour des rapports d'alerte, cela indiquerait le DMAP et l'ARMO. L'information de rapports d'alerte individuelle doit donc également identifier le processus d'application et l'objet au sein de ce processus qui est la source détectrice de l'alerte. En plus, les rapports d'alerte doivent inclure les informations suivantes:

- temps réseau de la détection;
- identificateur d'alerte individuel (de sorte que des doublons peuvent être détectés par le processus d'UAL);
- classe d'alertes (alarme ou événement);
- sens d'alarme (transition entrant en alarme, ou pas (c'est-à-dire soit retour à la normale soit un événement));
- catégorie d'alerte (diagnostic d'appareil, relative à une communication, relative à la sécurité, ou relative à un processus);
- priorité alerte (plages définies pour les priorités "high", "medium", "low", et "journal-only");
- type d'alerte (spécifique à un objet, et au sein de la catégorie d'alertes spécifique);

NOTE Voir 6.2.7.2 pour plus d'informations sur les alertes de communication et 6.1.2 pour plus d'informations sur les alertes de sécurité.

- taille des données associées en octets; et
- données associées pour la condition d'alerte.

Il convient que les données associées pour les diagnostics d'appareil soient définies pour la compatibilité avec la recommandation NAMUR NE107; il convient que de tels diagnostics indiquent si la condition de l'appareil est anormale, et le cas échéant la classe NAMUR: échec, ne relevant pas de la spécification, maintenance de diagnostic ou fonction de commande de diagnostic.

12.11.4 Récupération sur état d'alarme

En cas de perte de communication avec un appareil sans fil, les industries de transformation exigent que les conditions existantes soient récupérables par un appareil de réception d'alerte, comme en déterminant l'état lorsqu'un appareil de réception d'alerte démarre.

NOTE 1 Plusieurs conditions d'alarme peuvent coexister dans un appareil de commande de processus.

La récupération d'état d'alarme peut être demandée de l'ARMO. Une seule demande de récupération d'alarme déclenche une nouvelle production de rapports relatifs à toutes les conditions d'alarme existantes dans l'appareil d'une catégorie donnée. Lors de la récupération d'alarmes, l'appareil rapportant les alarmes doit fournir des alertes pour indiquer le moment où la récupération débute et le moment où la récupération est achevée.

NOTE 2 Les conditions d'événements étant sans état, elles ne sont donc pas récupérables.

12.12 Modèle d'interaction de communication

12.12.1 Généralités

La communication native dans la présente norme prend en charge à la fois le protocole natif et l'encapsulation de protocoles hérités par l'intermédiaire de la tunnellisation. Les types suivants de flux de communication sont anticipés pour les appareils conformes:

- communication unidirectionnelle en file d'attente (exemple: production de rapports d'alarme ou acquittement d'alarme);
- communication bidirectionnelle en file d'attente (exemple: lecture, écriture, invocation de méthode); et
- communication de publication unidirectionnelle en file d'attente (exemple: édition). L'emplacement réel des tampons utilisés pour contenir les données pour la communication de publication unidirectionnelle programmée est une question locale d'appareil.

NOTE Les publications de données programmées placées en file d'attente (publication périodique, publication de changement d'état, et publication commandée par une application) se produisent toutes (selon les besoins) dans la phase programmée. Les contrats de communication pour la communication périodique utilisent la communication de publication unidirectionnelle placée en file d'attente. Les contrats de communication pour la communication apériodique utilisent un paradigme de communication placée en file d'attente.

12.12.2 Communication de publication unidirectionnelle placée en file d'attente

12.12.2.1 Généralités

La communication unidirectionnelle en file d'attente est utilisée quand une application éditrice envoie un message vers une application abonnée. Le tampon contient le message à envoyer. Sur chaque contrat de publication unidirectionnelle en file d'attente, il y a un paramètre pour indiquer si le tampon doit être toujours émis (que le contenu ait été mis à jour ou pas), ou si le tampon doit être émis seulement s'il a été mis à jour depuis l'émission antérieure.

12.12.2.2 Contenu de tampon toujours émis

Dans la communication unidirectionnelle placée en file d'attente, si une suite de protocoles de communication d'édition reçoit une autre demande de service Publish ASL pour un contrat de communication particulier avant que le message précédent n'ait été émis, la nouvelle demande remplace la demande précédente. Dans l'abonné, si un nouveau message est reçu avant que le précédent n'ait été livré à l'application, le nouveau message doit remplacer le message non délivré précédent.

NOTE 1 Pour établir un contrat pour la communication périodique, le gestionnaire de système veille à ce que la capacité des appareils intermédiaires le long d'un chemin est adéquate pour prendre en charge la communication périodique.

NOTE 2 Il est anticipé qu'une application qui reçoit une publication plus ancienne après une plus récente peut choisir de rejeter la publication plus ancienne.

Si une suite de protocoles de communication d'édition ne reçoit pas une nouvelle demande de service pour le contrat lorsqu'il est temps d'émettre, la demande précédente doit être réémise. Si l'abonné reçoit la même demande de service d'application en succession, l'application abonnée doit traiter cette situation comme une réception d'un message en doublon. Le traitement d'application d'un message en doublon placé en file d'attente est laissé à l'application, et n'est pas défini par la présente norme.

12.12.2.3 Contenu de tampon émis en cas de changement seulement

Ce mode de communication placée en file d'attente prend en charge un mécanisme de communication de changement d'état.

Dans la communication unidirectionnelle en file d'attente, si une suite de protocoles de communication d'édition reçoit une demande de service pour un contrat de communication

avant que le message précédent n'ait été émis, la nouvelle demande remplace la demande précédente. Dans l'abonné, si un nouveau message est reçu avant que le précédent n'ait été livré à l'application, le nouveau message doit remplacer le message non délivré.

NOTE Pour établir un contrat pour la communication périodique, le gestionnaire de système veille à ce que la capacité des appareils intermédiaires le long d'un chemin est adéquate pour prendre en charge la communication périodique.

Si une suite de protocoles de communication d'édition ne reçoit pas une nouvelle demande de service pour le contrat lorsqu'il est temps d'émettre, la demande précédente ne doit pas être réémise. Si l'abonné reçoit la même demande de service d'application en succession, l'application abonnée doit traiter cette situation comme une situation d'erreur. Le traitement d'application d'un message en doublon placé en file d'attente est laissé à l'application, et n'est pas défini par la présente norme.

12.12.3 Communication unidirectionnelle placée en file d'attente

La communication unidirectionnelle en file d'attente prend en charge la distribution placée en file d'attente de services de communication ASL non confirmés (unidirectionnels). Pour répondre à ce type de besoin de communication, les couches inférieures des correspondants sont censées fournir un service de transfert de données placé en file d'attente.

Le traitement d'application d'un doublon d'un AlertReport doit entraîner l'envoi d'un autre AlertAcknowledgement. La réception d'un doublon d'un AlertAcknowledgement doit être ignorée. Le traitement d'application de doublons de messages Tunnel unidirectionnels placés en file d'attente est laissé à l'application, et n'est pas défini par la présente norme.

12.12.4 Communication bidirectionnelle placée en file d'attente

12.12.4.1 Généralités

La communication bidirectionnelle placée en file d'attente prend en charge la distribution placée en file d'attente de services de communication ASL confirmés (bidirectionnels). Pour répondre à ce type de besoin de communication, les couches inférieures des correspondants sont censées fournir un service de transfert de données placé en file d'attente.

Ce nombre maximal de demandes de service confirmées bidirectionnelles en file d'attente (client/serveur) simultanément en cours autorisées pour un contrat est indiqué au processus d'application par le contrat de communication lorsque le contrat est accordé. La valeur par défaut pour cette valeur maximale doit être 1, c'est-à-dire que la valeur par défaut indique que le contrat prend en charge une seule demande en cours à un moment quelconque.

Le traitement d'application d'un doublon de demande est d'envoyer une autre réponse. Le traitement d'application d'un doublon de réponse lorsqu'il est reçu une réponse qui ne concorde pas avec un identificateur de demande en cours doit être d'ignorer la réponse.

12.12.4.2 Répétitions de tentative et contrôle de flux

12.12.4.2.1 Généralités

L'AL définie par la présente norme doit suivre à la trace ce qui arrive aux demandes de service client/serveur placées en file d'attente qu'elle envoie. Cela est nécessaire pour deux raisons, pour assurer la fiabilité de la livraison et pour le contrôle de flux.

Pour la fiabilité de la livraison, l'application a besoin de pouvoir déterminer quand il convient qu'elle renvoie (répète) le message. Il y a deux situations dans lesquelles la répétition peut être nécessaire: la première quand la demande de message n'est pas arrivée à destination et la seconde quand la demande de message est arrivée, mais que la réponse de l'application n'a pas réussi à revenir au demandeur original. Le contrôle de flux est nécessaire pour vérifier que l'appareil de destination n'est pas submergé de messages qu'il ne peut pas traiter, et aussi pour protéger le réseau et optimiser le débit de réseau.

La présente norme prend en charge la notification d'encombrement explicite directe par la suite de protocoles de communication inférieure et prend en charge un écho de niveau d'application de retour à un client de demandeur de service à quatre parties si l'encombrement s'est produit sur le chemin pris pour la demande initiale de service.

Pour permettre simultanément plusieurs demandes en cours tout en permettant toujours à une application de réaliser à la fois la livraison fiable et le contrôle de flux, chaque demande de client doit contenir un identificateur unique. La réémission d'une demande (répétitions de tentative) doit utiliser le même identificateur. Cet identificateur permet à l'application de mettre en œuvre une technique de fenêtre glissante pour contrôler le flux. Le client doit démarrer un temporisateur de temporisation relatif au service lorsqu'il initie une demande de service de client. Ce temporisateur doit être basé sur les temps de propagation aller-retour (RTT) pour des messages, et il doit accorder suffisamment de temps pour qu'un message issu d'une application dans l'appareil X atteigne l'application de destination dans l'appareil Y, pour que l'application de serveur dans l'appareil Y produise une réponse, et pour que la réponse revienne à l'application demandeuse de service dans l'appareil X.

NOTE Cette méthode est communément connue dans les communications comme étant la communication utilisant un acquittement positif avec réémission.

La Figure 113 présente un exemple de trois messages de demande d'écriture en cours simultanées avec un seul message concaténé qui contient les réponses de toutes les demandes d'écriture en cours. La concaténation est utilisée pour économiser du trafic de messagerie.

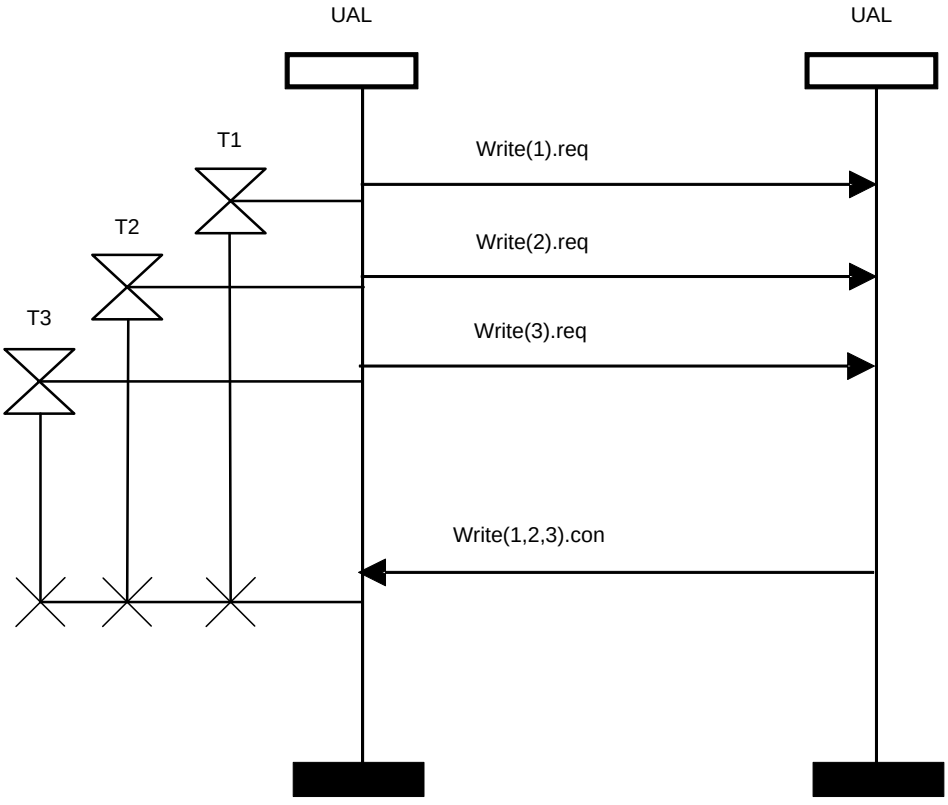

Figure 113 – Exemple réussi de plusieurs demandes en cours avec concaténation des réponses

12.12.4.2.2 Répétitions de tentative et intervalles de temporisation

12.12.4.2.2.1 Généralités

La méthode définie par l'IETF RFC 6298 doit être utilisée pour calculer une valeur appropriée pour l'intervalle de temporisation de répétitions de tentative (RTO). Pour calculer le RTO

courant, un client doit maintenir deux variables d'état, $SRTT$ temps de propagation aller-retour lissé) et $RTTV$ (variation du temps de propagation aller-retour), dans la portée d'un contrat.

Jusqu'à ce qu'une mesure du temps de propagation aller-retour (RTT) ait été faite pour un segment envoyé entre le client et le serveur, il convient que le client mette RTO = 3 s.

Lorsque la première mesure R de RTT est faite, le client doit mettre:

$SRTT = R$

$RTTV = R/2$

$RTO = SRTT + 4 \times RTTV$

Quand un RTT ultérieur est disponible, R est effectuée. Le client doit mettre à jour le $RTTV$, le $SRTT$, et le RTO en utilisant les calculs suivants, où la valeur recommandée pour β est 0,25, et la valeur recommandée pour α est 0,125:

$RTTV = (1 - \beta) \times RTTV + \beta \times |SRTT - R|$

$SRTT = (1 - \alpha) \times SRTT + \alpha \times R$

$RTO = SRTT + 4 \times RTTV$

Chaque fois que RTO est calculé, le RTO doit être arrondi selon les règles suivantes:

Si RTO < 1 s, mettre RTO = 1 s.

Si RTO < 60 s, mettre RTO = 60 s.

La détermination de l'occurrence de temporisation relève d'une initiative locale. Lorsqu'une temporisation a été déterminée comme s'étant produite, le repli exponentiel doit être utilisé pour les temporisations consécutives en mettant $RTO = RTO \times 2$ pour envoyer les répétitions de tentative. Il convient que la valeur maximale de 60 s soit utilisée pour fournir une limite supérieure à cette opération de doublement. Les répétitions de tentative cessent soit lorsqu'une réponse est reçue, soit lorsque la limite maximale de répétitions de tentative est atteinte. Le nombre maximal de répétitions de tentative autorisé pour une demande de client est indiqué par l'intermédiaire d'un attribut de l'objet de gestion UAP. La valeur sélectionnée pour le nombre maximal de répétitions de tentative autorisé relève d'une initiative locale.

NOTE L'IETF RFC 6298 contient une recommandation concernant la gestion du temporisateur TimeoutInterval.

12.12.4.2.2.2 Répétitions de tentative pour des messages sans ordre

Les messages sans ordre sont indépendants en ce que les réponses peuvent être reçues dans un ordre différent de l'ordre dans lequel les demandes ont été envoyées. En conséquence, chaque message de demande temporise et fait l'objet d'une répétition de tentative de manière indépendante.

La Figure 114 est un exemple de la façon dont une temporisation et une répétition de tentative du deuxième message dans une séquence de trois messages sans ordre, en raison de l'échec de la demande à atteindre le serveur, sont traitées.

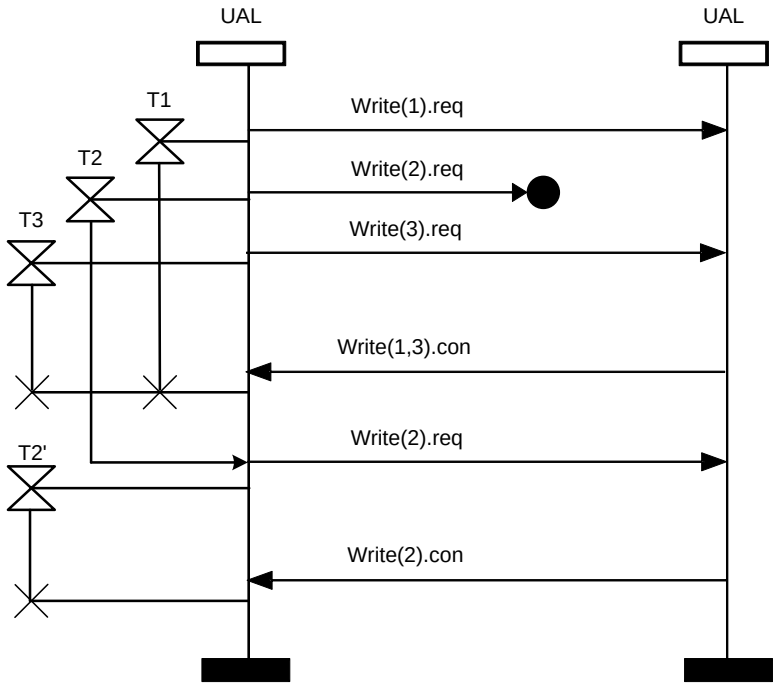

Figure 114 – Exemple de plusieurs demandes sans ordre en cours avec deuxième demande d'écriture initialement infructueuse

12.12.4.2.2.3 Répétitions de tentative pour des messages ordonnés

Les messages ordonnés sont dépendants de l'ordre; à savoir, les réponses ne peuvent pas être reçues dans un ordre différent de l'ordre dans lequel les demandes ont été envoyées. En conséquence, si un message plus tardif reçoit une réponse avant un message plus précoce, cela indique que le message pour lequel aucune réponse n'avait été reçue doit être temporisé et faire l'objet d'une répétition de tentative.

La Figure 115 est un exemple de la façon dont une temporisation et une répétition de tentative du deuxième message dans une séquence de trois messages sans ordre, en raison de l'échec de la demande à atteindre le serveur, sont traitées.

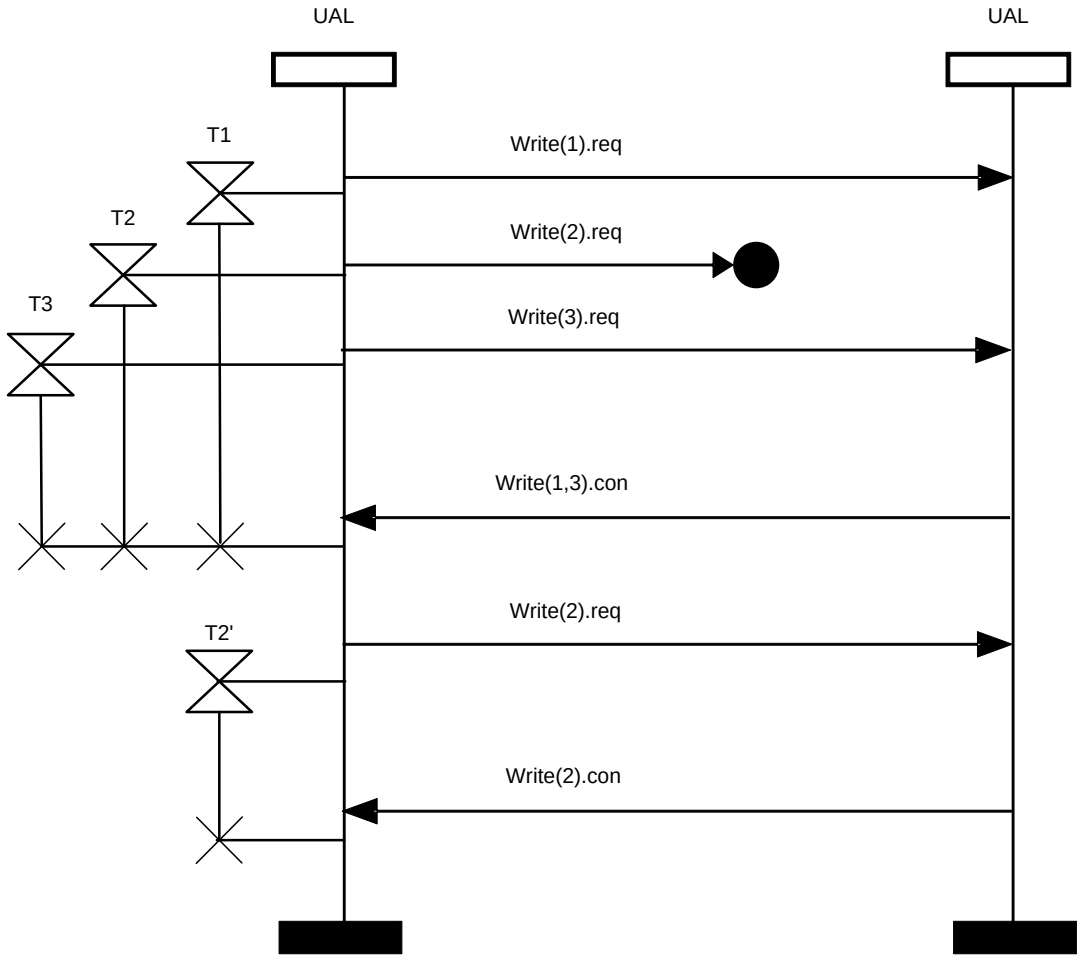

Figure 115 – Exemple de plusieurs demandes ordonnées en cours avec deuxième demande d'écriture initialement infructueuse

La livraison ordonnée concerne seulement le téléchargement montant/téléchargement descendant. Le Max_Send_Window_Size pour des contrats de communication de téléchargement montant/téléchargement descendant doit être fixé à 1. A ce titre, la livraison de messages ordonnée n'est pas prise en charge par les couches inférieures de la suite de protocoles définie par la présente norme.

12.12.4.2.3 Contrôle de flux

Les communications de client/serveur ne sont pas contrôlées par le débit de processus d'application; l'équité de débit d'AL est plutôt mise en application par les processus d'application sur une base par contrat afin de réduire au maximum l'équité de coût de l'encombrement sur le réseau.

Max_Send_Window_Size (Tableau 26) pour un contrat est le nombre maximal de demandes client qui peuvent simultanément être en attente d'une réponse dans la portée d'un contrat. Il convient (mais cela n'est pas exigé) que les clients utilisent des identificateurs de demande séquentiellement contigus. La valeur de Max_Send_Window_Size est établie sur une base contractuelle par le gestionnaire de système. L'OutstandingList représente les messages qui ont été envoyés et qui attendent actuellement une réponse.

L'AvailableSendWindowSize représente la fenêtre d'envoi utilisable, à savoir, l'ensemble de demandes client qui peuvent être envoyées, sans violer le Max_Send_Window_Size, en prenant en compte le nombre de messages contenus dans l'OutstandingList. Lorsque les fenêtres sont vides, et CurrentSendWindowSize est égal à Max_Send_Window_Size, la fenêtre d'envoi utilisable s'étire à partir de la dernière demande client acquittée pour le

prochain nombre Max_Send_Window_Size de demandes, et représente le jeu des demandes client qui peuvent être envoyées, sans violer le Max_Send_Window_Size.

Les applications doivent initialement mettre leur valeur pour que leur CurrentSendWindowSize soit un (1). Le RTT est alors mesuré par l'application pour n transactions complètes. S'il ne se produit aucune temporisation au cours de ces transactions, et si le Max_Send_Window_Size n'a pas été atteint, le CurrentSendWindowSize doit être incrémenté de un (1). La valeur de CurrentSendWindowSize doit être égale à la taille de la CurrentSendWindowLimit +1.

NOTE Ce mécanisme pour augmenter la taille de fenêtre est plus conservateur que celui habituellement utilisé pour répondre à des exigences d'évitement d'encombrement de TCP.

Une réponse étant reçue, la demande correspondante se déplace de la fenêtre d'envoi vers la fenêtre de réponse achevée, et la taille de AvailableSendWindowSize augmente de 1 si le Max_Send_Window_Size n'a pas été atteint. Si une temporisation se produit en attendant une réponse, la perte ou l'encombrement de message est indiqué(e). Si cela se produit, alors:

- Aucun message complémentaire ne doit être placé dans l'OutstandingList tant que l'OutstandingList n'a pas d'abord été vide.
- La CurrentSendWindowLimit doit être mise à un (1).
- Les messages qui étaient dans l'OutstandingList au moment de l'effondrement doivent faire l'objet de répétitions de tentative dans l'ordre, selon les politiques de répétitions de tentative définies ci-dessus. Les répétitions de tentative utilisent le repli exponentiel si la première tentative ne réussit pas. Les répétitions de tentative doivent continuer jusqu'à ce qu'une réponse soit reçue ou jusqu'à ce que le nombre maximal de répétitions de tentative ait été atteint. Lorsque l'une ou l'autre de ces conditions se produit, le traitement de messages est considéré comme achevé, et le message doit être retiré de l'OutstandingList.

Les demandes de client peuvent continuer, accumulant le CurrentSendWindowLimit à la valeur de Max_Send_Window_Size en utilisant la procédure décrite ci-dessus.

EXEMPLE dans un exemple de la façon dont les fenêtres sont utilisées dans une situation où il n'y a aucune répétition de tentative:

Soit Max_Send_Window_Size constant, égal au nombre maximal de demandes simultanément en cours permis par le contrat. Cette limite est établie par le gestionnaire de système.

Soit CurrentSendWindowSize la variable qui représente le nombre de demandes simultanément en cours qui existent pour le contrat à l'instant t. CurrentSendWindowSize est un nombre entier non négatif inférieur ou égal à Max_Send_Window_Size.

Soit UsedSendWindowSize la variable qui représente le nombre de demandes simultanément en attente qui attendent toujours des réponses.

AvailableSendWindowSize = CurrentSendWindowSize – UsedSendWindowSize.

Hypothèse: Max_Send_Window_Size = 3

T1: initialisation: CurrentSendWindowSize = 1; UsedSendWindowSize = 0; AvailableSendWindowSize = 1;

T2: message M1 envoyé: CurrentSendWindowSize = 1; UsedSendWindowSize = 1; AvailableSendWindowSize = 0;

T3: message M1, réponse reçue: CurrentSendWindowSize = 1; UsedSendWindowSize = 0; AvailableSendWindowSize = 1;

T4: message M2 envoyé: CurrentSendWindowSize = 1; UsedSendWindowSize = 1; AvailableSendWindowSize = 0;

T5: message M3, réponse reçue: CurrentSendWindowSize = 2; UsedSendWindowSize = 0; AvailableSendWindowSize = 2;

Le CurrentSendWindowSize a été incrémenté de 1, car:

a) il a été à la taille 1, et 2 transactions se sont achevées avec succès;

b) CurrentSendWindowSize < Max_Send_Window_Size.

T6: message M4 envoyé: CurrentSendWindowSize = 2; UsedSendWindowSize = 1; AvailableSendWindowSize = 1;

T7: message M5 envoyé: CurrentSendWindowSize = 2; UsedSendWindowSize = 2; AvailableSendWindowSize = 0;

T8 Message M4 et M5, réponses reçues: CurrentSendWindowSize = 2; UsedSendWindowSize = 0; AvailableSendWindowSize = 2;

T9: message M6 envoyé: CurrentSendWindowSize = 2; UsedSendWindowSize = 1; AvailableSendWindowSize = 1;

T10: message M7 envoyé: CurrentSendWindowSize = 2; UsedSendWindowSize = 2; AvailableSendWindowSize = 0;

T11: message M6, réponse reçue: CurrentSendWindowSize = 3; UsedSendWindowSize = 1; AvailableSendWindowSize = 2;

Le CurrentSendWindowSize a été incrémenté de 1, car:

a) il a été à la taille 2, et 3 transactions se sont achevées avec succès;

b) CurrentSendWindowSize < Max_Send_Window_Size.

T12: message M8 envoyé: CurrentSend WindowSize = 3; UsedSendWindowSize = 2; Available SendWindowSize = 1;

T13: message M9 envoyé: CurrentSendWindowSize = 3; UsedSendWindowSize = 3; AvailableSendWindowSize = 0;

T14: message M7, réponse reçue: CurrentSendWindowSize = 3; UsedSendWindowSize = 2; AvailableSendWindowSize = 1;

T15: message M10 envoyé: CurrentSendWindowSize = 3; UsedSendWindowSize = 3; AvailableSendWindowSize = 0;

La Figure 116 décrit une situation dans laquelle la fenêtre d'envoi courante ne s'est pas encore accumulée jusqu'à la taille limite maximale de fenêtre d'envoi. Dans cet exemple, la taille limite maximale de fenêtre d'envoi est de trois messages, un message dans la liste en cours a été envoyé et attend une réponse, et un message peut être envoyé avant que la limite de fenêtre d'envoi utilisable ne soit atteinte.

12.12.4.2.4 Recherche d'encombrement par sondage

Certaines configurations de système sont plus susceptibles que d'autres d'encourir une perte de message en raison d'un encombrement de réseau. Dans des configurations de système où l'encombrement est plus vraisemblable, une application peut souhaiter réguler ses demandes de service d'AL selon que l'encombrement de réseau est présent ou absent. Pour ce faire, une application peut rechercher l'encombrement par sondage. Pour effectuer un tel sondage, l'application peut s'engager dans un simple échange d'un seul message.

NOTE 1 Le sondage est prévu pour les besoins de diagnostic seulement. Un seul message est utilisé pour vérifier que les sondes ne surchargent pas le réseau et pour s'assurer que la réponse à une sonde est discernable.

La demande de message à utiliser lors du sondage doit être un service lecture non concaténé. La demande de lecture et la réponse de lecture correspondante pour la sonde doivent chacune s'inscrire au sein d'un seul fragment de DL. N'importe quel attribut d'objet peut être utilisé comme sonde; cependant, il convient (mais cela n'est pas exigé) que le même objet et le même attribut soient utilisés de façon cohérente pour le sondage. Par exemple, un attribut normalisé de l'UAPMO peut être utilisé pour sonder des UAP, et un attribut normalisé du DMO de DMAP pour sonder le DMAP car ces objets doivent être présents dans les applications correspondantes.

Si la temporisation de la sonde n'expire pas avant la réception de la réponse, alors il convient que l'application suppose qu'il n'y a aucun encombrement. Cependant, si la réponse n'est pas retournée avant que l'intervalle de temporisation des répétitions de tentative ne se soit écoulé, cela indique une plus forte probabilité de présence de l'encombrement de réseau. Dans cette situation, le processus d'application doit autoréguler ses activités de communication en mettant son CurrentWindowSize à 1. Voir 12.12.4.2.3. Si l'application souhaite envoyer un autre message de sondage d'encombrement, elle peut le faire en

utilisant le repli exponentiel tel que décrit en 12.12.4.2.2.1, mais elle doit utiliser un identificateur de demande temporellement discernable pour chaque sonde de message.

NOTE 2 Une telle distinction permet à une application de calculer le RTT spécifique au sondage d'encombrement et de prendre des décisions relatives à l'encombrement en conséquence en fonction des données de RTT relatives au sondage d'encombrement.

Par exemple, un UAP dans l'appareil X peut produire une demande de service lecture pour l'attribut d'état normalisé exigé de l'UAPMO exigé contenu au sein de l'application de destination dans l'appareil Y. Cette demande de lecture peut être traitée comme sonde d'encombrement initiée par un processus d'application.

Dans le cas spécifique d'un téléchargement descendant ou d'un téléchargement montant, une application peut rechercher l'encombrement par sondage. Dans ces situations, le sondage d'encombrement doit être accompli comme suit:

- Pour sonder avant de débuter une opération de téléchargement descendant, la sonde de client doit être une demande de lecture à l'attribut MaxDownloadSize de l'objet UploadDownload.
- Pour rechercher l'encombrement par sondage pendant une opération de téléchargement descendant, la sonde de client doit être une demande de service lecture de l'attribut de LastBlockDownloaded de l'objet UploadDownload.
- Pour la recherche par sondage avant de débuter une opération de téléchargement montant, la sonde de client doit être une demande de lecture à l'attribut MaxUploadSize de l'objet UploadDownload.
- Pour rechercher l'encombrement par sondage pendant une opération de téléchargement montant, la sonde de client doit être une demande de service lecture à l'attribut LastBlockUploaded de l'objet UploadDownload.

12.12.5 Contrat de service de communication

Un UAP fait une demande de contact au DMAP local par l'intermédiaire d'un SAP d'UAPME-n afin d'établir un accord pour un service de communication dont l'UAP a besoin. Si le besoin peut être satisfait, le DMAP fournit un identificateur de contrat de service à l'UAP qui représente l'accord. L'identificateur de contrat est passé de l'UAP à l'ASL lorsqu'il fait une demande de service d'ASL. Cet ID de contrat de service est alors utilisé par la suite de protocoles de communication inférieure pour identifier les caractéristiques spécifiques à une couche du contrat qui ont été établies dans les couches inférieures de suite de protocoles de communication par le DMAP local comme étant une partie intégrante de l'établissement du contrat de service. La communication d'informations exigées, de l'UAP vers le DMAP, afin d'acquérir un identificateur de contrat de service est une question interne à un appareil et, donc, n'est pas spécifiée par la présente norme.

Tous les contrats de communication ont un jeu d'informations de base. Les informations exigées complémentaires dépendent du type de relations de communication désirées. Par exemple, une relation éditer/s'abonner (P/S) pour la communication périodique exige des spécifications de la phase et de la période désirées.

La présente norme ne spécifie pas comment déterminer les informations dont l'UAP a besoin pour spécifier les caractéristiques d'un contrat. Par exemple, de telles informations peuvent être configurées, telles que la périodicité et la phase à utiliser dans une communication programmée, ou de telles informations peuvent être déterminées par le fournisseur de l'appareil qui contient l'UAP.

Les demandes de contrat peuvent être négociées à la baisse par le gestionnaire de système. Les politiques d'UAP concernant le traitement des contrats négociés à la baisse, ainsi que les politiques concernant le traitement d'un contrat décliné, ne relèvent pas du domaine d'application de la présente norme. Voir 6.3.11 pour des informations complémentaires relatives aux informations qui ont besoin d'être spécifiées pour demander un contrat.

La période d'édition est représentée par une valeur entière signée de 16 bits. Une valeur positive indique la période de publication sous la forme d'un multiple de 1 s (par exemple: une valeur de 5 spécifie une période d'édition de 5 s; une valeur de 3 600 indique une période de publication de 1 h). Une valeur négative indique une publication sur une fraction de 1 s (par exemple: -4 indique une publication tous les ¼ s, -2 indique une publication toutes les ½ s). Une valeur nulle indique qu'il convient qu'il ne se produise aucune publication.

Il convient que la périodicité sélectionnée soit basée sur l'efficacité de l'opération avec cette pratique de processus normalisée et typique.

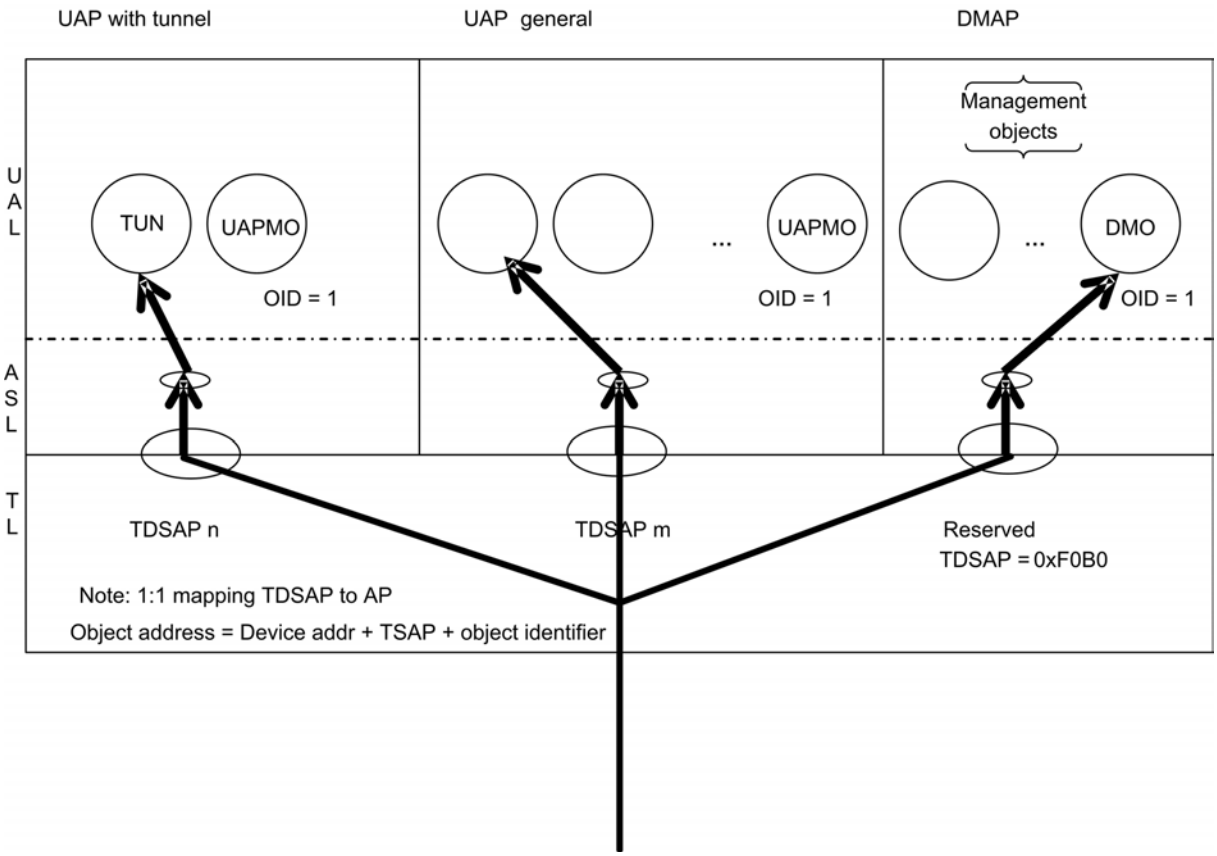
La connaissance par le DMAP du port de TSAP de destination n'est pas une exigence pour créer un contrat de service, car l'établissement de contrat est concerné par des ressources pour la communication sur des conditions de réseau, tandis que le port de destination est utilisé dans l'appareil de destination, après que la communication sur le réseau s'est produite.

NOTE Les politiques de répéter la tentative d'établissement d'un contact en cas d'échec d'établissement de contrat ou de révocation d'un contrat sont des comportements de l'appareil dans son ensemble (par opposition aux comportements d'un composant au sein de l'appareil). Les comportements au niveau d'un appareil sont débattus en 6.3.11.2.4.2.

12.13 Adressage d'AL

12.13.1 Généralités

Certaines informations sont exigées pour adresser un objet, un attribut d'objet, un élément d'attribut d'objet (par exemple, un élément d'une structure ou un élément d'une matrice), ou une méthode d'objet dans des communications natives. La Figure 119 représente le modèle d'adressage général pour les objets de processus d'UAL.



Légende

Object address = Device addr + TSAP + object identifier	Adresse d'objet = addr appareil + TSAP + identificateur d'objet

Figure 119 – Modèle d'adressage général

12.13.2 Adressage d'objet

Un objet est adressé dans les communications en monodiffusion en spécifiant:

- son adresse physique d'appareil conteneur;
- le TDSAP de DL qui est utilisé pour communiquer avec le processus UAL unique qui contient l'objet (c'est-à-dire, le TDSAP est en correspondance 1:1 à un processus d'application);
- un numéro de port T qui correspond à un TDSAP particulier; et
- l'identificateur d'objet unique au sein du processus d'UAL.

Des ports T doivent être assignés dans l'ordre consécutif à des TDSAP, en commençant par le premier port T disponible. Par exemple, le TDSAP numéro 0 doit être corrélé avec le premier port T 0xF0B0. Le TDSAP numéro 1 doit être corrélé avec le deuxième port, 0xF0B1, et ainsi de suite.

Des TDSAP particuliers, et leurs ports T correspondants, sont réservés par la présente norme afin d'être bien connus par toutes les applications. Spécifiquement, le DMAP dans chaque appareil doit avoir le numéro de port de transport 0xF0B0 réservé, qui est associé au TDSAP numéro 0. Le SMAP dans un appareil doit avoir le numéro de port de transport 0xF0B1 réservé, qui est associé au TDSAP numéro 1. Les appareils qui n'ont pas un SMAP présent ne doivent pas utiliser le numéro de port T de 0xF0B1.

Il convient que les UAP prévus pour un grand nombre de messages utilisent les ports T de 0xF0B2 à 0xF0BF, car ils sont représentés sous forme compressée sur le réseau, minimisant ainsi l'utilisation des ressources réseau, ainsi que l'encombrement de RF et la demande en énergie de l'appareil. Voir 11.4.4 pour plus de détails relatifs aux TDSAP et aux ports T.

Afin de réduire au maximum le codage des messages d'application, il convient que les identificateurs d'objet soient alloués consécutivement, en commençant à 1.

NOTE L'identificateur d'objet 0 est réservé par la présente norme à l'usage de l'objet de gestion de processus d'application contenu au sein de tous les processus d'application.

La communication en multidiffusion n'est pas prise en charge.

12.13.3 Adressage d'attribut d'objet

Un attribut d'un objet est adressé en spécifiant:

- l'adressage de son objet conteneur; et
- l'identificateur d'attribut d'objet au sein de l'objet.

Afin de réduire au maximum le codage des attributs de messages d'application, il convient que les attributs soient alloués consécutivement, en commençant à 1.

NOTE L'identificateur d'attribut 0 est réservé par la présente norme comme moyen de référence pour toute une somme.

12.13.4 Adressage d'attribut d'objet

12.13.4.1 Généralités

L'adressage pour des attributs est défini en fonction du type d'attribut. La présente norme prend en charge les types d'attribut suivants:

a) types scalaires normalisés définis par la présente norme;

b) matrices d'éléments homogènes ou hétérogènes à une seule dimension (unidimensionnelles) d'origine 1 du type a);

c) matrices d'éléments à deux dimensions (bidimensionnelles) d'origine [1,1], où la première dimension indexe une matrice homogène du type b).

Les structures de données normalisées définies par la présente norme sont modélisées et accédées sous la forme de matrices d'éléments hétérogènes unidimensionnelles d'origine 1. Ainsi l'accès au $k^{\text{ème}}$ membre d'une structure de données, tel qu'il est énuméré dans l'ordre de déclaration de ses éléments membres, est fourni en accédant à son $k^{\text{ème}}$ élément comme si la structure de données était une matrice hétérogène d'origine 1.

NOTE En termes de programmation, cela signifie que le $k^{\text{ème}}$ membre de la structure s, qui pourrait être référencé en programmation sous la forme s.memberName$_k$, est accédé comme s'il était $s[k]$, où k représente l'index ordinal d'origine 1 du membre dans la déclaration contenue.

Les éléments d'une matrice bidimensionnelle qui constituent eux-mêmes des structures ou des matrices sont accessibles uniquement en représentant ces éléments individuels sous la forme de chaînes d'octets de taille uniforme.

12.13.4.2 Scalaires

La présente norme prend en charge l'accès à des attributs qui sont scalaires et se présentent sous forme des types suivants:

- Boolean, mappé à Boolean8 ou à Boolean1 lorsqu'il se trouve dans une structure de données condensées;
- Integer, mappé à Integer8, Integer16, Integer32, Unsigned8, Unsigned16, Unsigned32, Unsigned64, Unsigned128, ou à UnsignedN où $N < 16$ lorsqu'il se trouve dans une structure de données condensées;
- Float, mappé à Float32 ou Float64;
- VisibleString, mappé à VisibleStringN lorsque N est fixe ou déterminé par le contexte;
- OctetString, mappé à OctetStringN lorsque N est fixe ou déterminé par le contexte;
- BitString, mappé à BitStringN lorsque N est fixe ou déterminé par le contexte;
- SymmetricKey, mappé à OctetString16 dans cette édition de la présente norme.

NOTE 1 Chaque BitString est représenté sous forme d'un nombre entier d'octets, ou sous forme d'un nombre approprié de bits adjacents lorsqu'il se trouve dans une structure de données condensées.

NOTE 2 Voir 12.22.3 sur les types de données pour les types scalaires pris en charge par la présente norme.

NOTE 3 OctetString et BitString fournissent un moyen pour l'acheminement transparent des informations inintelligibles pour la couche de protocole d'acheminement.

12.13.4.3 Adresses de protocole structuré traitées comme scalaires

Les adresses suivantes sont également considérées comme scalaires lorsqu'elles sont utilisées dans les structures de données de la présente norme, même si leurs propres normes de définition spécifient une sous-structure pour l'élément:

- IPv6Address, mappée à Unsigned128 pour la prise en charge d'une comparaison numérique simple;

NOTE 1 La sous-structure de cette classe d'adresse est spécifiée dans l'IETF RFC 2460 et dans ses normes associées.

- EUI64Address, mappée à Unsigned64 pour la prise en charge d'une comparaison numérique simple;

NOTE 2 La sous-structure de cette classe d'adresse est spécifiée dans les lignes directrices Guidelines for 64-bit Global Identifier (EUI-64™) de l'IEEE.

- DL16Address, mappée à Unsigned16 pour la prise en charge d'une comparaison numérique simple;

Dans l'IEEE 802.15.4, la valeur 0xFFFF est l'adresse DL16Address de diffusion, alors que toute valeur comprise dans la plage 0x0000..0x7FFD peut être assignée à une DLE sous forme d'adresse DL16Address en monodiffusion. Cependant, la présente norme réserve les valeurs 0 pour indiquer une adresse DL16Address non assignée. Ainsi, pour la présente norme, la plage des adresses DL16Addresses en monodiffusion est 0x0001..0x7FFF.

NOTE 3 L'IEEE 802.15.4 réserve la valeur 0xFFFE. L'IETF RFC4944 (6LoWPAN sur l'IEEE 802.15.4) spécifie que la plage 0x80FF..0x9FFF est réservée pour les sous-réseaux D locaux en multidiffusion. Le Paragraphe 9.1.6.4 spécifie que la plage 0xA000..0x0AFFF est réservée par la présente norme pour les numéros de graphes utilisés dans les chemins de source.

12.13.4.4 Matrices unidimensionnelles et structures de données normalisées

La présente norme prend en charge l'accès aux structures de données normalisées et aux matrices, qu'elles soient d'éléments scalaires ou de structures de données normalisées.

L'accès pris en charge à une matrice ou à une structure de données normalisée qui n'est pas contenue au sein d'une matrice se présente comme suit:

- une matrice unidimensionnelle ou une structure normalisée a peut être accessible en sa totalité en spécifiant l'accès au membre zéro (par exemple, une valeur "index" de 0, a[0]);
- un membre unique d'une matrice unidimensionnelle ou d'une structure normalisée a peut être accessible en identifiant l'index d'origine 1 du membre k souhaité, comme spécifié en 12.13.4.1;
- un membre scalaire k d'un membre de structure normalisée b d'une structure normalisée a (par exemple, $a.b.k$, où a et b sont les structures normalisées et k est une grandeur scalaire prise en charge par la présente norme);
- un élément de matrice unidimensionnelle b d'une structure normalisée a peut être accessible en totalité en spécifiant l'accès au membre zéro (par exemple, $a.b$[0], où a est une structure normalisée et b est une matrice unidimensionnelle, et la matrice b est composée soit de scalaires soit de structures normalisées, tels que définis par la présente norme);
- un élément simple d'une matrice unidimensionnelle b de structures normalisées qui est un membre d'une structure normalisée a (par exemple, $a.b[k]$, où a est une structure normalisée, b est une matrice unidimensionnelle composée soit de scalaires soit de structures normalisées, tels que définis par la présente norme, et k est l'index d'origine 1 du membre d'intérêt).

12.13.4.5 Matrices unidimensionnelles

La présente norme prend en charge l'accès à une matrice unidimensionnelle, dont les membres individuels sont des scalaires ou des structures de données normalisées telles que définies par la présente norme, comme suit:

- un élément simple d'une matrice unidimensionnelle constituée de scalaires (par exemple, $a[k]$, où a spécifie la matrice et k spécifie l'élément dans la matrice);
- une matrice unidimensionnelle de scalaires ou de structures de données normalisées peut être accessible en sa totalité (par exemple, a[0], où a spécifie la matrice, et 0 spécifie l'accès à la totalité de la matrice);

- un élément d'une matrice unidimensionnelle constituée de structures normalisées (par exemple, $a[k][0]$, où a spécifie la matrice, k spécifie l'élément dans la matrice qui est la structure normalisée, et 0 spécifie l'accès à la structure du membre entier);
- un membre scalaire d'une structure normalisée contenue dans une matrice unidimensionnelle (par exemple, $a[k].j$, où a spécifie la structure telle que définie par la présente norme, k spécifie l'élément dans la matrice qui est la structure normalisée, et j spécifie le membre au sein de la structure normalisée);
- une matrice unidimensionnelle contenue comme membre d'une matrice unidimensionnelle (par exemple, $a[k][0]$, où a est une matrice de structures normalisées, k spécifie un élément de la matrice, et 0 spécifie l'accès à la totalité de la matrice);
- un membre d'une matrice unidimensionnelle de scalaires ou de structures normalisées contenu comme membre d'une matrice unidimensionnelle (par exemple, $a[k][j]$, où a spécifie la matrice de portée extérieure, k spécifie un élément de cette matrice qui est lui-même une matrice, et j représente l'élément de la matrice de portée intérieure).

12.13.4.6 Matrices bidimensionnelles

La présente norme prend en charge l'accès à une matrice bidimensionnelle, composée d'une matrice homogène unidimensionnelle de matrices de scalaires homogènes ou hétérogènes unidimensionnelles, telles que définies par la présente norme, qui se présentent comme suit:

a) un élément scalaire d'une matrice bidimensionnelle (par exemple, $a[k][j]$);

b) une matrice bidimensionnelle en sa totalité (par exemple, $a[0][0]$);

c) une ligne d'une matrice bidimensionnelle (par exemple, $a[k][0]$); ou

d) une colonne d'une matrice bidimensionnelle (par exemple, $a[0][k]$).

NOTE La forme d'adressage d) spécifie une *tranche* de la matrice, où le résultat est une matrice unidimensionnelle dont les éléments sont le $k^{ème}$ membre de chaque sous-matrice. Ce mode d'accès par tranche permet un accès sélectif à tout membre (élément) de chaque structure de données de composant figurant dans une matrice de structures de données construites à l'identique.

12.13.5 Adressage de méthode d'objet

Une méthode d'objet est adressée en spécifiant:

- l'adressage de son objet conteneur; et
- l'index unique d'objet de l'identificateur de méthode d'objet.

12.14 Objets de gestion

Des objets de gestion normalisés pour gérer l'appareil comme un tout sont définis dans la présente norme. Ces objets sont définis en 6.2 et sont accessibles par un MP contenu dans une UAL qui peut inclure, par exemple, un objet de gestion pour prendre en charge l'identification de l'appareil, des objets de gestion pour chaque couche de la suite de protocoles de communication, et un objet de gestion pour rapporter des alertes issues de l'appareil.

NOTE Bien que chaque objet suive à la trace ses propres conditions d'événement et d'alarme, la production de rapports relatifs à de telles conditions est spécifiée par un seul ARMO pour l'appareil dans son ensemble. Cet objet gère les aspects comprenant, mais sans s'y limiter, la(les) file(s) d'attente de rapports d'alertes locale(s), le(s) temporisateur(s) local(locaux) associé(s) à la réémission si un acquittement d'alerte individuelle n'est pas reçu, le traitement de débordement de files d'attente d'alertes locales, et des demandes de récupération d'alarme. Voir 6.2.7.2 pour plus de détails.

12.15 Objets utilisateurs

12.15.1 Généralités

Les objets normalisés pouvant être contenus dans un UAP sont définis pour permettre l'interfonctionnabilité à travers les industries et les segments. Ces objets peuvent être

indépendants vis-à-vis de toute industrie (à savoir, applicables à travers les industries prises en charge par la présente norme), ou être dépendants d'une industrie (c'est-à-dire, applicables à une industrie prise en charge par la présente norme, mais non utilisés par les industries).

12.15.2 Objets indépendants vis-à-vis de toute industrie

12.15.2.1 Généralités

Les objets normalisés (UAPMO, ARO, UDO, Concentrator, Dispersion, Tunnel, et Interface) sont applicables à travers les industries prises en charge par la présente norme.

12.15.2.2 Objet de gestion d'UAP

12.15.2.2.1 Généralités

Il y a exactement un objet de gestion de UAP (UAPMO) adressable pour chaque UAP pris en charge par l'AL définie par la présente norme. L'identificateur d'objet numérique d'un objet indique une instance d'objet particulière. L'identificateur d'objet numérique de l'UAPMO dans chaque UAP doit être fixe et doit avoir la valeur un (1). Cet objet facilite la gestion commune des processus d'application au sein d'un appareil. Des attributs de cet objet sont utilisés pour spécifier des informations telles que la version/révision du processus d'application et le statut logique du processus d'application. Par exemple, un attribut de l'UAPMO indique si l'UAP correspondant est actif ou inactif.

NOTE 1 Un UAPMO peut prendre en charge la gestion d'un groupe (jeu) particulier d'objets au sein de l'UAP.

NOTE 2 L'instanciation dynamique des UAP ne relève pas du domaine d'application de la présente norme.

12.15.2.2.2 Attributs d'objet

Un UAPMO a les attributs définis dans le Tableau 240.

Tableau 240 – Attributs d'objet de gestion d'UAP *(1 de 2)*

Nom du type d'objet normalisé: UAP management object (UAPMO, objet de gestion d'UAP)				
Identificateur du type d'objet normalisé: 1				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant	N/A
UAP_ID	Identificateur-clé d'objet	SAP de TLDE associé	Type: Initiative locale (telle que définie par la TL locale) Classification: Constant	SAP de TDLE local
UAP_TL_Port	Identificateur-clé d'objet	Port T associé	Type: Unsigned16 Classification: Constant	NOTE 1 La spécification de l'UAP par rapport à sa TL locale relève d'une initiative locale. NOTE 2 Le transport définit le jeu de valeurs hexadécimales 0xF0B0+*n* (où *n* peut se situer dans la plage 0..15) pour spécifier la représentation la plus comprimée (en 4 bits) pour la communication
Réservé pour une utilisation future	0	-	-	-
VersionRevision	1	VersionRevision de l'UAP	Type: VisibleString Taille maximale: 64 octets Classification: Constant Accessibilité: Lecture seule	Identification lisible par l'homme associée à l'objet de gestion d'UAP NOTE Le fournisseur d'UAP détermine le contenu de cet attribut
Etat	2	Statut de l'UAP	Type: Unsigned8 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 1 Valeurs nommées: 0: inactif; 1: actif; 2: en panne.	Voir Tableau 241
Commande	3	Commande pour changer l'état de l'UAP	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0 Valeurs nommées: 0: aucune; 1: arrêt; 2: démarrage; 3: réinitialisation de logiciel; 4: réinitialisation de matériel	La valeur "none" ne doit pas être indiquée dans une demande d'écriture. Une réinitialisation de logiciel doit préserver les données de configuration/mise en service. Une réinitialisation de matériel renvoie l'application à ses valeurs de réglage d'usine par défaut

Tableau 240 *(2 de 2)*

Nom du type d'objet normalisé: UAP management object (UAPMO, objet de gestion d'UAP)				
Identificateur du type d'objet normalisé: 1				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
MaxRetries	4	Nombre maximal de répétitions de tentative de demande client que le processus d'application enverra afin d'avoir une communication C/S réussie	Type: Unsigned8 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 3 Plage valide: 0..8 Classification: Static Accessibilité: Lecture seule	Le nombre de répétitions de tentative envoyées pour un message particulier peut varier par message sur la base de la détermination du processus applicatif de l'importance du message. Par exemple, certains messages ne peuvent pas du tout faire l'objet de répétitions de tentative, et d'autres peuvent être répétés le nombre maximal de fois
Nombre d'objets dans l'UAP y compris cet UAPMO	8	Nombre d'objets dans l'UAP y compris cet UAPMO	Type: Unsigned8 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 1 Plage valide: > 0	Tous les UAP doivent avoir un UAPMO, par conséquent la valeur par défaut est indiquée comme étant égale à 1 (un). La valeur réelle de cet attribut doit être le nombre total d'objets contenus dans l'UAP, y compris l'UAPMO
Array of UAP contained objects	9	Identification des objets et du type contenus dans cet UAP	Type: Array of ObjectIDandType Classification: Static Accessibilité: Lecture seule	Voir Tableau 271
Static_Revision_ Level	10	Niveau de révision des données statiques associées à tous les objets de gestion	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Le niveau de révision est incrémenté chaque fois qu'une valeur d'attribut statique de n'importe quel objet contenu dans cet UAP change
Réservé pour usage futur par la présente norme	5..7 11..63	-	-	*N* octets de contenu présentement indéfini

12.15.2.2.3 Table d'états pour l'objet de gestion d'UAP

Le Tableau 241 décrit la table d'états pour l'objet de gestion d'UAP.

Tableau 241 – Table d'états pour l'objet de gestion d'UAP

Transition	Etat actuel	Evénement(s)	Action(s)	Etat suivant
T1	Inactive	Write(Command, Start)	Write.rsp(success)	Active
T2	Active	Write(Command,Stop)	Write.rsp(success)	Inactive
T3	Inactive	Write(Command,Stop)	Write.rsp(success)	Inactive
		Write(toute commande Reset)	Write.rsp(operationAccepted)	
T4	Active	Write(Command,Stop)	Write.rsp(success)	Active

12.15.2.2.4 Méthodes d'objets normalisés

Un objet de gestion d'UAP a des méthodes telles que définies dans le Tableau 242.

Tableau 242 – Méthodes d'objet de gestion d'UAP

Nom du type d'objet normalisé: UAP management object (objet de gestion d'UAP)		
Identificateur du type d'objet normalisé: 1		
Nom de méthode	**ID de méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.15.2.3 Objet récepteur d'alerte

12.15.2.3.1 Généralités

Il peut y avoir jusqu'à quatre objets récepteurs d'alerte dans un appareil, un par catégorie de rapports d'alerte. Ces objets récepteurs d'alerte peuvent recevoir plus d'une catégorie de rapports d'alerte. Les catégories des rapports d'alerte reçues par les objets d'alerte doivent être uniques; c'est-à-dire, si un objet récepteur d'alerte reçoit des alertes de catégorie X issues de l'ASL, aucun autre objet d'alerte dans l'appareil ne peut également recevoir des alertes de catégorie X issues de l'ASL. Ces objets récepteurs d'alerte peuvent être contenus dans les mêmes processus ou des processus différents (par exemple, un objet récepteur d'alerte pour des alertes de sécurité peut être contenu dans un processus d'application, alors qu'un autre pour des alertes de processus peut être contenu dans un autre processus d'application).

NOTE La séparation d'alertes, ou une consolidation et une production à nouveau de rapports d'alertes, s'il y a lieu, relève d'une initiative locale de processus d'application, ne relevant pas du domaine d'application de la spécification d'AL.

12.15.2.3.2 Attributs d'objet

Un objet récepteur d'alerte peut recevoir des alertes issues d'une ou plusieurs sources de rapports d'alerte. L'objet a les attributs définis dans le Tableau 243.

Tableau 243 – Attributs d'objet récepteur d'alerte

Nom du type d'objet normalisé: Alert-receiving object (objet récepteur d'alerte)				
Identificateur du type d'objet normalisé: 2				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
Catégories	1	BitString de catégories d'alerte indiquant quelle instance d'objet prend en charge la réception	Type: BitString Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0 Indices nommés: 0: alertes d'appareil; 1: alertes de communication; 2: alertes de sécurité; 3: alertes de processus; 4..7: réservés pour un usage futur par la présente norme	N/A
Erreurs	2	Compte de rapports reçus pour une catégorie que l'objet de réception indiqué ne prend pas en charge	Type: Unsigned16 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0	Revient à 0 lorsque la valeur maximale est atteinte
Réservé pour usage futur par la présente norme	3..63	-	-	*N* octets de contenu présentement indéfini

12.15.2.3.3 Table d'états pour le traitement d'AlertReport

Le Tableau 244 indique les états pour traiter la réception d'un AlertReport.

12.15.2.3.4 Méthodes d'objets normalisés

Un objet AlertReceiving a les méthodes définies dans le Tableau 245.

Tableau 245 – Méthodes d'objet AlertReceiving

Nom du type d'objet normalisé: Object AlertReceiving		
Identificateur du type d'objet normalisé: 2		
Nom de méthode	**ID de méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.15.2.4 Objet UploadDownload

12.15.2.4.1 Généralités

Un objet UploadDownload est utilisé soit pour télécharger en montant, soit pour télécharger en descendant, des informations vers un appareil. L'objet UploadDownload peut être utilisé pour prendre en charge des opérations telles que télécharger en descendant une nouvelle version de firmware d'exploitation ou télécharger en descendant le nouveau code contenu dans un UAP ou des données en masse exigées par l'UAP. L'objet UploadDownload maintient des informations de contrôle de révision pour spécifier ce qui a été téléchargé en descendant et/ou ce qui est disponible pour téléchargement montant.

Un objet UploadDownload est susceptible de prendre en charge le téléchargement montant ou le téléchargement descendant pour un seul jeu sémantique d'informations. Un objet UploadDownload doit prendre en charge une seule opération de téléchargement montant ou de téléchargement descendant à la fois.

Un processus peut avoir zéro ou plus d'instances de l'objet UploadDownload. Plusieurs instances de l'objet UploadDownload sont exigées si plus d'un jeu sémantique d'informations est nécessaire pour télécharger en montant ou télécharger en descendant son contenu exigé.

NOTE 1 L'effet local d'un téléchargement montant ou d'un téléchargement descendant de processus d'application (par exemple, la création de nouveaux objets visibles du réseau comme résultat d'un téléchargement descendant) relève d'une initiative locale, en dehors du domaine d'application de la présente norme.

NOTE 2 Les objets UploadDownload sont utilisables pour prendre en charge des opérations telles que le téléchargement montant d'informations statistiques ou historiques issues de l'appareil en vue de leur analyse. Un objet UploadDownload est utilisable pour mettre à jour le logiciel/firmware dans l'appareil cible.

NOTE 3 La prise en charge d'un téléchargement descendant en multidiffusion est un sujet de future normalisation. Pour prendre en charge des charges en multidiffusion à un ensemble spécifique d'appareils, il est actuellement envisagé d'utiliser un outil de configuration pour configurer les relations adresse de multidiffusion/appareil/objet pour les objets dans l'ensemble de multidiffusion.

12.15.2.4.2 Attributs d'objet

Un objet UploadDownload a les attributs définis dans le Tableau 246. Des attributs sont inclus dans ce type d'objet afin de fournir des conseils de temporisation des communications à un niveau application au client qui est en communication avec l'objet UploadDownload.

NOTE Les conseils supplémentaires au client, tels que ceux relatifs à la syntonisation de la temporisation des communications (par exemple, relatifs aux retards de communication réseau dus à la topologie du graphe de messagerie traversé, aux potentiels retards de mise en file d'attente, etc.), utilisables pour syntoniser le comportement d'application client, sont transparents au processus d'application, et par conséquent l'application elle-même ne peut pas fournir des conseils complets.

Tableau 246 – Attributs d'objet UploadDownload *(1 de 4)*

Nom du type d'objet normalisé: Objet UploadDownload				
Identificateur du type d'objet normalisé: 3				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
OperationsSupported	1	Indique si cet objet prend en charge les téléchargements montants et/ou les téléchargements descendants	Type: Unsigned8 Classification: Constant Accessibilité: Lecture seule Valeurs nommées: 0: uniquement le téléchargement montant en monodiffusion de la taille définie; 1: uniquement le téléchargement descendant en monodiffusion de la taille définie; 2: téléchargement montant en monodiffusion et téléchargement descendant en monodiffusion de la taille définie; 3..15: réservés pour usage futur par la présente norme	N/A
Description	2	Identification lisible par l'homme du contenu associé	Type: VisibleString TAILLE (0..64) Classification: Static Accessibilité: Lecture seule	
Etat	3	Etat de l'instance de l'objet UploadDownload	Type: Unsigned8 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0 Valeurs nommées: 0: inactive; 1: en téléchargement descendant; 2: en téléchargement montant; 3: en application; 4: DLComplete; 5: ULComplete; 6: DLError; 7: ULError	Voir le tableau d'états ci-dessous
Commande	4	Commande d'action à cet objet	Type: Unsigned8 Classification: Non-cacheable Accessibilité: Lecture/écriture Valeurs nommées: 0: réinitialisation; 1: application (utilisée pour Download uniquement); 2..15: réservés pour usage futur par la présente norme	Voir Tableau 254

Tableau 246 *(2 de 4)*

Nom du type d'objet normalisé: Objet UploadDownload				
Identificateur du type d'objet normalisé: 3				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
MaxBlockSize	5	Taille maximale d'un bloc qui peut être accepté pour un téléchargement descendant ou fourni pour un téléchargement montant	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 1 à (MaxNPDUsize – Max TL header size – max(sizeof (additional coding of AL UploadData service request), additional coding of sizeof(AL DownloadData service response)) Plage valide: 0..taille maximale pour les données dans une APDU	Unité: octets La valeur ne doit pas excéder la quantité maximum de données qui peuvent être acheminées dans une seule APDU conformément au contrat de communication. En outre, l'espace dans l'APDU doit être laissé pour le codage relatif à un service. Les tailles de bloc acheminées peuvent être plus petites que cette valeur, mais elles ne doivent pas être plus grandes
MaxDownloadSize	6	Taille maximale disponible pour le téléchargement descendant dans son ensemble	Type: Unsigned32 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Unité: octets
MaxUploadSize	7	Taille disponible pour le téléchargement montant	Type: Unsigned32 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Unité: octets
DownloadPrepTime	8	Temps exigé, en secondes, pour se préparer à un téléchargement descendant	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Temps exigé entre le moment de l'envoi de la réponse StartDownload et le moment où l'objet peut traiter un DownloadData
DownloadActivationTime	9	Temps en secondes pour que l'objet applique un contenu nouvellement téléchargé en descendant	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	N/A
UploadPrepTime	10	Temps exigé, en secondes, pour se préparer à un téléchargement montant	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Temps exigé entre le moment de l'envoi de la réponse StartUpload et le moment où l'objet peut accepter un UploadData

Tableau 246 *(3 de 4)*

Nom du type d'objet normalisé: Objet UploadDownload				
Identificateur du type d'objet normalisé: 3				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
UploadProcessingTime	11	Temps type en secondes pour que cet objet d'application traite une demande de télécharger en montant un bloc	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Ces informations sont prévues pour permettre à un client d'une opération Upload de syntoniser sa messagerie relative au téléchargement montant de façon à correspondre au fonctionnement de l'instance d'objet UploadDownload particulière. Par exemple, un client peut utiliser ce temps pour aider à déterminer sa politique de temporisations/répétions de tentative, ou à déterminer quand invoquer une méthode sur l'instance d'objet
DownloadProcessingTime	12	Temps type en secondes pour que cet objet d'application traite un bloc téléchargé en descendant	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Ces informations peuvent être utilisées par un client d'une opération Download pour syntoniser sa messagerie relative au téléchargement descendant de façon à correspondre au fonctionnement de l'instance d'objet UploadDownload particulière. Par exemple, un client peut utiliser ce temps pour aider à déterminer sa politique de temporisations/répétions de tentative, ou à déterminer quand invoquer une méthode sur l'instance d'objet
CutoverTime	13	Temps (en secondes) spécifié pour appliquer le contenu de téléchargement descendant	Type: TAINetworkTime Classification: Static Accessibilité: Lecture / Ecriture Valeur par défaut initiale: 0	Le contenu téléchargé en descendant s'appliquera au temps spécifié par cet attribut
LastBlockDownloaded	14	Numéro du dernier bloc téléchargé en descendant avec succès	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Mis à jour lorsqu'une réponse d'exécution à une méthode DownloadData est retournée. Le comptage des numéros de bloc doit commencer à 1 (un). Voir 12.15.2.4.5.3

Tableau 246 *(4 de 4)*

Nom du type d'objet normalisé: Objet UploadDownload				
Identificateur du type d'objet normalisé: 3				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
LastBlockUploaded	15	Numéro du dernier bloc téléchargé en montant avec succès	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Mis à jour lorsqu'une réponse d'exécution à une méthode UploadData est retournée. Le comptage des numéros de bloc doit commencer à 1 (un). Voir 12.15.2.4.5.3
ErrorCode	16	Erreur Upload ou Download	Type: Unsigned8 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0 Valeurs nommées: 0: noError; 1: timeout; 2: clientAbort; 18: InconsistentContent; 27: InsufficientDevice Resources; 3..17, 19..26, 28..63: réservés pour usage futur par la présente norme; 64..255: manufacturerSpecific	Mis à jour lorsqu'il se produit une erreur en téléchargeant en montant ou en téléchargeant en descendant vers cet objet. L'erreur est éliminée lorsque l'objet passe de l'état d'erreur à l'état inactif. Utiliser InconsistentContent pour indiquer que l'appareil n'a pas basculé comme programmé, en raison d'un problème avec la charge utile de téléchargement descendant. Utiliser InsufficientDevice Ressources pour indiquer que le téléchargement descendant n'a pas pu être achevé par manque de mémoire ou d'autres ressources
Réservé pour usage futur par la présente norme	16..63	-	-	-
La présente norme ne propose pas de politique de gestion de cycle de vie de produit ou de contrôle des versions de produit. La description peut être utilisée pour indiquer l'interchangeabilité des versions, ou pour identifier des caractéristiques/réparations/moutures de logiciel. La valeur maximale de tout codage complémentaire pour le codage d'application selon la présente norme est 9 octets. Les réalisateurs peuvent souhaiter consulter l'IETF RFC 2348 concernant les recommandations pour une taille maximale des PDU.				

12.15.2.4.3 Méthodes d'objets normalisés

L'initiation d'un transfert de données en masse en téléchargement montant ou téléchargement descendant exige d'abord de conclure un accord entre les objets d'application correspondants pour participer au transfert de données.

Toute coordination complémentaire exigée pour assurer la disponibilité de l'appareil répondeur à accepter une demande téléchargement montant ou téléchargement descendant relève de la responsabilité du processus d'UAL qui démarre une opération de transfert en masse.

La messagerie client/serveur pour accéder à des informations de coordination issues d'un attribut ou d'un ensemble d'attributs de l'objet UploadDownload peut être utilisée pour prendre en charge cette activité de coordination. Plus précisément, une demande de lecture peut être utilisée bien avant de démarrer le transfert en masse afin qu'un client recueille les informations relatives à la communication du transfert en masse qui sont spécifiques à une instance de l'objet UploadDownload. Une fois que l'accord est conclu, l'application client commande le moment où les données sont fournies (pour un téléchargement descendant) à l'objet UploadDownload, ou demandées (pour un téléchargement montant) en provenance de l'objet UploadDownload. Lorsque le transfert est achevé, le client indique que le transfert est terminé. En outre, le client peut fermer le transfert s'il détermine qu'il convient de ne pas mener le transfert de données entier à son terme.

L'application serveur peut demander que le transfert de données soit abandonné si elle détermine que le transfert de données ne peut pas être mené à son terme ou qu'il convient de ne pas le mener à son terme.

Il convient qu'une application serveur prenant une décision d'abandon basée sur un manque de communication issue du client permette au moins la prise en charge des répétitions normalisées de tentative par défaut et la politique de temporisation des répétitions de tentative pour la politique de communication client/serveur afin d'établir une temporisation appropriée.

Tout comme avec d'autres communications d'application, de la largeur de bande d'émission doit être allouée par un contrat de service de communication afin de prendre en charge un transfert de données en masse. La largeur de bande pour le transfert de données en masse n'est pas considérée comme étant une largeur de bande dédiée telle qu'utilisée pour la messagerie périodique, mais elle est plutôt considérée comme étant une largeur de bande partagée telle qu'utilisée pour la messagerie apériodique. L'utilisation de la largeur de bande partagée parmi tous les utilisateurs de largeur de bande partagée par un appareil est dépendante d'une combinaison de priorité de contrat global et de priorité de message. La priorité de contrat est définie par le gestionnaire de système. La priorité de message est définie par le processus d'application.

NOTE 1 Toute coordination ou ordonnancement exigé(e) de plusieurs images vers différents objets UploadDownload relève de la responsabilité du processus d'application hôte. Les différentes images chargeables ou téléchargeables nécessitent des instances d'objet UploadDownload distinctes.

NOTE 2 La sémantique et la syntaxe du contenu et de l'utilisation des informations téléchargées en montant ou téléchargées en descendant ne relèvent pas du domaine d'application de la présente norme. L'activité résultante dans le processus d'application de l'appareil fournissant des données de téléchargement montant ou acceptant des données de téléchargement descendant, autre que la mise à jour de l'objet UploadDownload lui-même, relève d'une initiative locale et, donc, ne relève pas du domaine d'application de la présente norme.

NOTE 3 L'application proxy au sein de l'appareil est unidirectionnelle pour qu'un seul appareil traite le téléchargement descendant plusieurs fois.

Le téléchargement montant à partir d'un seul appareil ou le téléchargement descendant vers un seul appareil utilise un protocole en monodiffusion; c'est-à-dire, le contenu de téléchargement montant ou de téléchargement descendant est envoyé en provenance/à destination d'un seul objet UploadDownload au sein d'un seul appareil.

NOTE 4 Les conventions relatives au contenu et/ou à la désignation des fichiers, si elles sont applicables à un téléchargement montant ou à un téléchargement descendant ne relèvent pas du domaine d'application de la présente norme.

Un objet UploadDownload a les méthodes définies dans le Tableau 247.

Tableau 247 – Méthodes d'objet UploadDownload

Nom du type d'objet normalisé: Objet UploadDownload		
Identificateur du type d'objet normalisé: 3		
Nom de méthode	**ID de méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
StartDownload	1	Cette méthode est utilisée par un client pour conclure un accord avec un objet UploadDownload afin de participer à un téléchargement descendant pour lequel le client fournira les données, un bloc à la fois
DownloadData	2	Cette méthode est utilisée par un client pour fournir des données à un objet UploadDownload pour une opération convenue de téléchargement descendant
EndDownload	3	Cette méthode est utilisée par un client pour mettre fin à une opération de téléchargement descendant soit qui s'est terminée avec succès, soit que le client souhaite abandonner
StartUpload	4	Cette méthode est utilisée par un client pour conclure un accord avec un objet UploadDownload afin de participer à un téléchargement montant pour lequel le client demandera les données, un bloc à la fois
UploadData	5	Cette méthode est utilisée par un client pour demander des données à un objet UploadDownload pour une opération convenue de téléchargement montant
EndUpload	6	Cette méthode est utilisée par un client pour mettre fin à une opération de téléchargement montant soit qui s'est terminée avec succès, soit que le client souhaite abandonner
Réservé pour usage futur par la présente norme	7..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre
L'approche utilisée pour le téléchargement montant et le téléchargement descendant a des racines dans les expériences de plusieurs normes acceptées, y compris, sans y être nécessairement limité, la Fieldbus Foundation, la Device Net International, l'IETF RFC 1350 et l'IETF RFC 2347. Les attributs de l'objet UploadDownload fournissent des informations au niveau application pour aider à la détermination de temporisation par un client et, donc, l'IETF RFC 2349 n'est pas suivie. La répétition de tentative d'acquittement telle que proposée dans l'IETF RFC 2347 n'est pas adoptée pour les raisons suivantes: • les cas d'utilisation pilotant la présente norme, et l'ensemble convenu d'exigences techniques auxquelles la présente norme devait satisfaire, disposent du grand volume de communications éditer/s'abonner (P/S), avec une utilisation très limitée des opérations de téléchargement montant/téléchargement descendant; • les opérations de téléchargement montant/téléchargement descendant qui ont été définies ne sont pas en temps critique; • l'application client reçoit un retour d'informations du serveur si le serveur est en train de récupérer des doublons, et peut choisir de mettre fin à l'opération; • l'application serveur sait quand elle envoie des messages d'erreur en retour au client, et peut choisir d'abandonner l'opération.		

12.15.2.4.4 Méthode StartDownload

12.15.2.4.4.1 Généralités

Le Tableau 248 décrit la méthode StartDownload de l'objet UploadDownload.

Tableau 248 – Méthode StartDownload de l'objet UploadDownload

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Objet UploadDownload</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 3</th></tr>
<tr><th>Nom de méthode</th><th>ID de méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="11">StartDownload</td><td>1</td><td colspan="3">Un client utilise la méthode StartDownload pour indiquer à une instance de l'objet UploadDownload qu'il désire télécharger en descendant des données à partir de l'objet</td></tr>

<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument</td><td>Description de l'argument</td></tr>
<tr><td colspan="4">Aucun</td></tr>
</table>

12.15.2.4.4.2 Description de la méthode

Un client utilise la méthode StartDownload pour indiquer à une instance de l'objet UploadDownload qu'il désire télécharger en descendant l'objet, et pour indiquer les paramètres du téléchargement descendant dans la liste d'arguments d'entrée. L'objet UploadDownload peut accepter ou rejeter le téléchargement descendant, en l'indiquant par l'intermédiaire de la liste d'arguments de sortie.

Si un objet UploadDownload accepte de participer à une opération de téléchargement descendant, il ne doit pas accepter une autre opération de téléchargement descendant, ou une opération de téléchargement montant, tant que l'opération de téléchargement descendant en cours n'est pas terminée ou l'objet n'a pas été réinitialisé.

12.15.2.4.4.3 Arguments d'entrée

Les arguments d'entrée comprennent:

- BlockSize, qui indique la taille d'un bloc de données en octets. Tous les blocs doivent avoir la même taille, sauf que le dernier bloc d'un téléchargement descendant peut contenir un plus petit nombre positif d'octets.
- DownloadSize, qui représente la taille totale des données devant être téléchargées en descendant, en octets;
- DownloadMode, qui indique le mode de fonctionnement désiré. La valeur valide pour cet argument indique la monodiffusion et elle est représentée par une valeur de zéro.

12.15.2.4.4.4 Arguments de sortie

Il n'y a aucun argument de sortie pour cette méthode.

12.15.2.4.4.5 Codes de réponse

Les codes suivants de retour d'informations sont valides pour cette méthode:

- operationAccepted;
- invalidBlockSize;
- invalidDownloadSize;
- unexpectedMethodSequence;
- insufficientDeviceResources;
- deviceHardwareCondition; et
- ceux qui sont définis par le fournisseur.

12.15.2.4.5 Méthode DownloadData

12.15.2.4.5.1 Généralités

Le Tableau 249 décrit la méthode DownloadData de l'objet UploadDownload.

Tableau 249 – Méthode DownloadData de l'objet UploadDownload

Nom du type d'objet normalisé: Objet UploadDownload				
Identificateur du type d'objet normalisé: 3				
Nom de méthode	**ID de méthode**	**Description de la méthode**		
DownloadData	2	Un client utilise la méthode DownloadData pour fournir des données à un objet UploadDownload qui a accepté d'être téléchargé en descendant		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument**	**Description de l'argument**
	1	BlockNumber	Unsigned16	BlockNumber téléchargé
	2	Data	OctetString	Les données pour le bloc téléchargé en descendant La taille maximale de cette chaîne peut varier, si bien qu'elle peut être différente pour des objets UploadDownload de destination différents
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument**	**Description de l'argument**
	1	CurrentBlockNumber	Unsigned16	Cet argument est présent si le serviceFeedbackCode indique soit un bloc hors séquence, soit un doublon

12.15.2.4.5.2 Description de la méthode

StartDownload est utilisé d'abord pour amener l'objet UploadDownload à être d'accord avec le téléchargement descendant.

Des données sont envoyées à un bloc à la fois, séquentiellement du bloc ayant le plus petit numéro au bloc ayant le grand numéro en utilisant la méthode de DownloadData. Une seule invocation de la méthode DownloadData peut être en cours à la fois; par exemple, si la méthode DownloadData pour le bloc n été invoquée, la méthode DownloadData pour le bloc n +1 ne doit pas être invoquée tant qu'une réponse de succès contenant les arguments de sortie pour le téléchargement descendant du bloc n n'a pas été reçue par le client.

L'objet UploadDownload peut indiquer qu'il a besoin d'abandonner par l'intermédiaire de l'argument de sortie MethodStatus.

Si un client d'une opération de téléchargement montant ou de téléchargement descendant produit plusieurs invocations de méthodes de transfert de données pour le même bloc, cela peut être dû soit à un problème relatif au réseau (par exemple, la demande n'atteint pas le serveur), soit à un problème au niveau de l'appareil serveur. Dans cette situation, le client peut utiliser la méthode appropriée d'arrêt d'opération (EndDownload ou EndUpload) pour mettre fin à l'opération.

Si un client d'un téléchargement montant ou d'un téléchargement descendant reçoit des réponses multiples de dataSequenceError, cela peut être dû soit à des problèmes relatifs au réseau (par exemple, perte d'une réponse d'invocation de méthode), soit à des problèmes au niveau de l'appareil serveur. Dans cette situation, le client peut utiliser la méthode appropriée d'arrêt d'opération (EndDownload ou EndUpload) pour mettre fin à l'opération. De même, si un objet UploadDownload a envoyé plusieurs réponses dataSequenceError, il peut inférer qu'il y a soit des problèmes relatifs au réseau, soit des problèmes au niveau de l'appareil client et il peut choisir d'abandonner l'opération. Si un objet d'UploadDownload indique l'abandon d'une opération, et cet abandon est perdu sur le réseau, la réponse envoyée à une méthode de données consécutive (DownloadData ou UploadData) ou à une méthode de terminaison (EndDownload ou EndUpload) indique que l'objet ne participe plus à une opération de téléchargement montant ou de téléchargement descendant avec ce client en envoyant une réponse indiquant "unexpectedMethodSequence".

12.15.2.4.5.3 Arguments d'entrée

Les arguments d'entrée comprennent:

- BlockNumber, qui est le numéro du bloc pour lequel des données sont fournies, où le comptage des numéros de bloc commence à 1 (un); et
- Data, qui représente les données pour le bloc téléchargé en descendant.

12.15.2.4.5.4 Arguments de sortie

Cet argument BlockNumber est présent si le serviceFeedbackCode indique soit un bloc hors séquence, soit un doublon. L'argument indique le dernier BlockNumber reçu. L'intention est de permettre au client de résoudre une erreur de réception de bloc hors séquence ou en doublon sans abandonner l'opération de téléchargement.

12.15.2.4.5.5 Codes de réponse

Les codes suivants de retour d'informations sont valides pour cette méthode:

- success;
- invalidBlockNumber;
- blockDataError (par exemple, mauvaise taille de bloc; problème de contenu);
- unexpectedMethodSequence;
- insufficientDeviceResources;
- deviceHardwareCondition;
- operationAborted;
- dataSequenceError (doublon, par exemple);
- timingViolation; et
- ceux qui sont définis par le fournisseur.

12.15.2.4.6 Méthode EndDownload

12.15.2.4.6.1 Généralités

Le Tableau 250 décrit la méthode EndDownload de l'objet UploadDownload.

Tableau 250 – Méthode EndDownload de l'objet UploadDownload

<table>
<tr><th colspan="6">Nom du type d'objet normalisé: Objet UploadDownload</th></tr>
<tr><th colspan="6">Identificateur du type d'objet normalisé: 3</th></tr>
<tr><th>Nom de méthode</th><th>ID de méthode (non négatif)</th><th colspan="4">Description de la méthode</th></tr>
<tr><td rowspan="8">EndDownload</td><td>3</td><td colspan="4">Un client utilise la méthode EndDownload pour indiquer que le téléchargement descendant se termine</td></tr>
<tr><td colspan="5">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument</td><td colspan="2">Description de l'argument</td></tr>
<tr><td>1</td><td>Rationale</td><td>Unsigned8</td><td colspan="2">Cet argument indique au client la raison de l'arrêt de l'opération de téléchargement descendant</td></tr>
<tr><td colspan="5">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument</td><td colspan="2">Description de l'argument</td></tr>
<tr><td colspan="5">Aucun</td></tr>
</table>

12.15.2.4.6.2 Description de la méthode

Un client utilise la méthode EndDownload pour indiquer que l'opération de téléchargement descendant se termine. L'arrêt peut se produire, par exemple, si le téléchargement descendant est arrivé à son terme ou si le client a choisi de mettre fin à l'opération de téléchargement descendant.

La méthode EndDownload peut être envoyée à partir d'un client qui est actuellement engagé dans une opération de téléchargement descendant, comme convenu par la méthode StartDownload.

12.15.2.4.6.3 Arguments d'entrée

L'argument Rationale (justification) indique la raison du client de mettre fin à l'opération de téléchargement descendant. La valeur utilisée doit être issue de l'ensemble suivant:

- 0: téléchargement descendant achevé avec succès; ou
- 1: abandon client

12.15.2.4.6.4 Arguments de sortie

Il n'y a aucun argument de sortie pour cette méthode.

12.15.2.4.6.5 Codes de réponse

Les codes suivants de retour d'informations sont valides pour cette méthode:

- success;
- operationIncomplete;
- unexpectedMethodSequence;
- timingViolation; et
- ceux qui sont définis par le fournisseur.

12.15.2.4.7 Méthode StartUpload

12.15.2.4.7.1 Généralités

Le Tableau 251 décrit la méthode StartUpload de l'objet UploadDownload.

Tableau 251 – Méthode StartUpload de l'objet UploadDownload

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Objet UploadDownload</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 3</th></tr>
<tr><th>Nom de méthode</th><th>ID de méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="8">StartUpload</td><td>4</td><td colspan="3">Un client utilise la méthode StartUpload pour indiquer à une instance de l'objet UploadDownload qu'il désire télécharger en montant des données à partir de l'objet</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>DownloadMode</td><td>Unsigned8</td><td>Le mode de fonctionnement désiré</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>BlockSize</td><td>Unsigned16</td><td>La taille d'un bloc de données en octets</td></tr>
<tr><td>2</td><td>UploadSize</td><td>Unsigned32</td><td>La taille totale des données devant être téléchargées en montant, en octets</td></tr>
</table>

12.15.2.4.7.2 Description de la méthode

Un client utilise la méthode StartUpload pour indiquer à une instance de l'objet UploadDownload qu'il désire télécharger en montant des données à partir de l'objet. L'objet UploadDownload peut accepter ou rejeter le téléchargement montant, en l'indiquant par l'intermédiaire de la liste d'arguments de sortie.

Si un objet UploadDownload accepte de participer à une opération de téléchargement montant, il ne doit pas accepter une autre opération de téléchargement montant ou une opération de téléchargement descendant tant que l'opération de téléchargement montant en cours n'est pas terminée ou l'objet n'a pas été réinitialisé.

12.15.2.4.7.3 Arguments d'entrée

Les arguments d'entrée comprennent:

- DownloadMode, qui spécifie le mode de fonctionnement désiré. La valeur valide pour cet argument indique la monodiffusion et elle est représentée par une valeur de zéro.

12.15.2.4.7.4 Arguments de sortie

Les arguments de sortie comprennent:

- BlockSize, qui indique la taille d'un bloc de données en octets. Tous les blocs doivent avoir la même taille, sauf que le dernier bloc d'un téléchargement montant peut contenir un plus petit nombre positif d'octets;
- UploadSize, qui indique la taille des données devant être téléchargées en montant, en octets.

12.15.2.4.7.5 Codes de réponse

Les codes suivants de retour d'informations sont valides pour cette méthode:

- success;
- unexpectedMethodSequence;
- insufficientDeviceResources;
- deviceHardwareCondition;
- ceux qui sont définis par le fournisseur.

12.15.2.4.8 Méthode UploadData

12.15.2.4.8.1 Généralités

Le Tableau 252 décrit la méthode UploadData de l'objet UploadDownload.

Tableau 252 – Méthode UploadData de l'objet UploadDownload

Sa taille maximale peut varier par instance d'objet UploadDownload téléchargé en montant</td></tr>
</table>

12.15.2.4.8.2 Description de la méthode

Un client utilise la méthode UploadData pour acquérir des données issues d'un objet UploadDownload qui a accepté d'être téléchargé en montant.

Le StartUpload est utilisé d'abord pour amener l'objet UploadDownload à être d'accord avec le téléchargement montant. Des données sont demandées à un bloc à la fois, séquentiellement du bloc ayant le plus petit numéro au bloc ayant le grand numéro. Une seule invocation de la méthode UploadData peut être en cours à la fois. Par exemple, si la méthode UploadData pour le bloc n a été invoquée, la méthode UploadData pour le bloc n + 1 ne doit pas être invoquée tant que la réponse de succès correspondante contenant les arguments de sortie n'a pas été reçue par le client.

L'objet UploadDownload peut indiquer qu'il a besoin d'abandonner par l'intermédiaire d'un argument de sortie.

12.15.2.4.8.3 Arguments d'entrée

L'argument BlockNumber spécifie le numéro du bloc pour lequel des données sont demandées. Le comptage des numéros de bloc doit commencer à 1 (un).

12.15.2.4.8.4 Arguments de sortie

L'argument Data contient les données pour le bloc demandé. Cet argument est présent si et seulement si le serviceFeedbackCode indique "success".

12.15.2.4.8.5 Service feedback codes (codes de retour d'informations relatives à un service)

Les codes suivants de retour d'informations sont valides pour cette méthode:

- success;
- unexpectedMethodSequence;
- insufficientDeviceResources;
- deviceHardwareCondition;
- operationAborted;
- dataSequenceError (par exemple: doublon, numéro de bloc non valide, numéro de bloc inattendu);
- timingViolation; et
- ceux qui sont définis par le fournisseur.

12.15.2.4.9 Méthode EndUpload

12.15.2.4.9.1 Généralités

Le Tableau 253 décrit la méthode EndUpload de l'objet UploadDownload.

Tableau 253 – Méthode EndUpload de l'objet UploadDownload

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Objet UploadDownload</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 3</th></tr>
<tr><th>Nom de méthode</th><th>ID de méthode (non négatif)</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="8">EndUpload</td><td>6</td><td colspan="3">Un client utilise la méthode EndUpload pour indiquer que l'opération de téléchargement montant se termine</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>Rationale</td><td>Unsigned8</td><td>Cet argument indique au client la raison de l'arrêt de l'opération de téléchargement montant</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument</td><td>Description de l'argument</td></tr>
<tr><td colspan="4">Aucun</td></tr>
</table>

12.15.2.4.9.2 Description de la méthode

Un client utilise la méthode EndUpload pour indiquer que l'opération de téléchargement montant se termine. L'arrêt peut se produire, par exemple, si le téléchargement montant est

arrivé à son terme ou si le client a choisi de mettre fin à l'opération de téléchargement montant.

La méthode EndUpload peut être envoyée à partir d'un client qui est actuellement engagé dans une opération de téléchargement montant, comme convenu par la méthode StartUpload.

12.15.2.4.9.3 Arguments d'entrée

L'argument Rationale indique la raison du client de mettre fin à l'opération de téléchargement montant. La valeur utilisée doit être issue de l'ensemble suivant:

- 0: téléchargement montant achevé avec succès; ou
- 1: abandon client

12.15.2.4.9.4 Arguments de sortie

Il n'y a aucun argument de sortie pour cette méthode.

12.15.2.4.9.5 Service feedback codes (codes de retour d'informations relatives à un service)

Les codes suivants de retour d'informations sont valides pour cette méthode:

- success;
- operationIncomplete;
- unexpectedMethodSequence;
- timingViolation;
- ceux qui sont définis par le fournisseur.

12.15.2.4.10 Table d'états pour le téléchargement descendant

Le Tableau 254 montre la table d'états du téléchargement descendant.

Tableau 254 – Table d'états du téléchargement descendant pour le mode de fonctionnement en monodiffusion *(1 de 2)*

Transition	Etat actuel	Evénement(s)	Action(s)	Etat suivant
T1	Idle	Execute.indicate(StartDownload)	Execute.response(success)	Downloading
T2	Downloading	Execute.indicate(DownloadData) La demande pour le bloc est issue du même objet client qui avait démarré le téléchargement descendant et les paramètres de données de téléchargement descendant sont acceptables	Execute.response(success)	Downloading
		Execute.indicate(StartDownload) ou Execute.indicate(any Upload Method)	Execute.response (objectStateConflict)	
		Execute.indicate(DownloadData) et la demande est issue d'un mauvais client, ou quelque chose est erroné dans les paramètres de données de téléchargement descendant ou dans la temporisation	Execute.response(appropriate error) où l'erreur appropriée peut être, par exemple, invalidArgument, incompatibleMode, timingViolation, etc. NOTE Il relève d'une initiative locale que l'objet UploadDownload détermine si/quand abandonner le téléchargement descendant.	
		Execute.indicate(EndDownload [Success]) et l'objet UploadDownload n'est pas d'accord avec le fait que le téléchargement descendant s'est terminé avec succès	Execute.response(incompatibleMode)	
		Write.indicate(StateCommand.Any value)	Write.response(objectStateConflict)	
T3	Downloading	Execute.indicate(EndDownload [Success])	Execute.response(success)	DLComplete
T4	DLComplete	Write.indicate(StateCommand, Apply)	Write.response(operationAccepted)	Applying (en application)
T5	Applying (en application)	Application réussie	Aucune	Idle
T6	Downloading	Temporiser en attendant une invocation de méthode ultérieure	Mettre à jour l'attribut ErrorCode de l'objet UploadDownload	DLError
		Execute.indicate(EndDownload[Abort])	Mettre à jour l'attribut ErrorCode de l'objet UploadDownload Execute.response (Success)	

Tableau 254 *(2 de 2)*

Transition	Etat actuel	Evénement(s)	Action(s)	Etat suivant
T7	Idle	Execute.indicate(toute méthode Download autre que StartDownload)	Execute.response(objectStateConflict)	Idle
		Execute.indicate(StartDownload) et la demande est inacceptable. Par exemple, un ou plusieurs arguments d'entrée ne sont pas acceptables	Execute.response(erreur appropriée) (invalidObjectID, par exemple)	
		Write.indicate(StateCommand.Any value autre que Reset)	Write.response(objectStateConflict)	
		Write.indicate(StateCommand.Reset)	Write.response(success)	
T8	DLComplete	Execute.indicate(toute méthode Download ou toute méthode Upload)	Execute.response(objectStateConflict)	DL_Complete
T9	Applying	Execute.indicate(toute méthode Download ou toute méthode Upload)	Execute.response(objectStateConflict)	Applying
		Write.indicate(StateCommand.Any value)	Write.response(objectStateConflict)	
T10	DLComplete	Write(StateCommand, Reset)	1. Rejeter le contenu du téléchargement descendant; et 2. Write.rsp(success)	Idle
T11	DLError	Write(StateCommand, Reset)	1. Rejeter le contenu du téléchargement descendant; 2. Effacer l'attribut ErrorCode; et 3. Write.req(success)	Idle
T12	DLError	Toute méthode Upload ou Download	Execute.response (objectStateConflict)	DLError
		Toute commande d'état autre que Write(StateCommand.Reset)	Write.req(objectStateConflict)	
T13	Applying	Echec d'application	Mettre à jour l'attribut ErrorCode de l'objet UploadDownload	DLError
T14	DLComplete	Temporiser en attendant une commande à appliquer	Mettre à jour l'attribut ErrorCode de l'objet UploadDownload	DLError

T9	ULError	Toute méthode Upload ou Download	Execute.response (objectStateConflict)	ULError
		Write(StateCommand.autre que Reset)	Write.req(error)	

La Figure 124 montre le diagramme d'états de téléchargement montant d'un objet UploadDownload.

12.15.2.4.12 Responsabilités du client relatives aux opérations de téléchargement montant/téléchargement descendant

Afin de traiter les retards de message tant dans les demandes que dans les réponses et éviter un effondrement par encombrement dû à une boucle de réémission, seule la première instance d'une réponse indiquant un succès doit amener le prochain bloc de données à être envoyé par l'intermédiaire d'une méthode DownloadData ou à être demandé par l'intermédiaire d'une invocation de méthode UploadData par le client.

NOTE L'intention est d'éviter de recréer des situations historiques telles qu'encourues avec le protocole trivial de transfert de fichier (TFTP), créant le syndrome d'apprenti-sorcier.

12.15.2.5 Objet Concentrator

12.15.2.5.1 Généralités

Un objet Concentrator représente un ensemble des données, recueillies à partir de plusieurs objets dans le même UAP, qui doivent être éditées par un seul service de demande d'édition. Cet objet optimise des messages de publication envoyés depuis un appareil. Plusieurs instances d'objet concentrateur peuvent être utilisées pour représenter plusieurs ensembles des données s'il y a lieu. Une liste d'attributs est fournie pour indiquer les valeurs de données qui sont éditées.

NOTE Le contenu édité représenté par cet objet est établi par configuration. La présente norme ne spécifie pas l'outil de configuration d'appareil.

Un abonné à des données produites par un objet concentrateur doit seulement être un objet dispersion. Il convient que les types de données associés à la liste d'attributs de l'objet

dispersion soient configurés de façon à concorder avec ceux produits par l'objet concentrateur.

Quand un objet concentrateur est configuré par une application hôte, telle qu'une passerelle, l'appareil est responsable d'établir des contrats selon les besoins pour prendre en charge les publications correspondantes. La conception est destinée à prendre en charge deux cas d'utilisation. Dans un cas, l'appareil rejoint le réseau et ensuite, l'hôte configure l'objet concentrateur. Dans l'autre cas, l'objet concentrateur est préconfiguré et l'appareil démarre de façon autonome la publication après qu'il a rejoint le réseau.

Un UAP peut avoir zéro ou plus d'instances de l'objet Concentrator.

12.15.2.5.2 Attributs d'objet

Un objet concentrateur a les attributs définis dans le Tableau 256.

La première fois qu'un UAP reçoit une demande read/write/execute issue d'un point d'extrémité pour lequel il n'a aucun contrat, il doit demander un contrat afin de pouvoir envoyer une réponse de service au point d'extrémité demandeur. L'UAP doit, selon les besoins, retarder la première réponse de service pour accorder du temps pour établir/modifier le contrat.

Tableau 256 – Attributs d'objet Concentrator *(1 de 2)*

Nom du type d'objet normalisé: Objet Concentrator				
Identificateur du type d'objet normalisé: 4				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
Concentrator ContentRevision	1	Suit un changement apporté à ce qui a été publié; assure que les objets Concentrator (éditeur) et Dispersion (abonné) sont en harmonie	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0	La révision doit être incrémentée lorsque le complément de données à publier change, à savoir CommunicationEndpoint ou Array of ObjectAttributeIndexAndSize sont modifiés. Attribut inclus dans l'en-tête du Tableau 347
CommunicationEndpoint	2	Sert à identifier l'objet qui reçoit la publication issue de cet objet	Type: Structure de point d'extrémité d'association de communication Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: L'élément valide de point d'extrémité de connexion configuré indique non configuré (c'est-à-dire que le point d'extrémité n'est pas valide)	Ecrire dans cet attribut en dernier lors de la configuration de cet objet; voir Tableau 265
Données de contrat de communication pour la communication programmée	3	Données correspondant au contrat de communication	Type: Communication contract data Classification: Static Accessibilité: Lecture seule	Mis à jour lorsque le contrat correspondant est établi ou résilié; voir Tableau 266
MaximumItems Publishable	4	Nombre maximal d'éléments qui peuvent être édités	Type: Unsigned8 Classification: Constant Accessibilité: Lecture seule Valeur par défaut: Initiative locale	Si cet attribut a une valeur de 0, il indique qu'il n'est pas configuré pour l'édition
NumberItemsPublishing	5	Nombre réel d'éléments publiés	Type: Unsigned8 Classification: Static Accessibilité: Lecture seule Valeur par défaut: 0	Mis à jour lorsque les attributs ObjectAttributeIndexAndSize sont configurés: incrémenté lorsqu'une autre valeur à éditer est ajoutée, et décrémenté lorsqu'une valeur à éditer est enlevée

Tableau 256 *(2 de 2)*

Nom du type d'objet normalisé: Objet Concentrator				
Identificateur du type d'objet normalisé: 4				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectAttributes	6	Matrice de données pour identifier chaque élément de données publié	Type: Array of Object AttributeIndexAndSize Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: La taille de l'élément est 0	ID d'objet, ID d'attribut, indice d'attribut et taille pour chaque valeur publiée Voir Tableau 264
Réservé pour usage futur par la présente norme	7..63	-	-	-

Les attributs Revision, NumItemsSubscribing et d'ObjAttrIdx peuvent être mis en œuvre dans un appareil afin qu'ils puissent être écrits d'une manière atomique dans une transaction de réseau unique par l'intermédiaire de la concaténation des APDU.

12.15.2.5.3 Méthodes d'objets normalisés

Un objet Concentrator présente les méthodes définies dans le Tableau 257.

Tableau 257 – Méthodes d'objet Concentrator

Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.15.2.6 Objet Dispersion

12.15.2.6.1 Généralités

Un objet dispersion est l'objet abonné correspondant à un objet concentrateur. Cet objet est configuré pour indiquer comment analyser le contenu édité d'un objet concentrateur. Si plusieurs démontages sont exigés, plusieurs objets utilisateurs dispersion doivent être utilisés. Un UAP peut avoir zéro ou plus d'instances de l'objet Dispersion.

NOTE Les objets concentrateur et dispersion sont les objets spéciaux prenant en charge un proxy de publication au sein d'un UAP. Ces objets sont distincts des processus d'application proxy, qui peuvent distribuer de l'information au travers de plusieurs UAP au sein de l'UAL.

12.15.2.6.2 Attributs d'objet

Un objet dispersion a les attributs définis dans le Tableau 258.

Tableau 258 – Attributs d'objet Dispersion *(1 de 2)*

Nom du type d'objet normalisé: Objet Dispersion				
Identificateur du type d'objet normalisé: 5				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
Concentrator ContentRevision	1	Suit les changements apportés au contenu souscrit. Assure que l'objet éditeur Concentrator et l'objet souscrivant Dispersion sont en harmonie	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0	Mis à jour lorsque le complément des données à éditer change. En cas de ContentRevision non concordant (Tableau 347), la publication ne doit pas être traitée
CommunicationEndpoint	2	Point d'extrémité de l'objet concentrateur qui édite des données vers l'objet dispersion en question	Type: Structure de point d'extrémité d'association de communication Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: L'élément valide de point d'extrémité de connexion configuré indique non configuré (c'est-à-dire que le point d'extrémité n'est pas valide) Plage valide: Voir la définition de la structure	Ecrire dans cet attribut en dernier lors de la configuration de cet objet
MaximumItemsSubscribing	3	Nombre maximal d'éléments qui peuvent être souscrits	Type: Unsigned8 Classification: Constant Accessibilité: Lecture seule Valeur par défaut: Initiative locale Plage valide: >0	Nombre maximal d'éléments dans la publication correspondante
NumItemsSubscribing	4	Nombre d'éléments auxquels s'abonner	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0	Nombre réel d'éléments dans la publication correspondante Une valeur de zéro indique que l'objet n'est pas configuré pour s'abonner

Tableau 258 *(2 de 2)*

Nom du type d'objet normalisé: Objet Dispersion				
Identificateur du type d'objet normalisé: 5				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Array of ObjectAttributeIndexAndSize	5	Matrice de données pour identifier chaque élément de données publié	Type: Array of ObjectAttributeIndexAndSize Classification : Static Accessibilité: Lecture/écriture Valeur par défaut: La taille de l'élément est 0	ID d'objet, ID d'attribut, indice d'attribut, et taille de données pour la destination au sein de l'application pour les informations éditées NOTE Pour sauter des données, l'objet de destination et l'attribut peuvent localement représenter un objet Null et un attribut Null.
Réservé pour usage futur par la présente norme	6..63	-	-	-

Les attributs Revision, NumItemsSubscribing et d'ObjAttrIdx peuvent être mis en œuvre dans un appareil afin qu'ils puissent être écrits d'une manière atomique dans une transaction de réseau unique par l'intermédiaire de la concaténation des APDU.

12.15.2.6.3 Méthodes d'objets normalisés

Un objet Dispersion présente les méthodes définies dans le Tableau 259.

Tableau 259 – Méthodes d'objet Dispersion

Nom du type d'objet normalisé: Objet Dispersion		
Identificateur du type d'objet normalisé: 5		
Nom de méthode	**ID de méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.15.2.7 Objet Tunnel

12.15.2.7.1 Généralités

L'objet tunnel (TUN) est utilisé pour prendre en charge le transport à haut rendement énergétique de messages encapsulés sur le réseau pour un seul protocole non natif. Le service de tunnel et une variation du service de publication sont définis pour cette encapsulation. Des structures de prise en charge sont fournies pour la déconstruction, le mapping et la reconstruction des paquets de protocoles non natifs afin de réduire les transactions et la taille de paquet.

NOTE L'utilisation de l'objet tunnel pour créer des convertisseurs de protocole est prévue pour être définie par l'organisation qui a défini le protocole natif utilisé dans le tunnel.

12.15.2.7.2 Attributs d'objet

Un objet tunnel a les attributs définis dans le Tableau 260.

Tableau 260 – Attributs d'objet Tunnel *(1 de 3)*

Nom du type d'objet normalisé: Objet Tunnel				
Identificateur du type d'objet normalisé: 6				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
Protocole	1	Type de protocole pris en charge par cet objet	Type: Unsigned8 Classification: Constant Accessibilité: Lecture seule Valeur par défaut: Initiative locale (spécifique au protocole) Plage valide: Voir Annexe M	Etablit le protocole spécifique qui est encapsulé dans des messages de tunnel. Seuls les tunnels de protocoles concordants échangent des données sensées
Status (configuration status)	2	Statut de configuration de communication de l'objet en question	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0 Valeurs nommées: 0: pas configuré; 1: configuration valide; 2: configuration invalide	Le statut d'objet n'est pas configuré lorsque le Protocol est mis à None et aucune communication ne se produit. Une fois que l'objet est configuré et un autre protocole est établi, l'objet tente d'appliquer la configuration et change le statut en conséquence
Flow_Type	3	Service de communication utilisé par cet objet	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeurs nommées: 0: tunnel à 2 parties; 1: tunnel à 4 parties; 2: éditer; 3: s'abonner	Configure le tunnel pour un type spécifique de communication et de rôle

Tableau 260 *(2 de 3)*

Nom du type d'objet normalisé: Objet Tunnel				
Identificateur du type d'objet normalisé: 6				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Update_Policy	4	Politique de mise à jour de communication périodique pour l'objet en question	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeurs nommées: 0: périodique; 1: changement d'état	Etablit la politique de publication périodique pour un éditeur et un abonné liés. Une mise à jour périodique édite à chaque occasion. Le changement de l'état édite sur des données fraîches ou au moins aussi souvent que le spécifie Stale_Limit
Period (période de publication de données)	5	Période de mise à jour de communication périodique pour l'objet en question	Type: Integer16 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0 Valeurs nommées: 0: non configuré	Etablit le temps de publication périodique pour un éditeur et un abonné liés. La publication isochrone est activée par une règle implicite. La publication ne commence pas tant qu'une période n'est pas établie. Voir 12.12.5
Phase (phase de publication idéale)	6	Phase de communication périodique au sein de la période pour l'objet en question	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Plage valide: 0..99	Etablit le temps de publication demandé au sein de la période pour un éditeur et un abonné liés. La phase réelle peut différer par des exigences de contrat. Il convient que les unités soient indiquées sous forme de pourcentage (%)
Stale_Limit (limite de données périmées)	7	Limite de données périmées de communication périodique pour cet objet	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture	Définit le temps d'arrivée maximal attendu de l'abonné comme un multiple de la période. Définit la fréquence minimale de publication pour le rapport relatif au changement d'état comme un multiple de la période
Max_Peer_Tunnels	8	Nombre maximum de tunnels de correspondants avec lesquels cet objet peut communiquer	Type: Unsigned8 Classification: Constant Accessibilité: Lecture seule	N/A

Tableau 260 *(3 de 3)*

Nom du type d'objet normalisé: Objet Tunnel				
Identificateur du type d'objet normalisé: 6				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Num_Peer_Tunnels	9	Nombre réel de tunnels de correspondants avec lesquels cet objet peut communiquer	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0	Incrémenté/décrémenté à mesure que des éléments de matrice de points d'extrémité de tunnel sont ajoutés et supprimés
Matrice de points d'extrémité de tunnel	10	Matrice de points d'extrémité d'association de protocoles	Type: Matrice de points d'extrémité de tunnel Classification: Static Accessibilité: Lecture/écriture Plage valide: Informations d'adresse pointant vers un ou plusieurs objets tunnel	Relie des objets tunnel distants pour la communication avec cet objet tunnel
Foreign_Source_Address	11	L'adresse source étrangère mise en correspondance avec la communication de cet objet	Type: IPv6Address Classification: Static Accessibilité: Lecture/écriture	Détient des informations d'adressage "static" devant être livrées à l'initiateur ou au correspondant à la réception du message
Foreign_Destination_Address	12	L'adresse de destination étrangère mise en correspondance avec la communication de cet objet	Type: IPv6Address Classification: Static Accessibilité: Lecture/écriture	Détient des informations d'adressage "static" devant être livrées à l'initiateur ou au correspondant à la réception du message
Connection_Info[ ]	13	Informations de connexion étrangères mises en correspondance avec la communication de cet objet	Type: OctetString Classification: Static Accessibilité: Lecture/écriture	Détient des informations "static" devant être livrées à l'initiateur ou au correspondant à la réception du message
Transaction_Info[ ]	14	Informations de transaction étrangères mises en correspondance avec la communication de cet objet	Type: OctetString Classification: Dynamic Accessibilité: Lecture/écriture	Détient des informations spécifiques à la transaction devant être livrées à un initiateur à l'achèvement d'une transaction
Réservé pour usage futur par la présente norme	15..63	-	-	

12.15.2.7.3 Méthodes d'objets normalisés

Un objet tunnel a les méthodes définies dans le Tableau 261.

Tableau 261 – Méthodes d'objet Tunnel

Nom du type d'objet normalisé: Objet Tunnel		
Identificateur du type d'objet normalisé: 6		
Nom de méthode	**ID de méthode**	**Description de la méthode**

Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.15.2.8 Objet d'interface

12.15.2.8.1 Généralités

L'objet d'interface fournit un point d'extrémité de messagerie générique pour l'interfaçage à un réseau. Cet objet peut être utilisé comme l'objet source ou de destination dans des interactions de messagerie natives exigées pour la prise en charge de la conversion de protocoles de passerelle et diverses applications de messagerie natives.

L'objet d'interface peut être indiqué dans des services client/serveur communication nécessaires pour les services read, write et execute natifs. L'objet d'interface peut également être référencé comme l'objet client communiquant avec un objet upload/download pour le transfert en masse.

Les communications référençant l'objet d'interface comme client doivent adhérer aux politiques de contrôle d'encombrement client/serveur définies dans la présente norme.

Dans la mesure du possible, les réalisateurs doivent considérer de mettre en tampon les valeurs récupérées de client/serveur plutôt que de créer des communications supplémentaires sur le réseau sans fil afin de récupérer à répétition ces valeurs dans des appareils qui ont besoin de préserver l'énergie. Les objets d'application utilisateur contenus dans les appareils de terrain fournissent des guides, par l'intermédiaire de leurs spécifications de la classification de données d'attribut, concernant quelles informations relatives à un objet il convient de placer en tampon.

NOTE 1 La publication et l'abonnement d'objet natifs sont accomplis en utilisant les objets concentrateur et dispersion.

NOTE 2 La structure réelle du tampon/cache et les exigences locales relatives au traitement des messages vers le cache sont considérées comme relevant d'une initiative locale, ne relevant pas du domaine d'application de la présente norme.

12.15.2.8.2 Attributs d'objet

Un objet d'interface a les attributs définis dans le Tableau 262.

Tableau 262 – Attributs d'objet d'interface

Nom du type d'objet normalisé: Objet d'interface				
Identificateur du type d'objet normalisé: 7				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
Réservé pour usage futur par la présente norme	1..63	-	-	-

12.15.2.8.3 Méthodes d'objets normalisés

Un objet d'interface a les méthodes définies dans le Tableau 263.

Tableau 263 – Méthodes d'objet d'interface

Nom du type d'objet normalisé: Objet d'interface		
Identificateur du type d'objet normalisé: 7		
Nom de méthode	**ID de méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.16 Types de données

12.16.1 Types de données de base

Les types de données de base pris en charge pour les attributs sont:

- les valeurs binaires;
- les entiers signés de 8 bits, de 16 bits et de 32 bits;
- les entiers non signés (unsigned) de 8 bits, de 16 bits, de 32 bits, de 64 bits et de 128 bits;
- les valeurs virgule flottante (floating point) de 32 bits et de 64 bits selon l'ISO/IEC/IEEE 60559 (IEEE 754);
- les chaînes représentant un texte visible, un bloc d'octets, ou une séquence de valeurs de bits (BitString);
- le temps: TAINetworkTime, TAITimeDifference, TAITimeRounded.

12.16.2 Types de données atomiques dérivées

Les types de données atomiques dérivées pris en charge pour les attributs sont:

- adresses:
  - adresse IPv6Address (mappée à un entier non signé de 128 bits);

  - adresse EUI64Address (mappée à un entier non signé de 64 bits);
  - adresse DL16Address (mappée à un entier non signé de 16 bits);
- identificateurs spécifiques à une couche (généralement mappés à des entiers non signés de 8 bits ou 16 bits);
- indices MIB (généralement mappés à des entiers non signés de 8 bits ou 16 bits).

12.16.3 Structures de données normalisées indépendantes vis-à-vis de toute industrie

12.16.3.1 Généralités

Les structures de données normalisées utilisées doivent être les structures de données acheminées par le protocole défini par la présente norme. Les structures de données normalisées indépendantes vis-à-vis de toute industrie sont résumées en Annexe L.

NOTE Les définitions de structures de données spécifiques à un fournisseur ne sont pas prises en charge.

12.16.3.2 Objet, attribut, indice et taille

Les éléments de ObjectAttributeIndexAndSize sont montrés dans le Tableau 264.

Tableau 264 – Type de données: ObjectAttributeIndexAndSize

Nom du type de données normalisé: ObjectAttributeIndexAndSize		
Code du type de données normalisé: 469		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
ObjectID	1	Type: Unsigned16 Classification: Static Accessibilité: Varie selon l'utilisation
AttributeID	2	Type: Unsigned16 Classification: Static Accessibilité: Varie selon l'utilisation
AttributeIndex	3	Type: Unsigned16 Classification: Static Accessibilité: Varie selon l'utilisation
Taille	4	Type: Unsigned16 Classification: Static Accessibilité: Varie selon l'utilisation NOTE Dans la pratique, cette taille maximale dépend des capacités de l'appareil.

12.16.3.3 Communication association endpoint (point d'extrémité d'association de communication)

La structure de données montrée dans le Tableau 265 est utilisée pour des points d'extrémité de communication tant pour les entrées que pour les sorties.

Tableau 265 – Type de données: Communication association endpoint (point d'extrémité d'association de communication) *(1 de 2)*

Nom du type de données normalisé: Point d'extrémité d'association de communication		
Code du type de données normalisé: 468		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Network address of remote endpoint	1	Type: IPv6Address Il s'agit d'une construction logique configurée pour l'appareil par le gestionnaire de système NOTE Le gestionnaire de système s'assure qu'une telle configuration prend en charge le remplacement d'appareil et les scénarios mobiles d'appareil. Classification: Static Accessibilité: Lecture/écriture
T-port at remote endpoint	2	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture
Object ID at remote endpoint	3	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture
Stale data limit	4	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture NOTE 1 Cet attribut a principalement un intérêt pour un abonné. NOTE 2 Le compte de valeurs d'entrée périmées consécutives qu'un abonné n'arrive pas à recevoir avant que l'abonné ne considère la valeur reçue précédemment comme étant non valide (Tableau 299). La péremption est indiquée par un numéro de séquence de fraîcheur inchangé (Tableau 347).
Data publication period	5	Type: Integer16 Classification: Static Accessibilité: Lecture/écriture NOTE Pour les unités de temps, voir 12.12.5
Ideal publication phase	6	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Plage valide: 0..99 (comme un pourcentage %) NOTE Cet attribut a principalement un intérêt pour un éditeur.
PublishAutoRetransmit	7	Type: Unsigned1 Classification: Static Accessibilité: Lecture/écriture Valeurs nommées[a] 0: émettre seulement si le contenu d'application a changé depuis la dernière publication; 1: émettre à chaque occasion périodique (indépendamment de la question de savoir si, oui ou non, le contenu d'application a changé depuis la dernière émission)

Tableau 265 *(2 de 2)*

Nom du type de données normalisé: Point d'extrémité d'association de communication		
Code du type de données normalisé: 468		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Configuration status	8	Unsigned8 Classification: Static Accessibilité: Read access Valeurs nommées: 0: pas configuré (point d'extrémité de connexion non valide); 1: configuré (point d'extrémité de connexion valide) NOTE Le propriétaire des données met cet élément à une valeur de 0 pour indiquer que le point d'extrémité n'est pas configuré, et à 1 pour indiquer que le point d'extrémité est configuré. Un point d'extrémité est considéré comme étant non configuré si la valeur de l'ID d'objet au point d'extrémité distant est 0.
a Le codage de cet attribut est l'inverse de l'attribut associé 12 du Tableau 27.		

12.16.3.4 Données de contrat de communication

La structure de données montrée dans le Tableau 266 est utilisée pour les données dynamiques importantes pour le processus d'application local qui est associé à un contrat de communication particulier.

NOTE 1 Il relève d'une initiative locale de s'assurer que les applications sont bien dressées en termes des contrats de communication qu'elles utilisent. L'AL ne normalise pas les mesures de contrôle relatives à la conformité aux contrats demandés.

NOTE 2 Comme partie intégrante de la négociation de contrat, de l'information suffisante est fournie à l'appareil demandeur de contrat afin de lui permettre de déterminer l'APDU de taille maximale que le contrat prend en charge. Par exemple, si la négociation de contrat détermine la taille maximale d'unité de données de service de réseau (NSDU), le type de sécurité en vigueur pour le contrat est localement déterminable pour le contrat. Si le type de sécurité en cours d'utilisation est connu, la taille d'en-tête de transport est acquise localement et soustraite de la taille de NPDU maximale, donnant ainsi la valeur pour la taille d'APDU maximale utilisable pour des communications utilisant ce contrat de communication particulier.

Tableau 266 – Type de données: Données de contrat de communication

Nom du type de données normalisé: Données de contrat de communication		
Code du type de données normalisé: 470		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
ContractID	1	Type: Unsigned16 Classification: Static Accessibilité: Lecture seule Plage valide: L'ensemble de valeurs valides est défini par la gestion de système
Contract_Status	2	Type: Unsigned8: Classification: Static Accessibilité: Lecture seule Valeur par défaut = 0 Valeurs nommées: 0: endpoint_not_configured, 1: awaiting_contract_establishment, 2: contract_active_as_requested, 3: contract_active_negotiated_down, 4: awaiting_contract_termination, 5: contract_establishment_failed, 6: contract_inactive
Actual_Phase	3	Type:Unsigned8 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0 (indiquant non assignée) Plage valide: 0..99 (en unités en pourcentage %)
Des informations supplémentaires sur le contrat réel, telles que les paramètres négociés à la baisse, peuvent être disponibles auprès du DMAP et peuvent ne pas être maintenues par l'UAP.		

12.16.3.5 Point d'extrémité de communication d'alertes

La structure de données montrée dans le Tableau 267 est utilisée pour des points d'extrémité de communication pour les rapports d'alertes.

Tableau 267 – Type de données: Point d'extrémité de communication d'alertes

Nom du type de données normalisé: Point d'extrémité de communication d'alertes		
Code du type de données normalisé: 471		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Network address of remote endpoint	1	Type: IPv6Address Il s'agit d'une construction logique configurée pour l'appareil par le gestionnaire de système NOTE Le gestionnaire de système s'assure qu'une telle configuration prend en charge le remplacement d'appareil et les scénarios mobiles d'appareil. Classification: Static Accessibilité: Lecture/écriture
T-port at remote endpoint	2	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture
Object ID at remote endpoint	3	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture

12.16.3.6 Point d'extrémité de tunnel

La structure de données montrée dans le Tableau 268 est utilisée dans des objets tunnel pour identifier des points d'extrémité de tunnel distants en vue de l'échange de charges utiles encapsulées.

Tableau 268 – Type de données: Point d'extrémité de tunnel

Nom du type de données normalisé: Point d'extrémité de tunnel		
Code du type de données normalisé: 475		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Network_Address (adresse réseau du point d'extrémité distant)	1	Type: IPv6Address Il s'agit d'une construction logique configurée pour l'appareil par le gestionnaire de système NOTE Le gestionnaire de système s'assure qu'une telle configuration prend en charge le remplacement d'appareil et les scénarios mobiles d'appareil. Classification: Static Accessibilité: Lecture/écriture
Transport_Port (port T au point d'extrémité distant)	2	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture
OID (ID d'objet au point d'extrémité distant)	3	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture

12.16.3.7 Descripteur de rapports d'alertes

Les éléments du descripteur de rapports d'alertes sont montrés dans le Tableau 269.

Tableau 269 – Type de données: Alert report descriptor (descripteur de rapports d'alertes)

Nom du type de données normalisé: Descripteur de rapports d'alertes		
Code du type de données normalisé: 499		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément**
Alert report disabled	1	Type: Boolean8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: Initiative locale
Alert report priority	2	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0 Plage valide: 0..15, comme spécifié en 12.17.5.2.2.22

12.16.3.8 Descripteur d'alarme analogique

Le descripteur d'alarme analogique est utilisé pour définir la production de rapports d'alarme pour une valeur analogique avec une seule condition de référence. Ses éléments sont montrés dans le Tableau 270.

Tableau 270 – Type de données: Descripteur de rapports d'alarmes de contrôle de processus pour analogique avec une seule condition de référence

Nom du type de données normalisé: Descripteur de rapports d'alarmes de contrôle de processus pour analogique avec une seule condition de référence		
Code du type de données normalisé: 498		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Alert report disabled	1	Type: Boolean8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: true
Alert report priority	2	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0 Plage valide: 0..15
Alarm limit	3	Type: Float32 Classification: Static Accessibilité: Lecture/écriture

12.16.3.9 Descripteur d'alarme binaire

Le descripteur d'alarme binaire est la même structure que le type de données pour le descripteur de rapports d'alertes, si bien qu'aucune description supplémentaire de type de données n'est exigée.

12.16.3.10 ObjectIDandType

Les éléments de ObjectIDandType sont montrés dans le Tableau 271.

Tableau 271 – Type de données: ObjectIDandType

Code du type de données normalisé: 473		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Adresse	1	IPv6Address
Port T	2	Unsigned16

12.17 Services d'application fournis par la sous-couche d'application

12.17.1 Généralités

Toutes les interfaces entre la DLE et les entités de couche (ou de sous-couche) ou entités de gestion adjacentes sont des interfaces internes au sein de l'appareil, et sont donc inobservables. Par conséquent, elles ne sont pas soumises à une normalisation.

Des services d'application sont fournis par l'ASL (au niveau du SAP d'ASLDE-n) pour la communication avec des objets natifs, qui sont soit des objets d'UAP, soit des objets de MP. Ce sont les seuls services qu'il convient d'utiliser pour le comportement conforme à la présente norme. Tous les appareils n'ont pas nécessairement besoin d'utiliser l'ensemble des services définis dans le présent document, et tous les objets ne prendront pas nécessairement en charge tous les services dans le présent document. Cependant, si ces services sont utilisés pour la communication entre ou parmi des objets natifs, il convient de les employer tels que définis dans la présente norme.

Il convient que les processus d'application utilisant des services d'ASL soient conçus de façon à tolérer la réception de doublons d'indications et de confirmations de services de l'ASL. Par exemple, si un acquittement de couche inférieure est perdu lorsqu'une réponse à une demande de lecture est envoyée, la couche inférieure peut répéter la tentative et, en conséquence, le client d'application peut recevoir un doublon de réponse à la demande de lecture.

Il est laissé à l'appareil la détermination de la meilleure manière de traiter l'encombrement/la contre-pression si cela est indiqué localement par la suite locale inférieure de protocole. Ce traitement peut, par exemple, limiter l'émission des messages à partir de l'appareil pendant une certaine période de temps, ou pour un certain ensemble de priorités de communication,

ou les deux. L'encombrement peut se produire, par exemple, dans des situations de charge de communication de réseau, et le traitement par l'appareil est destiné à limiter l'encombrement supplémentaire.

NOTE 1 La planification de capacité est une question de système et ne relève pas de la portée d'AL.

Le Tableau 273 résume les services fournis.

NOTE 2 Les services locaux qui ne se traduisent pas en communication réseau ne sont pas inclus dans le Tableau 273, car ils relèvent d'une initiative locale et, donc, sont dépendants d'une mise en œuvre.

NOTE 3 La confirmation locale de service d'ASL renvoyée à l'AP relève d'une initiative locale, et par conséquent elle n'est pas définie par la présente norme.

Tableau 273 – Services d'AL

Service fourni par l'ASL	Primitives applicables	Description	Mode d'utilisation
Services d'accès d'objet			
Read	Request Indication Response Confirmation	Lire une valeur d'attribut dans un objet	Client/server
Write	Request Indication Response Confirmation	Ecrire une valeur dans un objet	Client/server
Execute	Request Indication Response Confirmation	Exécuter une méthode sur un objet	Client/server
Services de publication			
Publish	Request Indication	Editer une ou plusieurs valeurs provenant d'un seul objet source	Publish/subscribe (éditer/s'abonner) NOTE Le contenu natif ainsi que le contenu non natif sont pris en charge
Services relatifs aux rapports d'alertes			
AlertReport	Request Indication	Rapporter une alerte	Source/puits (monodiffusion seulement). La source de ce service doit seulement être l'ARMO. Le puits de ce service doit seulement être l'objet récepteur d'alarme
AlertAcknowledge	Request Indication Response Confirmation	Acquitter une réception d'alerte individuelle	Client/serveur La source de ce service peut seulement être l'objet récepteur d'alarme
Prise en charge explicite pour la tunnellisation			
Tunnel	Request Indication Response Confirmation	Charge utile de tunnel sans analyse d'ASL (pour la compatibilité de protocoles non natifs)	Charge utile de tunnel sans analyse d'ASL (pour la compatibilité de protocoles non natifs). Ce service doit être utilisé seulement si les objets source et destination sont des objets tunnel tous les deux

NOTE 4 Si une demande de service local est mal formée, le fait de rapporter l'erreur à l'UAP demandeur relève d'une initiative locale et n'est donc pas traité dans la présente norme. Si souhaité, une mise en œuvre peut conserver les statistiques concernant les demandes de service localement reçues qui sont mal formées.

12.17.2 Modèle de communication d'application P/S (éditer/s'abonner)

La publication est un processus de communication qui est initié par un objet dans l'UAL éditrice et reçu par un objet dans l'UAL abonnée. La publication utilise des services d'ASL spécifiques à la publication de prise en charge. La publication se produit d'un objet d'éditeur vers un objet abonné. Tout objet peut agir comme éditeur ou comme abonné. Pour optimiser l'utilisation de largeur de bande de communication, des objets spéciaux (un objet concentrateur pour l'édition et un objet dispersion pour l'abonnement) sont définis pour la publication depuis/vers un ensemble d'objets dans un seul UAP en utilisant une seule invocation du service publish.

La raison sémantique de l'édition est purement un souci d'application. Ce modèle prend en charge la communication pour:

- les communications tamponnées périodiques déclenchées par un programme;
- les communications tamponnées déclenchées par une application; et
- les communications tamponnées déclenchées par un changement d'état.

Toutes les communications éditées ci-dessus utilisent le paradigme de flux de communication P/S. Pour des communications périodiques programmées, les applications d'abonné peuvent prendre en charge des méthodes de réponse de temporisation pour traiter une perte de publications individuelles et/ou une perte du point d'extrémité d'éditeur. Par exemple, une application d'abonnement peut utiliser le précédent contenu d'une valeur de publication, mais peut dégrader la qualité correspondante de la valeur. La perte de messages individuels peut avoir une plus courte temporisation que la temporisation utilisée par l'abonné pour déterminer la perte de l'éditeur.

La coordination d'une publication avec le programme de réseau est accomplie par l'intermédiaire de la configuration appropriée de point d'extrémité, qui pilote les demandes de contrat de communication. Une demande de contrat de communication est utilisée pour demander que le gestionnaire de système alloue la largeur de bande programmée pour la communication d'édition.

NOTE 1 La détermination de la politique réelle de temporisation lorsqu'une publication attendue n'est pas reçue est une question spécifique à un processus d'application qui n'est pas spécifiée par la présente norme.

NOTE 2 Les messages édités avec le contenu natif contiennent toujours un compteur de séquence et la/les valeur(s) de données courante(s). S'il n'y a aucun changement de valeur, le compteur de séquence indique que l'application d'édition fonctionne encore et n'a aucune nouvelle donnée à rapporter (cela s'appelle également un heartbeat, c'est-à-dire un signal de présence). Quelques appareils récepteurs maintiennent ce compteur de séquence pour déterminer si la valeur a changé afin de limiter le retraitement, alors que d'autres appareils récepteurs choisissent d'ignorer le compteur de séquence.

NOTE 3 Pour des communications périodiques programmées, les processus d'application utilisent souvent le temps de réseau commun pour synchroniser leurs activités à travers le réseau. Cette synchronisation est localement applicable par des éditeurs et des abonnés pour synchroniser leurs activités au programme de publication.

NOTE 4 Les données et la mesure continues dans la présente norme utilisent un modèle de communication P/S éprouvé de champ de système de commande et effectuent un effet de levier de la largeur de bande programmée pour une synchronisation de communication plus précise. S'il y a une exigence de communication plus personnalisée, elle est considérée comme étant une situation personnalisée ne relevant pas du domaine d'application de la présente norme ou possiblement comme étant une situation pour une considération dans le futur.

12.17.3 Communication tamponnée périodique programmée

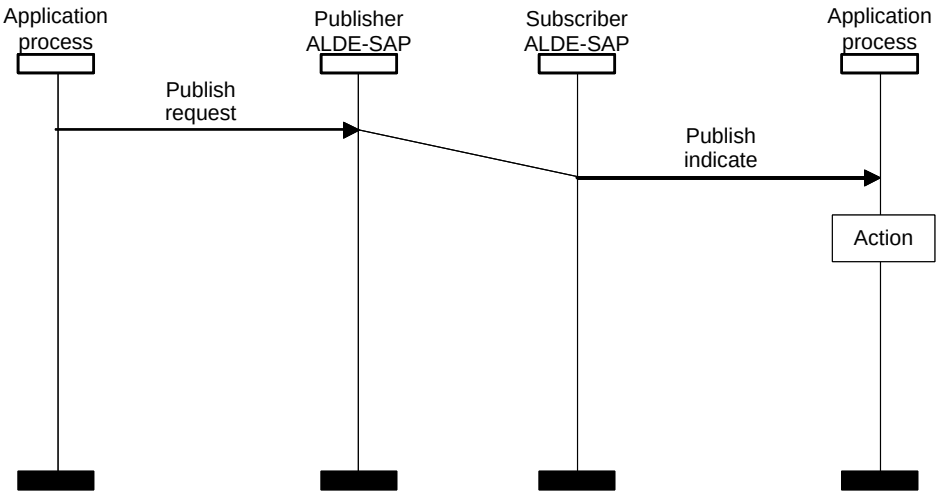
12.17.3.1 Généralités

Le service publish est utilisé pour la communication tamponnée unidirectionnelle vers tout au plus un abonné.

Il convient de configurer l'édition selon les capacités du système. Si un abonné n'est pas présent, cela représente généralement une situation provisoire ou d'erreur et n'est pas censé perdurer. La perte potentielle d'énergie en raison d'appareils configurés incorrectement ou défectueux peut être traitée par une reconfiguration ou par un remplacement d'appareil. Il existe de rares situations anormales pour lesquelles l'optimisation de la conception n'est pas exigée; par conséquent, la complexité exigée pour la publication seulement en présence d'un abonné réel l'emporte sur les éventuelles économies de communications.

Il n'est appliqué aucun acquittement ou aucune répétition de tentative aux interactions P/S. Une ASL éditrice reçoit une demande de service non confirmé et construit une APDU appropriée, qui est alors passée aux couches communication inférieures en vue du transfert de communication. Si une ASL éditrice reçoit une demande pour un service avant que la demande antérieure n'ait été acheminée, il convient que la nouvelle demande écrase la demande antérieure et il convient de ne pas émettre la demande antérieure. Si une ASL abonnée reçoit une nouvelle demande avant que la demande précédente n'ait été livrée à l'objet de destination, la nouvelle demande écrase la demande précédente, et la demande précédente est perdue.

Les services définis prennent en charge la publication d'un attribut arbitraire (une variable de processus, par exemple) issu d'un seul appareil, ou la publication d'un jeu d'attributs issus d'un appareil sans fil plus complexe (à capacité de plusieurs variables, par exemple). Les communications P/S ont lieu sur une relation de communication configurée, telle que montrée à la Figure 125.



Légende

Publisher ALDE-SAP	ALDE-SAP éditeur
Subscriber ALDE-SAP	ALDE-SAP abonné
Publish indicate	Indication d'édition
Action	Action

Figure 125 – Séquence de publication de primitives de service

L'abonné pour une publication peut être, par exemple, une passerelle.

NOTE 1 Le contenu des publications non natives ne relève pas du domaine d'application de la présente norme.

Les publications natives incluent la valeur d'attribut elle-même, et les informations de statut pour la valeur. Afin de prendre en charge la détection de doublons et la livraison dans le désordre, un simple compteur monotone d'un seul octet est inclus avec chaque valeur éditée.

NOTE 2 D'autres plans pour identifier de façon univoque un message édité, tels que l'utilisation d'un marqueur temporel en lieu et place d'un compteur, avaient été envisagés mais furent éliminés parce qu'ils requièrent plus d'énergie pour communiquer. Le temps de construction de TPDU, combiné à une indication de fraîcheur fournie par une couche inférieure, est souvent disponible localement. Les marqueurs temporels sur des publications de données sont utiles dans les passerelles de mise en tampon style unité terminale distante (RTU), mais pour de telles passerelles, un marqueur temporel de réception est également utilisable dans ce but, en particulier parce que toutes les publications utilisent un programme de saut de voie partagé, laissant une petite variance entre le temps de génération de données et le temps de réception de données.

La priorité de message P/S peut être fixe; dans ce cas, une mise en œuvre locale peut choisir de ne pas fournir la priorité par message. Si une application requiert des publications avec différents niveaux prioritaires, telles qu'une publication de basse priorité pour la surveillance de contrôle et une publication de haute priorité pour des variables de boucles de commande de haut débit (1 Hz et 4 Hz), des relations P/S distinctes peuvent être exigées.

L'éditeur d'AL et l'abonné d'AL ne communiquent pas explicitement pour établir ou rompre leur relation; cependant, l'établissement de relations de communication sécurisées peut forcer l'établissement de relations de transport. Les éditeurs et les abonnés établissent chacun de façon indépendante (asynchrone) leur partie de la relation. C'est-à-dire, soit l'UAP éditeur, soit un nombre quelconque des UAP abonnés, peut agir le premier pour établir sa partie d'une relation P/S. La messagerie de bout en bout ne peut pas débuter avant que l'éditeur et l'(les) abonné(s) n'aient établi leurs côtés respectifs de la relation de communication. Une fois que l'éditeur a créé un côté de la relation de communication et un abonné a créé l'autre côté de la relation de communication, des messages de publication peuvent être envoyés et livrés aux objets d'application correspondants.

Le fait de localiser dynamiquement les éditeurs en utilisant soit un service de découverte d'étiquette, soit un service de consultation d'annuaire centralisé, ne relève pas du domaine d'application de la présente norme. Par conséquent, la P/S est censée être compatible avec un mécanisme de configuration statique. Dans de futures versions, un mécanisme de découverte peut être utilisé. Dans l'une ou l'autre situation, les mêmes informations ont besoin d'être disponibles pour établir la relation P/S.

Des chemins de communication sont formés d'une manière transparente à l'AL

NOTE 3 La formation de chemins d'émission à l'appui de la P/S est importante pour assurer la livraison en temps utile, mais elle est laissée à la responsabilité du gestionnaire de système, qui forme des chemins à utiliser au cours de l'établissement de contrat de communication. Voir 6.3.11 pour plus de détails.

La publication est toujours une demande de service de transfert de données non confirmé. L'abonnement se traduit toujours par la réception d'une indication de service de transfert de données non confirmé.

NOTE 4 Est considéré comme étant un thème de gestion le fait d'assurer que la configuration de sécurité/les changements prennent en charge la P/S sans impact de l'AL. Il est sous-entendu que les considérations de sécurité contraignent souvent les relations permises.

La temporisation d'une publication programmée est coordonnée à travers le réseau et, à ce titre, dépend d'une vue coordonnée du temps à travers le réseau. La largeur de bande allouée pour les publications déclenchées par un programme a besoin d'être réservée pour s'assurer que les abonnés peuvent recevoir ce que leurs éditeurs envoient. Il convient que le programme soit configuré pour assurer le meilleur effort pour satisfaire aux dates limites de livraison, mais finalement, la responsabilité de l'éditeur de créer de nouvelles publications, et celle de l'abonné d'agir à la réception de celles-ci, dépendent de la programmation interne de l'appareil du processus d'application.

Les communications éditées s'appuient sur le support de service de publication fourni par la suite de protocoles de communication qui est sous-jacente à l'ASL. Un aspect important de cette suite inférieure de protocoles de communication est la capacité de fournir la

temporisation de communication spécifique afin de satisfaire aux exigences de programmation.

12.17.3.2 Publish

12.17.3.2.1 Généralités

Le service d'édition pour la présente norme est un service en monodiffusion utilisé pour mettre périodiquement à jour des données, d'une seule source de publication dans un AP (tout au plus) vers une seule destination d'abonné.

Le service d'édition peut également être utilisé d'une façon apériodique pour prendre en charge les modifications tant déclenchées par une application que déclenchées par un changement d'état. Sachant que le contenu d'un tampon est émis selon un programme, la communication éditée native inclut un indicateur de fraîcheur pour permettre à l'abonné de déterminer si, oui ou non, une valeur a changé.

NOTE La fraîcheur ne signifie pas des données inchangées, mais plutôt que la valeur a été nouvellement (fraîchement) acquise depuis qu'elle a été éditée la dernière fois.

Le Tableau 274 définit les primitives de service.

Tableau 274 – Service Publish

Nom du paramètre	Demande	Indication
Argument	M	M

12.17.3.2.2 Arguments

12.17.3.2.2.1 Service contract identifier

Ce paramètre identifie l'accord de contrat de service de communication qui a été conclu entre l'UAP demandant le service et le DMAP local. La valeur doit être située dans l'ensemble de valeurs valides pour un identificateur de contrat tel que défini par 6.3.11.

12.17.3.2.2.2 Priority

Ce paramètre définit la priorité de message du service qui est exigée de la communication. Les valeurs permises pour ce paramètre de service peuvent être une indication d'un message

de haute priorité ou d'un message de basse priorité. L'émission et la livraison des messages de haute priorité sont plus importantes que l'émission et la livraison des messages de basse priorité.

12.17.3.2.2.3 Discard eligible

Ce paramètre définit les conseils au réseau de communication relatifs à l'impact d'application du fait de rejeter le message d'application en cas d'encombrement de réseau. Les valeurs possibles sont true (le message peut être considéré pour le rejet), ou false (ne pas considérer le message pour le rejet).

NOTE Ces conseils sont fournis pour être utilisés par des routeurs qui sont construits pour utiliser une politique de rejet intelligent de messages plutôt qu'une politique de rejet aléatoire dans des situations d'encombrement de réseau.

12.17.3.2.2.4 End-to-end transmission time

Il s'agit du temps d'émission de la TLE en l'appareil demandeur vers la TLE en l'appareil récepteur. L'intervalle est marqué par deux instants, le premier instant étant la livraison à la TLE dans l'appareil demandeur, et le second instant étant la réception par TLE dans l'appareil de destination.

12.17.3.2.2.5 Published data size

Ce paramètre fournit à l'abonné le nombre d'octets des données à éditer.

12.17.3.2.2.6 Subscriber T-port

Ce paramètre identifie le port T associé de l'UAP d'abonné.

12.17.3.2.2.7 Subscriber TDSAP

Ce paramètre identifie le TDSAP d'abonné associé au port T d'abonné.

12.17.3.2.2.8 Subscribing object identifier

Ce paramètre spécifie la destination de l'identificateur d'objet dans l'application qui est abonnée à cette publication.

12.17.3.2.2.9 Publisher IPv6Address

Ce paramètre identifie l'adresse IPv6Address de l'éditeur.

12.17.3.2.2.10 Publisher TDSAP

Ce paramètre identifie de façon univoque les TDSAP associés des UAP d'éditeur. Le TDSAP établit un mapping 1:1 à un UAP. La valeur doit être un membre du jeu des TDSAP valides, tels que spécifiés par la TL.

12.17.3.2.2.11 Publisher T-port

Ce paramètre identifie le port T associé de l'UAP d'éditeur.

NOTE Une mise en œuvre peut inférer ce paramètre à partir du TDSAP d'éditeur. Il est donc inclus ici pour l'exhaustivité, telle que exigée par la présente norme pour le mapping logique à la définition de demande de service de données de transport.

12.17.3.2.2.12 Publisher object identifier

Ce paramètre identifie l'objet éditeur qui est la source de données éditées.

NOTE S'il y a plus d'une entrée dans la liste de données éditées, la source objet d'édition est une instance du type d'objet concentrateur.

12.17.3.2.2.13 DataStructureInformation

Ce paramètre indique la construction des informations devant être acheminées par l'intermédiaire de la publication. Il peut indiquer l'une des constructions suivantes:

- native individual value (valeur individuelle native);
- native sequence of values (séquence natives de valeurs); ou
- non-native data (données non natives, à savoir, les informations tunnellisées par l'intermédiaire d'un service de publication).

Les détails de ces alternatives se présentent comme suit:

a) La structure de données de chaque valeur native individuelle est comme suit:

1) Freshness value sequence number

Ce paramètre est présent si les informations relatives à la structure de données indiquent que la structure des données est une valeur individuelle native. Ce paramètre indique la fraîcheur des données.

2) Individual analog value and status

Ce paramètre est présent si la valeur native individuelle est une valeur analogique. Il contient la structure de données normalisées de statut de valeur qui indique des informations telles que la qualité de la valeur analogique correspondante et la valeur analogique elle-même.

3) Individual digital value and status

Ce paramètre est présent si la valeur native individuelle est une valeur numérique. Il contient la structure de données normalisées de statut de valeur qui indique des informations telles que la qualité de la valeur numérique correspondante et la valeur numérique elle-même.

b) La structure de données d'une liste de valeurs natives est comme suit:

1) Publishing content version

Ce paramètre est présent si la publication est pour des données natives de la liste, telles qu'envoyées en provenance un objet concentrateur. Ces informations assurent l'interprétation harmonieuse des informations éditées par l'abonné.

2) List of publish data

Ce paramètre représente la liste de données acheminées par l'intermédiaire du service publish.

3) Status and analog value

Il contient la structure de données normalisées de statut de valeur qui indique des informations telles que la qualité de la valeur analogique correspondante et la valeur analogique elle-même.

4) Status and digital value

Il contient la structure de données normalisées de statut de valeur qui indique des informations telles que la qualité de la valeur numérique correspondante et la valeur numérique elle-même.

c) Les données contenues dans le service publish qui sont non natives sont comme suit:

Ce paramètre contient les données non natives à éditer. Des données non natives sont acheminées sous la forme d'une chaîne d'octets.

12.17.4 Interactions client/serveur

12.17.4.1 Généralités

Les interactions client/serveur sont utilisées pour les communications apériodiques une à une. Ces relations utilisent la communication bidirectionnelle placée en file d'attente à la demande. Les services client/serveur définis par la présente norme sont soit un service à deux parties (ayant deux primitives de service, à savoir: .req et .ind), comme à la Figure 126, ou un service à quatre parties (ayant quatre primitives de service, à savoir: .req, .ind, .rsp, et .cnf), comme à la Figure 127, à la Figure 128 et à la Figure 129.

Lorsque l'ASL reçoit une demande de service client/serveur, elle construit une unité de données de protocole d'application (APDU) correspondante et demande un transfert placé en file d'attente auprès de la suite inférieure de protocoles de communication. L'ASL serveur reçoit une indication de réponse de service confirmé, qu'elle délivre à l'UAP et à l'objet de destination.

Pour les services avec des primitives en quatre parties, l'UAP serveur construit une réponse correspondante. Lorsque l'ASL reçoit la réponse de service client/serveur, elle construit une APDU de réponse et la présente à sa suite inférieure de protocoles de communication, qui fournit les services de communications orientés file d'attente pour livrer la réponse.

Dans une interaction client/serveur, chaque point d'extrémité de la communication peut agir comme client et/ou serveur. Une demande client est envoyée vers une seule destination (serveur). Cette demande indique la destination vers laquelle il convient d'envoyer la réponse. Une seule réponse est alors émise en provenance du serveur.

Les interactions telles que montrées à la Figure 127, à la Figure 128 et à la Figure 129 exigent qu'un identificateur de contrat de communication et la suite de protocoles de communication soient correctement configurés pour prendre en charge les exigences de l'application relatives à la messagerie client/serveur. La largeur de bande représentée par l'identificateur de contrat est considérée comme étant une largeur de bande partagée non programmée qui peut ne pas être réservée seulement pour être utilisée par le présent contrat.

Figure 129 – Modèle de client/serveur interactions à quatre parties: Echec de livraison de réponse

Lorsqu'une association client/serveur est sécurisée, une session de sécurité est impliquée. Afin d'optimiser l'élimination des connexions que le processus UAL connaît comme n'étant plus exigées, une interface locale pour résilier le contrat peut être utilisée. La résiliation de contrat peut être utilisée pour libérer une session de sécurité (s'il en existe une).

Pour initier la communication, le client demande à envoyer un message à un serveur. Le client spécifie l'identificateur de contrat local qui indique l'adresse IPv6Address du serveur. La communication identifie également l'application et l'objet de source particuliers faisant la demande, l'application et l'objet de destination censés recevoir la demande, ainsi que les informations réelles spécifiques à une instance de service.

Le serveur envoie une réponse au client spécifiant son identificateur de contrat local, qui indique l'adresse IPv6Address du client. La communication spécifie également des informations suffisantes pour livrer la réponse à l'objet d'application approprié et pour collationner la réponse avec la demande originale.

Un contrat de communication doit être établi entre le client et le serveur pour transporter la demande du client, et du serveur vers le client pour transporter la réponse du serveur.

En jouant le rôle d'un client, un client peut envoyer des demandes vers un serveur. En jouant le rôle d'un serveur, un serveur peut envoyer des réponses vers un client. Le client est responsable de la réponse de temporisation de serveur et de l'intégrité transactionnelle.

Un serveur simple pourrait prendre en charge une seule transaction en cours avec un client particulier. Si un retard prolongé se produit pour recevoir une réponse, le client peut, par exemple, temporiser et envoyer de nouveau la demande. Si cela se produit, des doublons de réponses peuvent être reçus. Si un serveur a des ressources pour prendre en charge plusieurs transactions en cours avec un client, les demandes et les réponses peuvent arriver dans le désordre. Pour prendre en charge cette situation, un identificateur de demande est utilisé pour activer/désactiver la collation de demande/réponse.

S'il y a un besoin de plusieurs messages client ou serveur comme partie intégrante d'une séquence de communication, la mise en œuvre peut considérer d'utiliser la concaténation d'ASL. Au-delà de la concaténation, le flux continu de messages est une responsabilité spécifique à un processus d'application ne relevant pas du domaine d'application de la norme.

Les caractéristiques de communications pour des interactions client/serveur telles que la temporisation de réponse relèvent d'une initiative locale, ne relevant pas du domaine d'application de la présente norme. Par exemple, elles peuvent être fixées par la construction d'appareil ou déterminées par un programme d'application au sein d'un appareil, ou être configurées pour l'appareil sur une base par processus d'application ou même sur une base par contrat. Des interactions client/serveur sont habituellement utilisées pour la configuration (telle que la configuration relative à un contrôle de processus ou la configuration d'objet de gestion) et l'échange ad hoc d'informations.

Il convient que les communications client/serveur n'interfèrent pas avec des communications programmées, car il est essentiel que la largeur de bande d'émission soit allouée pour prendre en charge des contrats de communication de messagerie client/serveur. L'intention est d'assurer la capacité de reconfigurer un appareil.

Occasionnellement, seulement un seul échange client/serveur est exigé. Cela peut entraîner un surdébit substantiel pour établir les chemins et la sécurité. A d'autres moments, plusieurs échanges client/serveur se produisent entre les mêmes points d'extrémité.

NOTE Toute altération des chemins de communication (pour compenser l'interférence, par exemple) se produit d'une manière transparente à l'AL.

Le client spécifie la priorité de message désirée pour des demandes de service. Le serveur spécifie la priorité de message désirée pour des réponses de service.

Il convient que les messages de plus haute priorité se déplacent idéalement à l'avant des files d'attente de messages de suite de protocoles d'émission hiérarchisés par ordre de priorité prenant en charge des communications client/serveur. Si possible, il convient que l'allocation de largeur de bande de messages de client/serveur sur le réseau accorde l'accès d'abord aux demandes de message de priorité plus haute. La sécurité est présumée être établie sur une base de contrat et, donc, la sécurité par message n'est pas fournie.

D'autres considérations pour le repli d'émission, telles que basées sur un encombrement de réseau, sont une responsabilité globale d'appareil et ne sont pas une responsabilité spécifique de l'AL.

12.17.4.2 Services client/serveur

12.17.4.2.1 Généralités

Les services suivants sont fournis comme communications client/serveur:

- read;
- write;
- execute; et
- tunnel.

NOTE Tunnel comme primitive à deux parties est également utile pour la communication source/puits.

12.17.4.2.2 Codes de retour d'informations relatives à un service

Les services C/S à quatre parties fournissent un code de retour d'informations relatives à un service pour indiquer le résultat du service du point de vue du serveur. Une plage de codes est réservée pour les additions spécifiques à un fournisseur.

12.17.4.3 Lecture

12.17.4.3.1 Généralités

Le service de lecture est utilisé pour lire un attribut d'un objet dans un processus d'UAL.

Le Tableau 275 définit les primitives du service de lecture.

12.17.4.3.2 Argument

12.17.4.3.2.1 Service contract identifier

Voir 12.17.3.2.2.1.

12.17.4.3.2.2 Priority

Voir 12.17.3.2.2.2.

12.17.4.3.2.3 Discard eligible

Voir 12.17.3.2.2.3.

12.17.4.3.2.4 End-to-end transmission time

Voir 12.17.3.2.2.4.

12.17.4.3.2.5 Forward congestion notification

Ce paramètre indique si la demande a rencontré un encombrement de réseau sur son chemin allant du client vers le serveur.

12.17.4.3.2.6 Server T-port

Ce paramètre identifie l'UAP serveur associé au port T serveur.

12.17.4.3.2.7 Server TDSAP

Ce paramètre identifie le TDSAP serveur associé au port T serveur.

12.17.4.3.2.8 Server object identifier

Ce paramètre identifie un objet serveur à partir duquel il est souhaité lire des données.

12.17.4.3.2.9 Client/source address

Ce paramètre identifie l'adresse IPv6Address pour le client de cette demande.

12.17.4.3.2.10 Client/source TDSAP

Ce paramètre identifie le TDSAP associé de l'UAP client ou serveur. L'UAP contient l'objet qui est à l'origine de la demande.

12.17.4.3.2.11 Client T-port

Ce paramètre identifie l'UAP client associé au port T.

12.17.4.3.2.12 Client object identifier

Ce paramètre identifie l'objet client qui initie la demande de service.

12.17.4.3.2.13 Application request identifier

Identificateur fourni par l'UAP pour représenter de façon univoque cette demande.

12.17.4.3.2.14 Data to be read

Ce paramètre identifie les valeurs de données que le client souhaite lire.

12.17.4.3.2.15 Attribute identifier

Ce paramètre identifie l'attribut de l'objet serveur, dont il est souhaité lire la valeur.

12.17.4.3.2.16 Attribute index/indices

Ce paramètre identifie l'indice ou les indices pour les informations d'intérêt à partir de l'attribut. Il peut y avoir:

- zéro indice, comme dans le cas d'une valeur scalaire;
- un seul indice, par exemple, pour accéder
  - à un élément d'une matrice unidimensionnelle, ou
  - à un membre d'une structure de données normalisée; ou
- deux indices, par exemple, pour accéder
  - à un élément d'une matrice bidimensionnelle ou
  - à un membre d'une structure normalisée contenue dans une matrice unidimensionnelle de structures de données normalisées identique, ou
  - une tranche unidimensionnelle d'une matrice bidimensionnelle, ou

– une tranche unidimensionnelle d'une matrice unidimensionnelle constituée de structures de données normalisées identiques, extrayant sous la forme d'une matrice unidimensionnelle une tranche sectionnelle d'un membre unique à travers ces structures de données identiques.

12.17.4.3.3 Result

12.17.4.3.3.1 Service contract identifier

Voir 12.17.3.2.2.1.

12.17.4.3.3.2 Priority

Voir 12.17.3.2.2.2.

12.17.4.3.3.3 Discard eligible

Voir 12.17.3.2.2.3.

12.17.4.3.3.4 End-to-end transmission time

Voir 12.17.3.2.2.4.

12.17.4.3.3.5 Forward congestion notification

Voir 12.17.4.3.2.5.

12.17.4.3.3.6 Forward congestion notification echo

Ce paramètre indique si la demande de service a rencontré un encombrement de réseau sur son chemin allant du client vers le serveur.

12.17.4.3.3.7 Server IPv6Address

Ce paramètre identifie l'adresse IPv6Address pour le serveur de cette demande.

12.17.4.3.3.8 Server TDSAP

Voir 12.17.4.3.2.7.

12.17.4.3.3.9 Server T-port

Voir 12.17.4.3.2.6.

12.17.4.3.3.10 Server object identifier

Voir 12.17.4.3.2.8.

12.17.4.3.3.11 Client T-port

L'UAP contient l'objet qui est à l'origine de la demande. Voir 12.17.4.3.2.11.

12.17.4.3.3.12 Client TDSAP

L'UAP contient l'objet qui est à l'origine de la demande. Voir 12.17.4.3.2.10.

12.17.4.3.3.13 Client object identifier

Voir 12.17.4.3.2.12.

12.17.4.3.3.14 Application request identifier

Ce paramètre est un identificateur fourni par le client pour représenter de façon univoque cette demande.

12.17.4.3.3.15 Value read

La valeur read indique le résultat de l'opération demandée, et si la lecture est un succès, la taille et la valeur de l'attribut d'objet devant être lu.

12.17.4.3.3.16 Service feedback code

Le service feedback code indique si l'opération demandée a réussi ou pas. Si elle n'a pas réussi, il fournit des informations indiquant pourquoi elle n'a pas réussi.

12.17.4.3.3.17 Value size

Value size indique le nombre d'octets contenus dans la valeur de données. Il est présent si et si seulement si le service feedback code correspondant indique un succès.

12.17.4.3.3.18 Data value

Data value est la valeur de données qui ont été lues dans l'objet serveur, l'attribut et l'indice d'attribut identifiés. Il est présent si et seulement si le service feedback code indique un succès et le paramètre Value size est différent de zéro.

12.17.4.4 Write

12.17.4.4.1 Généralités

Le service d'écriture est utilisé pour écrire une valeur ou un ensemble de valeurs dans un ou plusieurs attributs d'un ou plusieurs objets dans un processus d'application.

Une écriture dans une structure contenant des éléments tant inscriptibles qu'en lecture seule est permise. Dans cette situation, les éléments en lecture seule doivent être inaltérés.

Le Tableau 276 définit les primitives du service d'écriture.

Voir 12.17.4.3.2.7

12.17.4.4.2.8 Server object identifier

Voir 12.17.4.3.2.8

12.17.4.4.2.9 Client/source address

Ce paramètre identifie l'adresse IPv6Address associée de l'UAP client ou source. L'UAP contient l'objet qui est à l'origine de la demande.

12.17.4.4.2.10 Client/source TDSAP

Ce paramètre identifie le TDSAP associé de l'UAP client ou serveur. L'UAP contient l'objet qui est à l'origine de la demande.

12.17.4.4.2.11 Client T-port

Voir 12.17.4.3.2.11.

12.17.4.4.2.12 Client object identifier

Voir 12.17.4.3.2.12.

12.17.4.4.2.13 Application request identifier

Identificateur fourni par l'UAP pour représenter de façon univoque cette demande.

12.17.4.4.2.14 Data to write

Ce paramètre identifie la valeur d'attribut et de données cibles que le client souhaite écrire.

12.17.4.4.2.15 Attribute identifier

Ce paramètre identifie l'attribut de l'objet serveur, dont il est souhaité lire la valeur.

12.17.4.4.2.16 Attribute index/indices

Ce paramètre identifie l'indice ou les indices pour les informations d'intérêt à partir de l'attribut. Voir 12.17.4.3.2.16.

12.17.4.4.2.17 Value size

Value size indique le nombre d'octets contenus dans la valeur de données.

12.17.4.4.2.18 Data value

Data value est la valeur de données qu'il est souhaité d'écrire dans l'objet serveur, l'attribut et l'indice d'attribut identifiés.

12.17.4.4.3 Result

12.17.4.4.3.1 Service contract identifier

12.17.4.4.3.10 Server object identifier

Ce paramètre identifie un objet serveur dans lequel il est souhaité écrire des données.

12.17.4.4.3.11 Client/source T-port

Ce paramètre identifie l'UAP client associé au port T.

12.17.4.4.3.12 Client TDSAP

Ce paramètre identifie le TDSAP client associé au port T. L'UAP contient l'objet qui est à l'origine de la demande.

12.17.4.4.3.13 Client object identifier

Voir 12.17.4.3.2.12.

12.17.4.4.3.14 Application request identifier

Voir 12.17.4.3.3.14.

12.17.4.4.3.15 Service feedback code

Voir 12.17.4.3.3.16.

12.17.4.5 Execute

12.17.4.5.1 Généralités

Le service Execute est utilisé pour exécuter sur un objet une méthode visible du réseau.

NOTE L'utilisation du service Execute pour établir une méthode de rappel est un moyen de fournir à un serveur le temps approprié pour un message retardé, fournissant des informations en retour au client par l'intermédiaire d'un rappel, plutôt que devoir fournir des résultats d'exécution en temps utile dans la réponse.

Le Tableau 277 définit les primitives du service Execute.

12.17.4.5.2.13 Application request identifier

Voir 12.17.4.3.2.13.

12.17.4.5.2.14 Method identifier

Ce paramètre identifie une méthode de l'objet serveur qu'il est souhaité d'exécuter.

12.17.4.5.2.15 Size of input parameters

Size of input parameters indique le nombre d'octets contenus dans les paramètres d'entrée.

NOTE Les demandes de service Execute et les réponses comprennent la taille en octets du flux de paramètres contenu pour permettre l'analyse (cela est notamment utile dans les scénarios de concaténation d'APDU).

12.17.4.5.2.16 Input parameters

La chaîne de paramètres d'entrée est une chaîne d'octets qui contient les paramètres d'entrée pour la méthode qu'il est demandé d'exécuter. Elle est présente si et seulement si size of input parameters est présent et a une valeur supérieure à zéro.

12.17.4.5.3 Result

12.17.4.5.3.12 Client TDSAP

Voir 12.17.4.4.3.12.

12.17.4.5.3.13 Client object identifier

Voir 12.17.4.3.2.12.

12.17.4.5.3.14 Application request identifier

Voir 12.17.4.3.3.14.

12.17.4.5.3.15 Execution result

Il contient le résultat de la demande de service d'exécution de la méthode.

12.17.4.5.3.16 Service feedback code

Le service feedback code indique si l'exécution de méthode correspondante a réussi ou pas. Si elle n'a pas réussi, il fournit des informations indiquant pourquoi elle n'a pas réussi.

12.17.4.5.3.17 Size of output parameters

Size of output parameters indique le nombre d'octets contenus dans les paramètres de sortie.

12.17.4.5.3.18 Output parameters

La chaîne de paramètres de sortie est une chaîne d'octets qui contient les paramètres de sortie pour la méthode qui a été exécutée. Elle est présente si et seulement si size of output parameters est présent et a une valeur supérieure à zéro.

12.17.5 Messages unidirectionnels placés en file d'attente acycliques non programmés (source/puits)

12.17.5.1 Généralités

La messagerie unidirectionnelle placée en file d'attente acyclique non programmée est également appelée parfois messagerie source/puits. Ce type d'interaction est utilisé pour les alertes. Les messages envoyés en utilisant ce protocole sont mis en file d'attente par les couches de communication inférieures en vue de l'émission. La réception des messages est non confirmée. Il n'y a ni contrôle de flux ou de débit du processus d'application ni détection de message perdu pour ce mode d'interaction. Comme les communications client/serveur, ces communications exigent l'utilisation d'un contrat de communication, et spécifient la priorité de message sur une base par message.

La largeur de bande pour des communications source/puits n'est pas considérée comme dédiée, mais plutôt comme provenant de la largeur de bande non dédiée (partagée).

Les interactions unidirectionnelles acycliques non programmées dans la présente norme prennent en charge la distribution de messages placés en file d'attente un à un à la demande. Des rapports d'alertes pour la communication de réseau sont toujours émis à partir d'un initiateur, l'ARMO, et sont toujours envoyés vers un seul type de destinataire de message, un objet récepteur d'alerte (ARO).

L'acquittement de la réception d'une alerte peut seulement être issu d'un destinataire de rapport d'alerte (ARO), et est envoyé vers l'objet (ARMO) qui a rapporté l'alerte.

Les services suivants sont fournis pour prendre en charge les communications de messages unidirectionnels placés en file d'attente acycliques non programmés.

- AlertReport;
- AlertAcknowledge; et
- Tunnel.

Le service Tunnel est inclus comme un service source/puits pour qu'il puisse tirer profit des capacités de multidiffusion dans le futur. Un tel développement potentiel est un sujet pour une normalisation future.

12.17.5.2 Service AlertReport

12.17.5.2.1 Généralités

AlertReport est utilisé pour rapporter une alerte en utilisant des services de communication unidirectionnels placés en file d'attente. Le contenu du rapport d'alerte dépend du type d'alerte rapporté et de la catégorie de l'alerte. Les AlertReport peuvent être répétés tant qu'un AlertAcknowledge pour l'AlertReport n'a pas été reçu.

La Figure 130, la Figure 131 et la Figure 132 indiquent l'ordonnancement des messages de rapports d'alertes.

Figure 132 – AlertReport, échec d'acquittement

NOTE 1 La politique de temporisation/répétition des AlertReport est définie sur l'ARMO. Voir 6.2.7.2 pour plus de détails.

La production de rapports d'alerte utilise deux services distincts de communication d'application à deux parties. Pour rapporter une alerte, l'AP utilise le service AlertReport. Dans la présente version de la norme, le destinataire d'un AlertReport doit acquitter l'AlertReport en utilisant le service AlertAcknowledge.

NOTE 2 L'utilisation de deux services distincts, AlertReport et AlertAcknowledgement, permet qu'une seule et même alerte soit envoyée vers plusieurs destinations dans une future révision à la présente norme.

La surveillance et la vérification pour détecter un acquittement, ainsi que la production à nouveau d'un rapport relatif à la condition d'alerte pour laquelle un acquittement n'a pas été reçu relèvent de la responsabilité de l'appareil rapporteur d'alerte. La production à nouveau d'un rapport relatif à une alerte qui n'est plus actuelle, et pour laquelle une indication d'AlertAcknowledge n'a pas été reçue, relève d'une initiative locale. Par exemple, si une situation de diagnostic se produit et une alerte est rapportée, et ensuite l'appareil rapporteur se réamorce de telle manière que la situation de diagnostic ne soit plus actuelle, l'appareil pourrait ne pas rapporter à nouveau l'alerte de diagnostic qui était en vigueur avant le réamorçage bien qu'aucun AlertAcknowledge n'ait été reçu.

AlertReport utilise le même modèle de communication comme étant une primitive client/serveur à deux parties. Le Tableau 278 définit les primitives de service pour le service AlertReport.

12.17.5.2.2 Argument

12.17.5.2.2.1 Service contract identifier

Voir 12.17.3.2.2.1.

12.17.5.2.2.2 Priority

Voir 12.17.3.2.2.2.

12.17.5.2.2.3 Discard eligible

Voir 12.17.3.2.2.3.

12.17.5.2.2.4 End-to-end transmission time

Voir 12.17.3.2.2.4.

12.17.5.2.2.5 Alert reporting management object TDSAP

Ce paramètre indique le TDSAP de l'application qui émet ce rapport d'alerte.

12.17.5.2.2.6 Alert reporting management object T-port

Ce paramètre indique le port T de l'application qui émet ce rapport d'alerte.

12.17.5.2.2.7 Alert reporting management object

Ce paramètre représente l'identificateur d'objet de l'ARMO qui rapporte l'alerte.

12.17.5.2.2.8 Sink T-port

Ce paramètre identifie l'UAP de puits associé au port T.

12.17.5.2.2.9 Sink TL data service access point

Ce paramètre indique le TDSAP correspondant au puits du port T.

12.17.5.2.2.10 Sink object identifier

Ce paramètre spécifie l'objet puits de destination dans l'application vers laquelle cette demande de service doit être envoyée.

12.17.5.2.2.11 Alert source IPv6Address

Ce paramètre identifie l'adresse IPv6Address de la source de cette demande.

12.17.5.2.2.12 Alert source TDSAP

Ce paramètre identifie le TDSAP associé de l'UAP source.

12.17.5.2.2.13 Source T-port

Ce paramètre identifie l'UAP source d'application émetteur associé au port T.

12.17.5.2.2.14 Individual alert report

Ce paramètre contient une alerte individuelle rapportée par cette invocation de service.

12.17.5.2.2.15 Individual alert identifier

Ce paramètre identifie de façon univoque le rapport d'alerte individuelle. Des séquences distinctes de valeurs d'identificateur pour les catégories de rapports d'alertes doivent être maintenues. La valeur de ce paramètre doit augmenter de façon monotone et doit repasser par zéro lorsque la valeur maximale est atteinte. Elle est incluse lorsqu'un rapport d'alerte individuelle est acquitté. Elle est également utilisée par un récepteur d'alerte pour déterminer si un rapport d'alertes ou un ensemble de rapports d'alertes d'une catégorie particulière a été manqué. Si une condition de rapport manqué est détectée, il convient d'accomplir une opération de récupération d'alarme. Se référer aux attributs Alarm_Regen de l'ARMO en 6.2.7.2 pour plus de détails relatifs au déclenchement de la régénération.

12.17.5.2.2.16 Alert source transport port

Ce paramètre identifie l'UAP contenant l'objet qui a détecté l'alerte par l'intermédiaire de son port T associé.

12.17.5.2.2.17 Alert source object

L'objet source d'alerte indique l'instance d'objet qui a détecté la condition d'alarme.

NOTE L'objet gestion de rapports d'alertes rapporte les conditions d'alerte détectées par un ou plusieurs objets détecteurs d'alerte.

12.17.5.2.2.18 Detection time

Ce paramètre spécifie le temps auquel la condition d'alerte a été détectée. Cette valeur indique le temps réseau auquel la condition d'alerte a été détectée. La façon de rendre les informations de temps disponibles à une application rapportant une alerte est une question locale d'appareil, non spécifiée par la la présente norme.

NOTE La conversion du temps réseau en temps social (temps d'horloge murale), lorsque souhaitée, est accomplie dans la passerelle. Voir 5.6 pour plus de détails.

12.17.5.2.2.19 Alert class

Ce paramètre indique s'il s'agit d'un type d'alerte événement (sans état) ou alarme (orientée état).

12.17.5.2.2.20 Alarm direction

Pour les alertes qui sont orientées état (les alarmes), il indique si le rapport concerne une condition d'alarme ou un retour à la normale à partir d'une condition d'alarme.

12.17.5.2.2.21 Alert category

La catégorie d'alertes indique si l'alerte est une alerte de diagnostics d'appareil, une alerte de diagnostics de communication, une alerte de sécurité ou une alerte de processus.

12.17.5.2.2.22 Alert priority

La priorité d'alerte est une valeur qui suggère l'importance de l'alerte. Plus la valeur est grande, plus l'alerte est importante. Les systèmes d'hôte mettent en correspondance les priorités d'appareil aux priorités d'alerte d'hôte qui comprennent habituellement les priorités "urgent", "high", "medium", "low" et "journal". Le mapping recommandé des valeurs de priorité d'alerte en ces catégories est comme suit:

- 0..2: journal
- 3..5: low
- 6..8: medium
- 9..11: high
- 12..15: urgent

Sachant que l'interprétation des priorités d'alerte se produit principalement dans les appareils initiateur et récepteur prévus, d'autres assignations qui reflètent une catégorisation différente sont permises.

12.17.5.2.2.23 Type d'alerte

Le type d'alerte fournit des informations complémentaires relatives à l'alerte, spécifiques à la catégorie d'alerte).

12.17.5.2.2.24 Associated-data size

Associated-data size spécifie la taille de toutes données spécifiques à une alerte acheminées avec l'alerte.

12.17.5.2.2.25 Associated data

Associated data fournit un moyen d'acheminer des données spécifiques à une alerte

12.17.5.3 Service AlertAcknowledge

12.17.5.3.1 Généralités

AlertAcknowledge est un service à deux parties qui est utilisé pour acquitter une alerte individuelle auprès d'un objet de gestion de rapports d'alertes. Pour les rapports d'alerte en monodiffusion, la réception d'un AlertAcknowledge doit entraîner la cessation des demandes de répétitions de tentative d'AlertReport pour l'alerte individuelle correspondante.

Un AlertAcknowledge doit être envoyé pour chaque AlertReport reçu.

NOTE Si un AlertReport double a été reçu, soit l'application qui a envoyé l'AlertReport n'a pas reçu l'AlertAcknowledge dans sa temporisation/temps de répétitions de tentative, soit le message d'AlertAcknowledgement n'a pas été reçu. Etant donné que l'application envoyant l'AlertAcknowledge ne sait pas quelle situation s'est produite, un doublon d'acquittement est envoyé.

Le service AlertAcknowledge est décrit dans le Tableau 279.

Tableau 279 – Service AlertAcknowledge

Nom du paramètre	Demande	Indication

12.17.5.3.2 Argument

12.17.5.3.2.1 Service contract identifier

Voir 12.17.3.2.2.1.

12.17.5.3.2.2 Priority

Voir 12.17.3.2.2.2.

12.17.5.3.2.3 Discard eligible

Voir 12.17.3.2.2.3.

12.17.5.3.2.4 End-to-end transmission time

Voir 12.17.3.2.2.4.

12.17.5.3.2.5 Source IPv6Address

Ce paramètre identifie l'adresse IPv6Address pour la source de cette demande.

12.17.5.3.2.6 Source TDSAP

Ce paramètre identifie le TDSAO associé de l'AP source de primitive de service. Le TDSAP établit un mapping 1:1 à un UAP.

12.17.5.3.2.7 Source T-port

Ce paramètre identifie l'UAP source d'application émetteur associé au port T.

12.17.5.3.2.8 Source object identifier

Ce paramètre identifie l'objet qui initie l'acquittement d'alerte.

12.17.5.3.2.9 Destination T-port

Ce paramètre identifie le processus d'application pour recevoir l'acquittement d'alerte, car une seule application est associée à un port T.

12.17.5.3.2.10 Destination TDSAP

Ce paramètre identifie le SAP de TDLE correspondant au port de transport de destination.

12.17.5.3.2.11 Destination object identifier

Ce paramètre identifie l'objet dans le processus d'application de l'appareil pour recevoir l'acquittement.

12.17.5.3.2.12 Individual alert identifier

Ce paramètre identifie l'alerte individuelle qui est acquittée.

12.17.6 Aspects communs client/serveur et à la source/puits

12.17.6.1 Messagerie individuelle ou concaténée pour client/serveur et/ou source/puits

Les messages client/serveur et source/puits peuvent être envoyés sous la forme d'une unité de données de service de transport (TSDU) individuelle ou peuvent être concaténés ensemble au sein d'une seule TSDU. La concaténation prend en charge les messages de primitives tant à quatre parties ("request" et "response") qu'à deux parties ("request" seulement). La concaténation permet que des messages client/serveur soient combinés dans la TSDU avec des messages de source/puits. La façon de déterminer et d'accomplir la concaténation des APDU est une question locale d'appareil. Il convient que les concaténations s'abstiennent d'inclure plus de deux services, car cela peut se traduire par une communication avec plus de salves.

NOTE 1 Le débat relatif à la violation d'acquittement en laps de temps de l'IETF RFC 2525 fournit le contexte de la concaténation d'acquittements de message et les ramifications de la présence de plus deux tels acquittements dans une PDU.

NOTE 2 La P/S (éditer/s'abonner) prend déjà en charge l'inclusion de plusieurs valeurs issues d'un UAP dans un seul message. Voir 12.15.2.5 et 12.15.2.6 pour de plus amples détails.

La concaténation peut être utilisée pour réduire le surdébit d'émission et/ou livrer un jeu de messages à l'ASL correspondante comme un bloc.

Tous les messages au sein de la concaténation doivent avoir une priorité de message commune, et doivent indiquer la communication par l'intermédiaire d'un contrat de communication commun.

Le nombre de services d'ASL qui peuvent être concaténés par une ASL construisant la PDU concaténée est limité par la taille d'APDU maximale correspondant au contrat de communication devant être utilisé pour les messages.

L'ASL recevant une APDU concaténée doit analyser et traiter chaque APDU individuellement du début à la fin jusqu'à ce que la fin de la TSDU ait été atteinte. Si une erreur de protocole est détectée pendant l'analyse d'une APDU concaténée, une seule erreur d'APDU mal formée est indiquée et la partie restante de l'APDU doit être rejetée.

Une concaténation de services d'ASL peut contenir:

- des primitives de service d'ASL homogènes (par exemple, toutes les demandes de service); ou
- des primitives de service d'ASL hétérogènes (par exemple: flux client/serveur, demandes et réponses; peuvent être mélangés);
- des primitives de flux de communication d'application homogènes (toutes les client/serveur, par exemple); ou
- des primitives de types de flux de communication d'application hétérogènes (par exemple: client/serveur et source/puits).

L'AL elle-même ne donne aucune exigence sur la façon dont des réponses aux services inclus dans une concaténation sont retournées; la détermination de celle-ci est laissée à la discrétion de l'application réceptrice. Par exemple, si une demande client/serveur concaténée contient les demandes de service (A, B, C) et une autre demande de service client/serveur concaténée contient les demandes de service (D, E), les réponses client/serveur à celles-ci peuvent:

– ne pas être exigées (par exemple: A, B, et D peuvent être des services à quatre parties qui exigent une réponse, mais C et E peuvent être des services à deux parties qui n'exigent pas de réponse);
– ne pas être concaténées du tout et être retournées dans un ordre quelconque (par exemple, réponse A, réponse B, réponse E, réponse D, réponse C, toutes dans des APDU distinctes);
– être partiellement concaténées, dans un ordre quelconque (par exemple: la réponse retournée peut être B, C dans une APDU, A dans une autre APDU);
– utiliser une seule APDU pour répondre à une demande concaténée, mais les réponses peuvent être concaténées dans n'importe quel ordre (par exemple: la réponse retournée peut être concaténée sous la forme BCA);
– être complètement concaténées dans le même ordre (par exemple, la réponse est retournée en étant concaténée sous la forme ABC);
– être complètement concaténées différemment des demandes reçues (par exemple, la réponse peut être retournée sous la forme BD, ACE).

La façon et le moment de l'initiation d'une communication par une ASL déterminent le moment auquel créer une concaténation ainsi que le moment auquel livrer la concaténation à la suite inférieure de protocoles de communication en vue de l'acheminement; cela relève d'une initiative locale. Cependant, la présente norme doit spécifier la structure globale d'une TSDU contenant des APDU concaténées.

La présente norme ne donne pas d'exigence relative à l'ordre dans lequel les services inclus dans la messagerie concaténée sont traités par la destination. Ainsi l'ordre des réponses n'est pas tenu d'être le même que l'ordre des demandes incluses dans la concaténation.

NOTE 3 Une mise en œuvre qui définit des services locaux pour encadrer les constructions concaténées peut fournir un contrôle supplémentaire sur le contenu de concaténation.

La Figure 133 montre une réponse concaténée pour plusieurs demandes d'écriture en cours sans perte de message. Des temporisations sont décrites en 12.12.4.2.2.1.

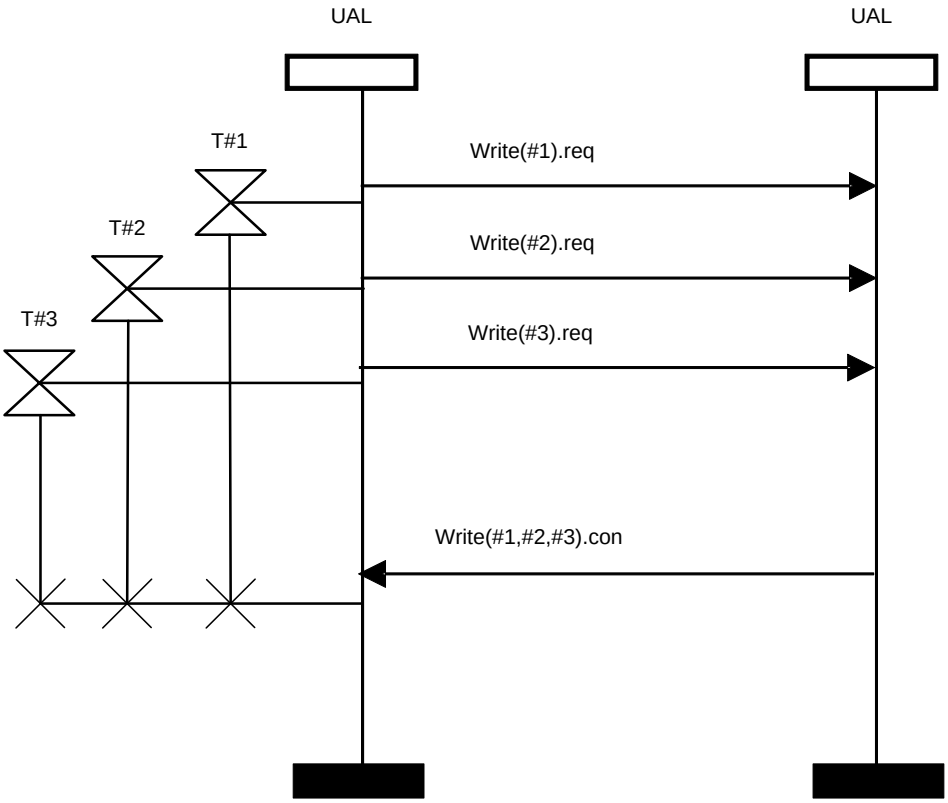

Figure 133 – Réponse concaténée pour plusieurs demandes d'écriture en cours (pas de perte de message)

12.17.6.2 Services communs de sous-couche d'application pour la messagerie client/serveur et source/puits – Tunnel

12.17.6.2.1 Généralités

Le service tunnel peut utiliser un modèle de primitives de service de communication soit à deux parties (source/puits), soit à quatre parties (client/serveur).

La responsabilité d'inclure au sein de la charge utile non native de messages tunnel les informations pour permettre la concordance de primitives de service, l'accomplissement du traitement approprié au niveau application des situations d'erreur telles que la détection de doublons de message et la détection d'une livraison dans le désordre, etc., doit incomber au processus d'application.

Le service tunnel peut être utilisé pour encapsuler les communications tant client/serveur que source/puits telles que définies par la présente norme. Ce service identifie un message comme étant destiné à un tunnel de protocoles non natifs. L'identificateur de service est exigé pour que l'ASL puisse analyser un message et déterminer de le passer à un tunnel de protocoles hérités ou de le traiter comme étant un message natif. Le service tunnel fournit un seul niveau d'encapsulation de message pour un tunnel de protocoles. L'APDU non native est passée à l'objet de destination spécifié dans la demande de service tunnel.

Une application de tunnellisation peut établir la politique de répétitions de tentative pour des demandes à deux parties (source/puits) qu'elle envoie.

Le Tableau 280 définit les primitives du service Tunnel.

Tableau 280 – Service Tunnel

Nom du paramètre	Demande	Indication	Réponse	Confirmation

12.17.6.2.2 Argument

12.17.6.2.2.1 Service contract identifier

Voir 12.17.3.2.2.1.

12.17.6.2.2.2 Priority

Voir 12.17.3.2.2.2.

12.17.6.2.2.3 Discard eligible

Voir 12.17.3.2.2.3.

12.17.6.2.2.4 End-to-end transmission time

Voir 12.17.3.2.2.4.

12.17.6.2.2.5 Forward congestion notification

Ce paramètre indique si la demande a rencontré un encombrement de réseau sur son chemin allant du client vers le serveur.

12.17.6.2.2.6 Application destination T-port

Ce paramètre identifie l'UAP à la destination pour cette demande de service.

12.17.6.2.2.7 Application destination TDSAP

Ce paramètre représente le TDSAP correspondant au port de destination de transport d'AL.

12.17.6.2.2.8 Application destination object identifier

Ce paramètre identifie l'objet dans l'application réceptrice.

12.17.6.2.2.9 Application source IPv6Address

Ce paramètre identifie l'adresse IPv6Address pour le client de cette demande.

12.17.6.2.2.10 Application source TDSAP

Ce paramètre identifie le TDSAP associé de l'UAP source d'application. Le TDSAP établit un mapping 1:1 à un UAP. L'UAP contient l'objet à l'origine de demande dans le client.

12.17.6.2.2.11 Application source T-port

Ce paramètre identifie l'UAP qui est la source pour cette demande de service.

12.17.6.2.2.12 Application source object identifier

Ce paramètre indique l'objet source d'application qui a initié la demande de service Tunnel.

12.17.6.2.2.13 Payload size

Ce paramètre indique le nombre d'octets du paramètre de charge utile de tunnel.

12.17.6.2.2.14 Tunnel payload data

Ce paramètre représente les données (APDU de protocole hérité, par exemple) qui doivent être acheminées vers l'objet serveur.

12.17.6.2.3 Result

12.17.6.2.3.1 Service contract identifier

Voir 12.17.3.2.2.1.

12.17.6.2.3.2 Priority

Voir 12.17.3.2.2.2.

12.17.6.2.3.3 Discard eligible

Voir 12.17.3.2.2.3.

12.17.6.2.3.4 End-to-end transmission time

Voir 12.17.3.2.2.4.

12.17.6.2.3.5 Forward congestion notification

Ce paramètre indique si la réponse de service a rencontré un encombrement de réseau sur son chemin allant du serveur vers le client.

12.17.6.2.3.6 Forward congestion notification echo

Ce paramètre indique si la demande de service a rencontré un encombrement de réseau sur son chemin allant du client vers le serveur.

12.17.6.2.3.7 Application destination T-port

Ce paramètre identifie l'UAP à la destination pour cette demande de service.

12.17.6.2.3.8 Application destination TDSAP

Ce paramètre représente le TDSAP correspondant au port de destination de transport d'AL.

12.17.6.2.3.9 Application destination object identifier

Ce paramètre indique l'objet de destination d'application qui a initié la demande de service Tunnel.

12.17.6.2.3.10 Application source IPv6Address

Ce paramètre identifie l'adresse IPv6Address pour le client de cette demande.

12.17.6.2.3.11 Application source TDSAP

Ce paramètre identifie le TDSAP associé de l'UAP source d'application. Le TDSAP établit un mapping 1:1 à un UAP. L'UAP contient l'objet à l'origine de demande dans le client.

12.17.6.2.3.12 Application source T-port

Ce paramètre indique l'objet source d'application qui a initié la demande de service Tunnel.

12.17.6.2.3.13 Application source object identifier

Ce paramètre indique l'objet tunnel source d'application qui a initié la demande de service Tunnel.

12.17.6.2.3.14 Payload size

Ce paramètre indique le nombre d'octets du paramètre de charge utile de tunnel.

12.17.6.2.3.15 Tunnel payload data

Ce paramètre représente les données (APDU de protocole hérité, par exemple) qui doivent être acheminées vers l'objet serveur.

12.18 Utilisation du flux d'AL relative aux services de couche inférieure

12.18.1 Généralités

Tous les types de messagerie (par exemple, publication, client/serveur, source/puits, transfert en masse) et toutes les qualités de service peuvent circuler par le TDSAP commun pour le processus d'application. Le Tableau 281 indique le mapping des flux d'AL aux services de TL fournis.

Tableau 281 – Caractéristiques des flux d'application

Type de flux d'application	Placé en tampon ou placé en file d'attente	Périodique (programmé)	Sensible à l'ordre	Fiabilité	Non acquitté	Importance du message		
						Elevée	Moyenne	Faible
Edition/abonnement périodique	En tampon	Oui	Oui	Non	Oui	[a]	[a]	[a]
Client/serveur	En file d'attente	Non	Non	Non	Oui	[a]	[a]	[a]
Source/puits	En file d'attente	Non	Non	Non	Oui	[a]	[b]	[a]

[a] Parmi les alternatives d'importance de message, celle qui est sélectionnée s'applique.

[b] Aucun cas d'utilisation identifié.

12.18.2 Utilisation d'AL des TDSAP

L'ASL communique avec les couches inférieures de la suite de protocoles de communication par l'intermédiaire des TDSAP. L'information communiquée à la TL pour le mapping de TDSAP est un sous-ensemble des informations communiquées à l'ASL à partir de l'UAP au niveau de l'ASAP. Il y a un TDSAP bien connu dans la présente norme, à savoir le TDSAP numéro 0, qui est utilisé pour des communications avec les objets représentés par l'application DMAP.

Les TDSAP qui ne sont pas bien connus peuvent être associés à un et un seul processus d'application particulier. C'est-à-dire, il y a une relation de mapping univoque (1:1) entre un TDSAP et un processus d'UAL. Les TDSAP étant locaux, les entités distantes indiquent un port T qui représente une application correspondante. Les ports T sont en correspondance univoque (1:1) avec les TDSAP. Les relations processus d'UAL/TDSAP/port de données de transport doivent survivre à un redémarrage d'application.

NOTE Quinze TDSAP sont disponibles pour une émission compressée. Voir 11.6 pour plus de détails.

12.18.3 Mapping des primitives de service d'AL aux primitives de service de TL

Le Tableau 282 indique le mapping de primitives de service d'application à des services de transport.

Tableau 282 – Mapping de primitives de service d'AL à des primitives de service de TL

Primitive de service d'application	Service de transport	Données acheminées entre sous-couche application et service de transport
Publish.request Read.request, Read.response Write.request, Write.response Execute.request, Execute.response Tunnel.request, Tunnel.response AlertReport.request AlertAcknowledge.request	T-DATA.request	Contract_ID APDU_size APDU Message priority Discard eligibility Source TDSAP Destination T-port NOTE 1 L'ID de contrat indique l'adresse de destination et la priorité du contrat. NOTE 2 Le port T source peut être déterminé à partir du TDSAP source, mais il est explicitement passé pour concorder avec l'interface fournie par la TL.
Publish.indicate Read.indicate, Read.confirmation Write.indicate, Write.confirmation Execute.indicate, Execute.confirmation Tunnel.indicate, Tunnel.confirmation AlertReport.indicate AlertAcknowledge.indicate	T-DATA.indicate	Source IPv6Address Source T-port APDU_size (équivalent à TSDU size) APDU (équivalent de TSDU) Explicit congestion notification (ECN) Destination TDSAP Destination T-port Transport time (temps de livraison de bout en bout dans un seul sens, en secondes)

12.19 Gestion d'AL

12.19.1 Généralités

La gestion d'AL prend en charge l'objet local de gestion de sous-couche d'application de DMAP. L'accès aux attributs et aux méthodes de cet objet est défini par l'ASL. Pour la présente norme, l'ASL fournit l'accès pour lire une valeur configurée dans la MIB de l'ASL, pour écrire une valeur configurée dans la MIB de l'ASL, et pour prendre en charge la réinitialisation de l'ASL.

12.19.2 Traitement de sous-application des unités de données de protocole d'application mal formées

L'ASL prend en charge le fait d'informer le DMAP local d'un problème potentiel d'appareil/de communication si un seuil configuré par la gestion d'AL est atteint dans les limites de la période de temps configurée pour les APDU mal formées reçues en provenance d'un appareil source particulier. Quelques exemples d'APDU mal formées sont:

- APDU de taille incorrecte (trop longue ou trop courte);
- identificateur de service non valide; ou
- mauvaise utilisation de service (par exemple, la primitive "response" a été indiquée dans la PDU pour un service client/serveur ou source/puits à deux parties).

L'intention de cette information est de permettre au DMAP de fournir des informations à la gestion de niveau supérieur. Cela peut être important, par exemple, pour permettre de détecter que l'attaque d'une APDU mal formée se produit.

L'ASL peut être configurée pour aviser le DMAP chaque fois qu'une APDU mal formée est reçue.

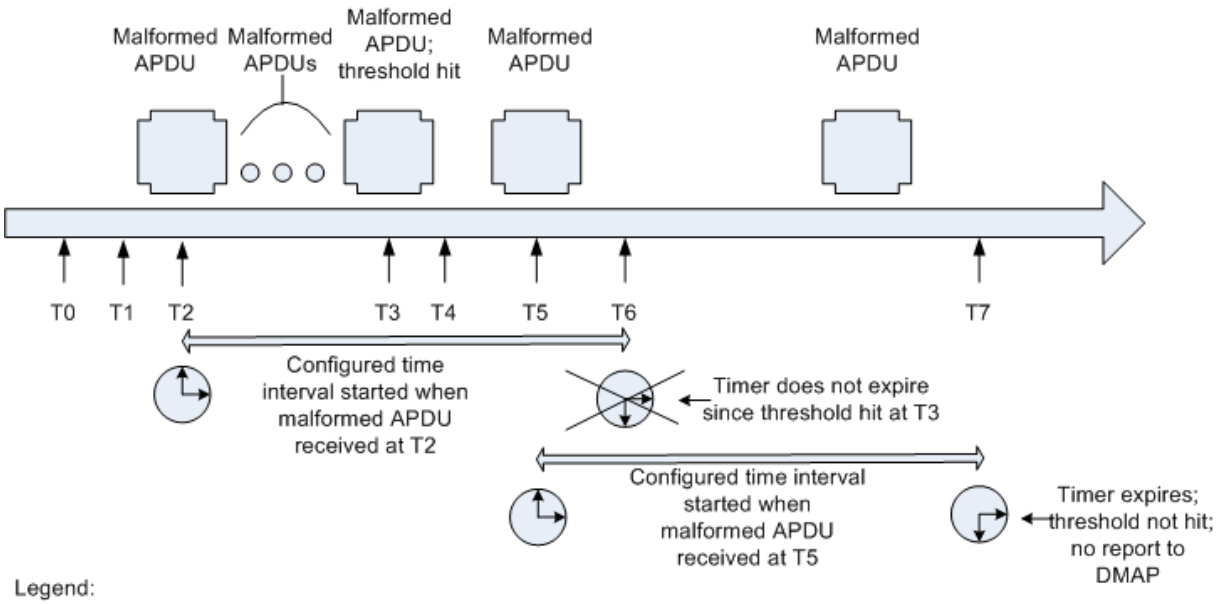
L'ASL peut être configurée avec des valeurs différentes de zéro pour un seuil et un intervalle de temps. Lorsqu'elle est ainsi configurée, l'ASL maintiendra, en interne, des compteurs et temporisateurs individuels pour chaque adresse de source réseau en provenance de laquelle une APDU mal formée a été reçue. Le compte débute avec la réception de la première APDU mal formée en provenance d'un appareil et se poursuit soit tant que la valeur-seuil d'APDU mal formées n'est pas atteinte, soit tant que l'ASL_TimePeriodForMalformedAPDUs n'a pas expiré.

Si la valeur-seuil d'APDU mal formées est atteinte avant ou à l'expiration de l'intervalle de temps configuré, le DMAP est avisé et le décompte et l'intervalle de temps pour l'appareil sont réinitialisés.

Si le seuil d'APDU mal formées n'est pas atteint dans les limites de l'intervalle de temps configuré, les compteurs et les temporisateurs sont intérieurement réinitialisés.

NOTE La façon dont le DMAP est avisé d'une APDU mal formée ou qu'un seuil est atteint dans un intervalle de temps relève d'une initiative locale et n'est donc pas spécifiée par la présente norme.

La Figure 134 montre le traitement des APDU mal formées.



Legend:
T0 – malformed APDU threshold is set to non-zero value
T1 – malformed APDU counting interval is set to non-zero value
T2 – first malformed APDU arrives from source device "X", time interval for counting malformed APDUs starts
T3 – threshold of malformed APDUs is reached
T4 – report to DMAP after which internal ASL internal counter resets
T5 -- another malformed APDU arrives again from source device "X"
T6 - original calculation of expiration of time interval for malformed APDUs from device "X" , starting from receipt of malformed APDU at T2
T7 – time interval started at T5 expires without threshold being hit; ASL internal counter resets

NOTE: The order of performing steps T0 and T1 is not important.

Légende

Anglais	Français
Malformed APDU	APDU mal formée
Malformed APDUs	APDU mal formées
Malformed APDU; threshold hit	APDU mal formée; seuil atteint

Anglais	Français
Configured time interval started when malformed APDU received at T2	L'intervalle de temps configuré a démarré lorsqu'une APDU mal formée a été reçue à T2
Timer does not expire since threshold hit at T3	Le temporisateur n'expire pas, car le seuil est atteint à T3
Configured time interval started when malformed APDU received at T5	L'intervalle de temps configuré a démarré lorsqu'une APDU mal formée a été reçue à T3
Timer expires; threshold not hit; no report to DMAP	Temporisateur expiré; seuil non atteint; pas de rapport à DMAP
Legend:	Légende:
T0- malformed APDU threshold is set to non-zero value	T0 – le seuil d'APDU mal formées est mis à une valeur différente de zéro
T1- malformed APDU counting interval is set to non-zero value	T1 – l'intervalle de comptage d'APDU mal formées est mis à une valeur différente de zéro
T2- first malformed APDU arrives from source device “X”, time interval for counting malformed APDUs starts	T2- la première APDU mal formée arrive de l'appareil source « X », l'intervalle de temps pour compter les APDU mal formées démarre
T3- threshold of malformed APDUs is reached	T3 – le seuil des APDU mal formées est atteint
T4- report to DMAP after which internal ASL internal counter resets	T4 – rapporter au DMAP après quoi le compteur interne d'ASL interne se réinitialise
T5- another of malformed APDU arrives again from source device “X”	T5- une autre APDU mal formée arrive encore de l'appareil source « X »
T6- original calculation of expiration of time interval for malformed APDUs from deviced “X”, starting from malformed APDU at T2	T6- calcul initial de l'expiration d'intervalle de temps pour les APDU mal formées issues de l'appareil « X », en commençant par l'APDU malformée à T2
T7- time interval started at TS expired without threshold being hit; ASL internal counter resets	T7- l'intervalle de temps démarré à T5 a expire sans que le seuil ait été atteint; le compteur interne d'ASL se réinitialise
NOTE The order of performing steps T0 and T1 is not important	NOTE L'ordre d'exécution des étapes T0 et T1 n'est pas important

Figure 134 – Gestion et traitement des APDU mal formées reçues en provenance de l'appareil X

12.19.3 Attributs de l'objet de gestion de sous-couche d'application

Le Tableau 283 décrit les attributs pris en charge par l'objet de gestion de sous-couche d'application (ASLMO).

Tableau 283 – Attributs d'ASLMO *(1 de 2)*

Nom du type d'objet normalisé: Application sublayer management object (ASLMO, objet de gestion de sous-couche d'application)				
Identificateur du type d'objet normalisé: 121				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Valeur par défaut: 7 Plage valide: 7	N/A
Réservée pour un usage futur	0	-	-	-
MalformedAPDUsAdvise	1	Indique s'il convient que l'ASL indique au DMAP local chaque occurrence d'une APDU mal formée	Type: Boolean Classification: Static Accessibilité: Lecture/écriture Valeur par défaut initiale:false	Si ce paramètre a la valeur True, l'ASL doit passer au DMAP local chaque APDU mal formée qu'elle reçoit
TimeIntervalForCountingMalformedAPDUs	2	Cet attribut spécifie l'intervalle de temps pour que l'ASL compte les APDU mal formées reçues en provenance d'un appareil particulier. Le compte se produit à partir de la détection de la première APDU mal formée provenant d'un appareil. Cet intervalle est communément appliqué aux APDU provenant de toutes les adresses IPv6Addresses. L'unité utilisée pour cet attribut est la seconde	Type: TAITimeDifference Classification: Static Accessibilité: Lecture/écriture Valeur par défaut initiale: 0 Plage valide: 0 ≤ valeur ≤ à 86 400 s Le nombre de jours n'est pas inclus (il est toujours égal à zéro)	Si l'intervalle de temps expire sans que le seuil soit atteint, les informations correspondantes de compteur et de temporisateur de l'ASL mal formée doivent être réinitialisées à zéro (0)
MalformedAPDUsThreshold	3	Valeur-seuil commune à appliquer aux APDU mal formées reçues en provenance de chaque appareil	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut initiale: 0	Si ce seuil est atteint dans l'intervalle de temps spécifié, une alerte de communication doit être rapportée indiquant l'appareil qui envoyait des APDU mal formées. Si une valeur-seuil est établie alors que le compte est en cours, et la valeur établie est inférieure au seuil antérieur si bien que le nouveau seuil a été dépassé, une alerte d'APDU mal formée doit être rapportée

Tableau 283 *(2 de 2)*

Nom du type d'objet normalisé: Application sublayer management object (ASLMO, objet de gestion de sous-couche d'application)				
Identificateur du type d'objet normalisé: 121				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
MalformedAPDUAlertDescriptor	4	Décrit comment une alerte mal formée est rapportée sur le réseau	Type: Descripteur de rapports d'alertes Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: [true 7]	
MaxDevicesForWhichMalformed APDUsCanBeCounted	5	Décrit la capacité de comptages des APDU mal formées de l'ASL en termes de nombre maximal d'appareils pour lesquels les comptes peuvent être maintenus simultanément	Type: Unsigned16 Classification: Constant Accessibilité: Lecture seule	Une valeur minimale exigée peut être établie par exemple en fonction du rôle de l'appareil
Réservé pour usage futur par la présente norme	6..63	-	-	-

Les attributs classés comme étant "constant" ou "static" doivent être préservés dans les redémarrages et les pannes de courant.

12.19.4 Méthodes de l'objet de gestion de sous-couche d'application

12.19.4.1 Méthodes d'objets normalisés

Un ASLMO a les méthodes définies dans le Tableau 284.

Tableau 284 – Méthodes de l'objet de gestion de sous-couche d'application

Nom du type d'objet normalisé: Application sublayer management object (ASLMO, objet de gestion de sous-couche d'application)		
Identificateur du type d'objet normalisé: 121		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Reset	1	Réinitialisation des données d'application
Réservé pour usage futur par la présente norme	2..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.19.4.2 Méthode Reset

Le Tableau 285 spécifie les primitives de la méthode Reset.

Tableau 285 – Méthode Reset

<table>
<tr><th colspan="5">Nom du type d'objet normalisé: Application sublayer management object (ASLMO, objet de gestion de sous-couche d'application)</th></tr>
<tr><th colspan="5">Identificateur du type d'objet normalisé: 121</th></tr>
<tr><th>Nom de la méthode</th><th>ID de la méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="8">Reset</td><td>1</td><td colspan="3">Réinitialisation de sous-couche d'application</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>ResetType</td><td>Type: Unsigned8

Valeurs nommées:
0: non utilisé
1: réinitialiser aux valeurs de réglage d'usine par défaut
2: réinitialiser aux valeurs de réglage configurées
3: réinitialiser à chaud (réinitialisation aux valeurs de réglage configurées et toutes les éventuelles informations relatives au contrat de communication)
4: réinitialiser toutes les données dynamiques (relatives aux statistiques, par exemple)
Valeurs 5..255 réservées</td><td>Type de réinitialisation souhaité</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td colspan="4">Aucun</td></tr>
</table>

12.19.4.3 Arguments d'entrée

Le paramètre ResetType indique le type de réinitialisation souhaité. La sous-couche peut être réinitialisée:

- aux valeurs de réglage d'usine par défaut;
- pour seulement maintenir les valeurs de réglage configurées (le cas échéant);
- pour seulement maintenir le jeu de valeurs de réglage configurées et de contrat de communication (le cas échéant); ou
- pour toutes les statistiques dynamiques seulement.

NOTE Un exemple de valeurs de réglage d'usine par défaut est:

– paramètre de configuration MalformedAPDUsAdvise indiquant "disabled";

– paramètre de configuration TimeIntervalForCountingMalformedAPDUs indiquant 100 APDU; et

– paramètre de configuration MalformedAPDUsThreshold indiquant un intervalle de temps de zéro.

12.19.4.4 Arguments de sortie

Il n'y a aucun argument de sortie pour cette méthode.

12.19.4.5 Codes de réponse

Les codes suivants de retour d'informations sont valides pour cette méthode:

- success;
- invalidArgument; et
- ceux qui sont définis par le fournisseur.

12.19.5 Alertes de l'objet de gestion de sous-couche d'application

Le Tableau 286 définit les alertes pour l'ASLMO.

Tableau 286 – Alertes d'ASLMO

Nom(s) du type d'objet normalisé: Application sublayer management object (ASLMO, objet de gestion de sous-couche d'application)					
Identificateur du type d'objet normalisé: 121					
Description de l'alerte: Alerte APDU mal formée					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alerte**	**Données associées**	**Description des données associées incluses à l'alerte**
Evénement	Communication diagnostic	malformedAPDU CommunicationAlert	7 (à savoir une alerte de priorité "medium" de mi-plage)	Aucun type normalisé spécial n'est défini, car le contenu de protocole ne correspond pas à un attribut de l'ASLMO. Plutôt, il est construit au sein du protocole comme une séquence implicite, dont la construction est identifiable par la combinaison de la classe d'alertes, de la catégorie d'alerte et du type d'alerte	Trois éléments sont inclus dans la séquence suivante: a) adresse source des APDU mal formées (adresse IPv6Address) b) valeur-seuil dépassée (Unsigned16) c) intervalle de temps dans lequel le seuil a été dépassé (TAITimeDifference)

12.19.6 Services de DMAP invoqués par la sous-couche d'application

Si l'intervalle des APDU mal formées de l'ASL et le seuil des APDU mal formées de l'ASL qui étaient configurés sont tous deux différents de zéro, l'ASL doit commencer à garder les statistiques des APDU mal formées. Si le seuil est atteint avant ou à l'expiration de l'intervalle de temps configuré, l'ASL doit rapporter au DMAP qu'il convient de générer une alerte de diagnostic de communication. Les données fournies par l'ASL au DMAP doivent inclure:

a) une indication que la situation malformedAPDUsThresholdReached a été atteinte; et

NOTE Cela est indiqué au cas où le seuil d'APDU mal formées serait atteint pour des APDU mal formées reçues en provenance d'une seule adresse N source dans l'intervalle configuré d'APDU mal formées d'ASL.

b) les informations de diagnostics relatives aux APDU mal formées détectées, telles que:
   - le nombre des APDU reçues qui n'avaient pas la longueur correcte;
   - le nombre des APDU reçues avec un identificateur de service non valide; et

– le nombre des APDU reçues avec un identificateur de service mal utilisé; et

c) l'adresse IPv6Address source des APDU mal formées; et

d) la valeur-seuil qui avait été atteinte; et

e) la durée temporelle sur laquelle les APDU mal formées avaient été reçues.

Cet intervalle de temps est calculé comme étant le temps allant de la détection de la première APDU issue de l'appareil indiqué par l'ASL jusqu'à la détection de l'APDU mal formée qui a conduit à ce que la limite du seuil d'ASL soit atteinte pour l'appareil indiqué. Cette durée temporelle doit être inférieure ou égale à l'intervalle de temps configuré qui est établi dans les paramètres de gestion d'ASL.

12.19.7 Objets normalisés des industries de transformation

12.19.7.1 Généralités

Les objets normalisés définis dans la présente norme sont inclus pour traiter des besoins fondamentaux de l'industrie de transformation. La théorie de terrain unifiée (pour le contrôle de processus) qui sous-tend la présente norme définit les objets de terrain normalisés en effectuant un effet de levier sur les définitions existantes d'objets d'appareils de terrain à partir de normes de contrôle de processus orientées objet et éprouvées sur le terrain. L'ensemble d'objets a été sélectionné selon des caractéristiques d'utilisation communes et il est défini pour permettre l'interfonctionnabilité et l'interopérabilité (dans son domaine d'application) limitée parmi des appareils.

NOTE 1 La terminologie utilisée dans le présent document, notamment SOE, PV, OP, OOS, MAN et AUTO, est la terminologie commune aux industries de transformation.

NOTE 2 La présente norme présume que des restrictions d'accès aux attributs d'objet, au besoin pour satisfaire à des exigences d'utilisation de système, sont mises en vigueur par des appareils d'interface humaine et/ou des appareils passerelles.

Pour prendre en charge les marqueurs temporels utilisés dans les rapports d'alarme dans l'industrie de contrôle de processus, la construction de valeur de temps utilisée pour représenter le temps doit prendre en charge une exactitude de codage de 1 ms. Cette exactitude est nécessaire pour prendre en charge une résolution à grande vitesse typique des applications de séquences d'événements (SOE) des industries de transformation.

12.19.7.2 Objets d'application utilisateur dans les industries de transformation

Une liste de base d'objets d'application utilisateur est anticipée pour le profil des industries de contrôle de processus. Les objets de terrain unifiés (UFO) définis dans la présente norme sont:

- analog input object (objet d'entrée analogique);
- analog output object (objet de sortie analogique);
- binary input object (objet d'entrée binaire);et
- binary output object(objet de sortie binaire).

Le mode de commande d'objet d'application prend en charge les modes suivants:

- Le mode cible est le mode auquel l'appareil a été commandé de passer. Il peut être différent du mode réel si l'appareil ne peut pas accepter le mode cible en raison d'une erreur, etc.
- Le mode réel est le mode courant de l'objet.
- Le mode normal est le mode de fonctionnement du bloc qui est désiré par le technicien de commande responsable. Le mode normal est l'un des modes autres qu'OOS, qui est spécifié comme étant le "fonctionnement normal" pour le bloc.
- Les modes autorisés représentent l'ensemble de modes qui sont valides pour cet objet. Il s'agit d'un filtre qui peut être appliqué pour limiter le mode cible du bloc. Par

exemple, le mode manuel peut être désactivé de cette façon. OOS est toujours inclus dans l'ensemble de modes autorisés.

Les modes suivants sont pris en charge:

– hors service (OOS): l'appareil ne mesure pas activement la valeur PV ou n'accepte pas la valeur OP. Un autre nom commun pour ce mode est "inactive". La valeur et le statut associé indiquant l'état d'OOS sont encore communiqués par l'appareil. Cela ne vise pas à désactiver la communication;
– manuel (MAN): la valeur de processus peut être saisie manuellement par l'opérateur, utilisée pour la commande de boucle ouverte avec humain dans la boucle ou pour neutraliser une mesure fautive. Egalement utile pour des essais; et
– automatique (AUTO): l'appareil mesure activement la valeur PV ou accepte la valeur OP.

Un attribut structuré doit être ajouté pour chaque type de rapport d'alerte pris en charge par l'objet. Cet attribut prend en charge l'activation/désactivation d'un rapport d'alerte et établit les priorités d'alertes.

Pour des alarmes, un attribut structuré peut en plus être exigé pour établir des limites d'alarme, pour indiquer si une alarme est présente.

12.19.7.3 Analog input user object (objet utilisateur d'entrée analogique)

12.19.7.3.1 Généralités

Un objet utilisateur normalisé d'entrée analogique représentant une encapsulation d'une entrée analogique est défini. Si plusieurs entrées analogiques sont représentées par un appareil, il convient que plusieurs objets utilisateur d'entrée analogiques soient instanciés. Les attributs spécifiques à un type d'objet relatifs à cet objet incluent:

- process value: une valeur en virgule flottante représentée en unités d'étude et statut;
- mode: un attribut structuré représentant un mode cible, un mode réel, un mode autorisé, et un mode normal;
- corresponding concentrator object: spécifie le concentrateur associé pour éditer la PV; et
- scale: représente la plage et les unités de la valeur de processus par l'intermédiaire d'un attribut structuré qui indique les limites 0 % et 100 % de la plage de valeurs nominale, une représentation codée d'unités d'étude, ainsi que le nombre de chiffres significatifs qu'il convient d'utiliser pour l'affichage

Des alertes normalisées pour cet objet seront également définies.

12.19.7.3.2 Attributs d'objet

Un objet d'entrée analogique a les attributs définis dans le Tableau 287.

Tableau 287 – Attributs de l'objet d'entrée analogique

Nom du type d'objet normalisé: Analog input object (objet d'entrée analogique)				
Identificateur du type d'objet normalisé: 99				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
PV	1	Variable de mesure en unités d'étude du capteur	Type: Process control value and status for analog value Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: NaN Etat: Inconnu; Sous-état: Inconnu; Condition limite: Non limité Plage valide: Voir la définition de la structure process control value and status for analog value	Valeur de processus analogique et statut pour la valeur en question. L'accessibilité s'effectue uniquement en lecture/écriture lorsque MODE.Target=MAN. Voir 12.19.7.2. Lorsqu'une écriture dans la PV est effectuée, l'appareil peut mettre cela en œuvre comme une écriture dans une variable interne non visible du réseau et utiliser la valeur non visible pour construire la valeur qu'elle représente pour la PV. Selon le cas, l'appareil peut rapporter pour la PV un statut différent de celui qui avait été fourni dans la demande d'écriture.
Mode	2	Mode	Type: Process control mode Classification: Static Accessibilité: Lecture seule pour le mode réel; le mode cible, le mode autorisé et le mode normal ont tous un accès en lecture/écriture Valeur par défaut: La valeur du mode réel indique OOS Plage valide: Voir la définition du type de structure Process control mode	Valeurs de mode réel, de mode cible, de mode autorisé et de mode normal
Réservée pour un usage futur	3	-	-	-

Nom du type d'objet normalisé: Analog input object (objet d'entrée analogique)				
Identificateur du type d'objet normalisé: 99				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Echelle	4	Plage et unités de la variable de mesure	Type: Process control scaling data	Information de mise à l'échelle pour la valeur de processus analogique
			Classification: Static	
			Accessibilité: Lecture/écriture	
			Valeur par défaut: Les valeurs des unités d'étude pour 0 % et pour 100 % indiquent TOUTES LES DEUX 0	
			Plage valide: Voir la définition du type de structure scale	
Réservé pour usage futur par la présente norme	5..25	-	-	*N* octets de contenu présentement indéfini

12.19.7.3.3 Méthodes d'objets normalisés

Un objet d'entrée analogique a les méthodes définies dans le Tableau 288.

Tableau 288 – Méthodes de l'objet d'entrée analogique

Nom du type d'objet normalisé: Analog input object (objet d'entrée analogique)		
Identificateur du type d'objet normalisé: 99		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.19.7.3.4 Alertes

Une entrée analogique peut rapporter les alertes montrées dans le Tableau 289. Si une alerte est prise en charge, un attribut de descripteur d'alerte correspondant doit être ajouté à l'objet d'entrée analogique pour décrire les caractéristiques de l'alerte.

Tableau 289 – Alertes d'entrée analogique

Nom(s) du type d'objet normalisé: Analog input						
Identificateur du type d'objet normalisé: 99						
Description de l'alerte: alertes d'entrée analogique						
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type(s) d'alerte (Enumerated: en fonction de la catégorie d'alertes)**		**Priorité d'alerte**	**Données associées: type et taille**	**Description des données associées incluses à l'alerte**
Alarme	Processus	1	Elevée	Toute	Type: Float32	Variable de processus
Alarme	Processus	2	HighHigh	Toute	Type: Float32	Variable de processus
Alarme	Processus	3	Faible	Toute	Type: Float32	Variable de processus
Alarme	Processus	4	LowLow	Toute	Type: Float32	Variable de processus
Alarme	Processus	5	DeviationLow	Toute	Type: Float32	Variable de processus
Alarme	Processus	6	DeviationHigh	Toute	Type: Float32	Variable de processus
Alarme	Processus	0	OutOfService	Toute	Type: Float32	Variable de processus

12.19.7.4 Analog output user object (objet utilisateur de sortie analogique)

12.19.7.4.1 Généralités

Un objet normalisé utilisateur de sortie analogique représente une encapsulation d'une sortie analogique. Si plusieurs sorties analogiques sont représentées par un appareil, il convient que plusieurs objets utilisateur de sorties analogiques soient instanciés. Les attributs spécifiques à un type d'objet relatifs à cet objet incluent:

- commanded output value: une valeur en virgule flottante représentée en unités d'étude et statut;
- mode: un attribut structuré représentant un mode cible, un mode réel, un mode autorisé, et un mode normal;
- Readback: valeur et statut de la position réelle;
- provider of OP value: indique la source de la valeur OP;
- corresponding concentrator object: spécifie le concentrateur associé pour éditer la valeur Readback; et
- scale: représente la plage et les unités de la valeur de processus par l'intermédiaire d'un attribut structuré qui indique les limites 0 % et 100 % de la plage de valeurs nominale, une représentation codée d'unités d'étude, ainsi que le nombre de chiffres significatifs qu'il convient d'utiliser pour l'affichage

12.19.7.4.2 Attributs d'objet

Un objet de sortie analogique a les attributs définis dans le Tableau 290.

Tableau 290 – Attributs de sortie analogique *(1 de 2)*

Nom du type d'objet normalisé: Analog output object (objet de sortie analogique)				
Identificateur du type d'objet normalisé: 98				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
OP	1	Valeur de sortie pour l'actionneur	Type: Process control value and status for analog value structure Classification: Dynamic Accessibilité: Lecture/écriture Valeur par défaut: NaN Etat: Inconnu; Sous-état: Inconnu; Condition limite: Non limité Plage valide: Voir la définition de la structure process control value and status for analog value	Il s'agit de l'attribut normalisé qui sert d'attribut de destination pour une publication issue d'un autre objet
Mode	2	Mode	Type: Process control mode Classification: Static Accessibilité: Lecture seule pour le mode réel; le mode cible, le mode autorisé et le mode normal ont tous un accès en lecture/écriture Valeur par défaut: La valeur du mode réel indique OOS Plage valide: Voir la définition du type de structure Process control mode	Valeurs de mode réel, de mode cible, de mode autorisé et de mode normal
Réservée pour un usage futur	3	-	-	-
Readback	4	Valeur Readback – la position réelle de l'OP	Type: Process control value and status for analog value Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: NaN; Etat: Inconnu; Sous-état: Inconnu; Condition limite: Non limité Plage valide: Voir la définition de la structure process control value and status for analog value	Valeur de processus analogique et statut pour la valeur en question. Il s'agit de l'attribut normalisé qui est édité à partir de cet objet. Si cet objet est étendu et, de ce fait, un autre attribut a besoin d'être édité, un/des objet(s) concentrateur(s) représente(nt) la/les publication(s) résultante(s)

Tableau 290 *(2 de 2)*

Nom du type d'objet normalisé: Analog output object (objet de sortie analogique)				
Identificateur du type d'objet normalisé: 98				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Réservée pour un usage futur	5	-	-	-
Echelle	6	Plage et unités de la variable de sortie	Type: Process control scaling data structure	Informations de mise à l'échelle
			Classification: Static	
			Accessibilité: Lecture/écriture

12.19.7.4.3 Méthodes d'objets normalisés

Un objet de sortie analogique a les méthodes définies dans le Tableau 291.

Tableau 291 – Méthodes de l'objet de sortie analogique

Nom du type d'objet normalisé: Analog output object (objet de sortie analogique)		
Identificateur du type d'objet normalisé: 98		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme.
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.19.7.4.4 Alertes

Une sortie analogique peut rapporter les alertes montrées dans le Tableau 292. Si une alerte est prise en charge, un attribut de descripteur d'alerte correspondant doit être ajouté à l'objet de sortie analogique pour décrire les caractéristiques de l'alerte.

Tableau 292 – Alertes de sortie analogique

Nom(s) du type d'objet normalisé: Sortie analogique						
Identificateur du type d'objet normalisé: 98						
Description de l'alerte: objet de sortie analogique						
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type(s) d'alerte (Enumerated: en fonction de la catégorie d'alertes)**		**Priorité d'alerte**	**Données associées: type et taille**	**Description des données associées incluses à l'alerte**
Alarme	Processus	1	Elevée	Toute	Type: Float32	Variable de processus
Alarme	Processus	2	HighHigh	Toute	Type: Float32	Variable de processus
Alarme	Processus	3	Faible	Toute	Type: Float32	Variable de processus
Alarme	Processus	4	LowLow	Toute	Type: Float32	Variable de processus
Alarme	Processus	5	DeviationLow	Toute	Type: Float32	Variable de processus
Alarme	Processus	6	DeviationHigh	Toute	Type: Float32	Variable de processus
Alarme	Processus	0	OutOfService	Toute	Type: Float32	Variable de processus

12.19.7.5 Binary input user object (objet utilisateur d'entrée binaire)

12.19.7.5.1 Généralités

Un objet normalisé utilisateur d'entrée binaire représente une encapsulation d'une seule entrée binaire. Si plusieurs entrées binaires sont représentées par un appareil, il convient que plusieurs objets utilisateur d'entrée binaires existent pour les représenter. Les attributs spécifiques à un type d'objet relatifs à cet objet incluent:

- process value: valeur binaire et statut;
- mode: un attribut structuré représentant un mode cible, un mode réel, un mode autorisé, et un mode normal; et
- corresponding concentrator object: spécifie le concentrateur associé pour éditer la valeur de processus.

12.19.7.5.2 Attributs d'objet

Un objet d'entrée binaire a les attributs définis dans le Tableau 293.

Tableau 293 – Attributs de l'objet d'entrée binaire

Nom du type d'objet normalisé: Binary input object (objet d'entrée binaire)				
Identificateur du type d'objet normalisé: 97				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
PV_B	1	Variable de mesure discrète	Type: Process control value and status for discrete value Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0 Etat: Inconnu; Sous-état: Inconnu; Condition limite: Non limité Plage valide: Voir la définition de la structure process control value and status for discrete value	Valeur de processus binaire et statut pour la valeur en question. Il s'agit de l'attribut normalisé qui est édité à partir de cet objet. Si cet objet est étendu et, de ce fait, un autre attribut a besoin d'être édité, un/des objet(s) concentrateur(s) représente(nt) la/les publication(s) résultante(s). L'accessibilité s'effectue uniquement en lecture/écriture dans le mode MAN. Voir 12.19.7.2. Lorsqu'une écriture dans la PV_B est effectuée, l'appareil peut mettre cela en œuvre comme une écriture dans une variable interne non visible du réseau et utiliser la valeur non visible pour construire la valeur qu'elle représente pour la PV_B. Selon le cas, l'appareil peut rapporter pour la PV_B un statut différent de celui qui avait été fourni dans la demande d'écriture.
Mode	2	Mode	Type: Process control mode Classification: Static Accessibilité: Lecture seule pour le mode réel; le mode cible, le mode autorisé et le mode normal ont tous un accès en lecture/écriture Valeur par défaut: La valeur du mode réel indique OOS Plage valide: Voir la définition du type de structure Process control mode	Valeurs de mode réel, de mode cible, de mode autorisé et de mode normal
Réservé pour usage futur par la présente norme	3..25	-	-	*N* octets de contenu présentement indéfini

12.19.7.5.3 Méthodes d'objets normalisés

Un objet d'entrée binaire a les méthodes définies dans le Tableau 294.

Tableau 294 – Méthodes de l'objet d'entrée binaire

Nom du type d'objet normalisé: Binary input object (objet d'entrée binaire)		
Identificateur du type d'objet normalisé: 97		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Spécifique à une mise en œuvre	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.19.7.5.4 Alertes

Une sortie analogique peut rapporter les alertes montrées dans le Tableau 295. Si une alerte est prise en charge, un attribut de descripteur d'alerte correspondant doit être ajouté à l'objet d'entrée binaire pour décrire les caractéristiques de l'alerte.

Tableau 295 – Alertes d'entrée binaire

Nom(s) du type d'objet normalisé: Binary input object (objet d'entrée binaire)						
Identificateur du type d'objet normalisé: 97						
Description de l'alerte: alertes d'entrée binaire						
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type(s) d'alerte (Enumerated: en fonction de la catégorie d'alertes)**		**Priorité d'alerte**	**Données associées: type et taille**	**Description des données associées incluses à l'alerte**
Alarme	Processus	1	DiscreteAlarm	Toute	Type: Boolean	Process value
Alarme	Processus	0	OutOfService	Toute	Type: Boolean	Process value

12.19.7.6 Binary output user object (objet utilisateur de sortie binaire)

12.19.7.6.1 Généralités

Un objet normalisé utilisateur de sortie binaire représente une encapsulation d'une seule sortie binaire. Si plusieurs sorties binaires sont représentées par un appareil, il convient que plusieurs objets utilisateur de sorties binaires existent pour les représenter. Les attributs spécifiques à un type d'objet relatifs à cet objet incluent:

- commanded output value: valeur binaire et statut;
- mode: un attribut structuré représentant un mode cible, un mode réel, un mode autorisé, et un mode normal;
- provider of OP value: indique la source de la valeur OP;
- Readback value: valeur binaire et statut; et
- corresponding concentrator object: spécifie le concentrateur associé pour éditer la valeur Readback_B.

12.19.7.6.2 Attributs d'objet

Un objet de sortie binaire a les attributs définis dans le Tableau 296.

Tableau 296 – Attributs de sortie binaire

Nom du type d'objet normalisé: Binary output object (objet de sortie binaire)				
Identificateur du type d'objet normalisé: 96				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur-clé d'objet	Identificateur unique pour l'objet	Type: Unsigned16 Classification: Constant Plage valide: > 0	N/A
Réservée pour un usage futur	0	-	-	-
OP_B	1	Variable de mesure discrète	Type: Process control value and status for discrete value structure Classification: Dynamic Accessibilité: Lecture/écriture Valeur par défaut: 0 Etat: Inconnu; Sous-état: Inconnu; Condition limite: Non limité Plage valide: Voir la définition de la structure process control value and status for discrete value	Il s'agit de l'attribut normalisé qui est l'attribut de destination pour une publication issue d'un autre objet
Mode	2	Mode	Type: Process control mode Classification: Static Accessibilité: Lecture seule pour le mode réel; le mode cible, le mode autorisé et le mode normal ont tous un accès en lecture/écriture Valeur par défaut: La valeur du mode réel indique OOS Plage valide: Voir la définition du type de structure Process control mode	Valeurs de mode réel, de mode cible, de mode autorisé et de mode normal
Réservée pour un usage futur	3	-	-	-
Readback_B	4	Valeur Readback – la position réelle de l'actionneur	Type: Process control value and status for discrete value Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: 0; Etat: Inconnu; Sous-état: Inconnu; Condition limite: Non limité Plage valide: Voir la définition de la structure process control value and status for analog value	Valeur de processus analogique et statut pour la valeur en question. Il s'agit de l'attribut normalisé qui est édité à partir de cet objet. Si cet objet est étendu et, de ce fait, un autre attribut a besoin d'être édité, un/des objet(s) concentrateur(s) représente(nt) la/les publication(s) résultante(s).
Réservé pour usage futur par la présente norme	5..25	-	-	*N* octets de contenu présentement indéfini

12.19.7.6.3 Méthodes d'objets normalisés

Un objet de sortie binaire a les méthodes définies dans le Tableau 297.

Tableau 297 – Méthodes de l'objet de sortie binaire

Nom du type d'objet normalisé: Binary output object (objet de sortie binaire)		
Identificateur du type d'objet normalisé: 96		
Nom de la méthode	**ID de la méthode**	**Description de la méthode**
Null	0	Réservé par la présente norme pour usage futur
Réservé pour usage futur par la présente norme	0..127	Ces identificateurs de méthode sont réservés pour usage futur par la présente norme
Implementation-specific use	128..255	Ces identificateurs de méthode sont disponibles pour une utilisation spécifique à une mise en œuvre

12.19.7.6.4 Alertes

Une sortie binaire peut rapporter les alertes montrées dans le Tableau 298. Si une alerte est prise en charge, un attribut de descripteur d'alerte correspondant doit être ajouté à l'objet de sortie binaire pour décrire les caractéristiques de l'alerte.

Tableau 298 – Alertes de sortie binaire

Nom(s) du type d'objet normalisé: Binary output object (objet de sortie binaire)						
Identificateur du type d'objet normalisé: 96						
Description de l'alerte: alertes de sortie binaire						
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type(s) d'alerte (Enumerated: en fonction de la catégorie d'alertes)**		**Priorité d'alerte**	**Données associées: type et taille**	**Description des données associées incluses à l'alerte**
Alarme	Processus	1	DiscreteAlarm	Toute	Type: Boolean	Process value
Alarme	Processus	0	OutOfService	Toute	Type: Boolean	Process value

12.19.8 Profil des industries d'automation d'usine

12.19.8.1 Généralités

Des objets normalisés complémentaires pour prendre en charge les besoins de l'automation d'usine peuvent être ajoutés dans de futures versions de la présente norme. Une idée plus détaillée, spécifique à l'automation d'usine, est accordée à une version ultérieure de l'activité de normalisation de la présente norme. Les exemples des objets qui peuvent être définis pour satisfaire aux besoins de l'automation d'usine peuvent inclure:

a) binary input user object (un contact, par exemple);

b) binary output user object (une bobine, par exemple);

c) analog input user object;

d) analog output user object;

e) register input user object (par exemple, pour établir un mapping de 16 bits d'informations à deux états souvent trouvées dans les registres d'entrée de PLC);

f) register output user object, (par exemple, pour établir un mapping de 16 bits d'informations à deux états souvent trouvées dans les registres de sortie de PLC);

g) multi-state input user object (par exemple, pour établir un mapping de 8 bits d'informations d'état pour une soupape avec des états énumérés tels que s'ouvrant, ouverte, se fermant, fermée ou pour établir un mapping d'un moteur unidirectionnel avec des états tels que éteint, démarrant, en marche, s'arrêtant); et

h) multi-state output user object (par exemple, pour établir un mapping de 8 bits d'informations de sortie d'état pour un appareil de sortie avec des états énumérés).

Des alertes normalisées pour ces objets peuvent aussi être définies.

12.19.8.2 Objets spécifiques à un fabricant

Les fournisseurs peuvent aussi définir des objets personnalisés spécifiques à un fournisseur ou spécifiques à un appareil. Un exemple d'un objet spécifique à un fournisseur pour les systèmes de processus est un objet d'affichage équipé dans lequel une chaîne peut être stockée pour être montrée à une personne à proximité de l'appareil.

12.20 Structures de données normalisées de l'industrie de contrôle de processus

12.20.1 Généralités

Les structures de données normalisées utilisées dans l'industrie de contrôle de processus doivent être les structures de données acheminées par le protocole défini par la présente norme. Les structures de données normalisées indépendantes vis-à-vis de toute industrie et les structures de données dans l'industrie de contrôle de processus sont toutes les deux résumées en Annexe L.

NOTE Les définitions de structures de données spécifiques à un fournisseur ne sont pas prises en charge.

12.20.2 Statut pour des informations analogiques

Le statut pour des informations analogiques est un octet de format fixe condensé contenant les éléments montrés dans le Tableau 299.

Tableau 299 – Octet Status

<table>
<tr><th colspan="2">Bit 7 (MSB)</th><th>Bit 6</th><th>Bit 5</th><th>Bit 4</th><th>Bit 3</th><th>Bit 2</th><th>Bit 1</th><th>Bit 0 (LSB)</th></tr>
<tr><td colspan="2">Qualité</td><td></td><td><réservé></td><td colspan="3">Sous-état dépendant de la qualité</td><td colspan="2">Condition limite</td></tr>
<tr><td colspan="2">0 = bad
(il convient de ne pas utiliser la valeur)</td><td></td><td rowspan="4">Ce bit doit toujours être mis à zéro</td><td colspan="3">Valeurs nommées lorsque la qualité=bad:
0: non spécifique;
1: erreur de configuration;
2: non connecté;
3: défaillance d'appareil;
4: défaillance de capteur;
5: pas de communication avec lastUsableValue;
6: pas de communication sans lastUsableValue;
7: hors service (la valeur n'est pas calculée)</td><td colspan="2" rowspan="4">Valeurs nommées:
0: non limité;
1: limite basse;
2: limite haute;
3: constant (à la fois limite haute et limite basse)</td></tr>
<tr><td colspan="2">1 = uncertain
(valeur d'une qualité inférieure à la normale)</td><td></td><td colspan="3">Valeurs nommées lorsque la qualité=uncertain:
0: non spécifique;
1: dernière valeur utilisable;
2: entrée substituée ou manuelle;
3: valeur initiale;
4: conversion de capteur inexacte;
5: limites de plage dépassées;
6: en dessous de la normale;
7: réservée</td></tr>
<tr><td colspan="2">2 = good
(la qualité de la valeur est bonne, mais une condition d'alarme peut exister)</td><td></td><td colspan="3">Valeurs nommées lorsque la qualité=good:
0: il n'existe pas de condition spéciale;
1..7: réservées</td></tr>
<tr><td colspan="2">3 = reserved</td><td></td><td colspan="3">Toutes les valeurs sont réservées.
Au sein de la présente norme, ils doivent toujours être mis à zéro</td></tr>
<tr><td colspan="9">NOTE Les définitions pour l'octet de statut sont un sous-ensemble de celles définies par la HART Communication Foundation, la Fieldbus Foundation, et l'OPC Foundation.</td></tr>
</table>

12.20.3 Valeur et statut pour les informations analogiques

Sachant que le statut n'indique pas une substitution, les écritures déclenchées par un réseau en utilisant ces structures de types de données analogiques ne sont pas autorisées par la présente norme.

La structure des informations analogiques est montrée dans le Tableau 300.

Tableau 300 – Type de données: Valeur de contrôle de processus et statut pour la valeur analogique

Nom du type de données normalisé: Valeur de contrôle de processus et statut pour la valeur analogique		
Code du type de données normalisé: 65		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Status	1	Type: BitString8 Classification: Dynamic Ensemble de valeurs valides: Voir Tableau 299
Value	2	Type: Float32 Classification: Dynamic

12.20.4 Valeur et statut pour les informations binaires

Sachant que le statut n'indique pas une substitution, les écritures déclenchées par un réseau dans ces structures de types de données numériques ne sont pas autorisées.

La structure des informations numériques est montrée dans le Tableau 301.

Tableau 301 – Type de données: Valeur de contrôle de processus et statut pour la valeur binaire

Nom du type de données normalisé: Valeur de contrôle de processus et statut pour la valeur binaire		
Code du type de données normalisé: 66		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Status	1	Type: BitString8 Accessibilité: Peut varier selon l'utilisation Ensemble de valeurs valides: Voir Tableau 299
Valeur	2	Type: Boolean

12.20.5 Mode contrôle de processus

Les éléments dans le "process control mode" sont montrés dans le Tableau 302.

Tableau 302 – Type de données: Mode contrôle de processus

Nom du type de données normalisé: Mode contrôle de processus		
Code du type de données normalisé: 69		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Cible	1	Type: BitString8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: OOS Ensemble de valeurs valides: Voir Tableau 303
Actual	2	Type: BitString8 Classification: Dynamic Accessibilité: Lecture seule Valeur par défaut: OOS Ensemble de valeurs valides: Voir Tableau 303
Autorisé	3	Type: BitString8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: OOS Ensemble de valeurs valides: Voir Tableau 303
Valeur normale	4	Type: BitString8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: OOS Ensemble de valeurs valides: Voir Tableau 303

La valeur de chaque élément de la structure mode est représentée par un bitstring contenant les bits dans le Tableau 303, ou les bits <réservé> doivent être mis à zéro (0).

Tableau 303 – Type de données: Bitstring de mode contrôle de processus

Bit 7	Bit 6	Bit 5	Bit 4	Bit 3	Bit 2	Bit 1	Bit 0
<réservé>	<réservé>	<réservé>	AUTO	MAN	<réservé>	<réservé>	OOS

A savoir:

- OOS seul est égal à 0x01, avec la valeur décimale équivalente de 1.
- MAN seul est égal à 0x08, avec la valeur décimale équivalente de 8.
- AUTO seul est égal à 0x10, avec la valeur décimale équivalente de 16.

12.20.6 Mise à l'échelle

Les éléments dans le "process control scaling" (mise à l'échelle de contrôle de processus sont montrés dans le Tableau 304.

Tableau 304 – Type de données: Mise à l'échelle du contrôle de processus

Nom du type de données normalisé: Mise à l'échelle du contrôle de processus		
Code du type de données normalisé: 68		
Nom de l'élément	**Identificateur de l'élément**	**Type scalaire de l'élément**
Unités d'étude à 100 % (la plage supérieure du paramètre d'objet associé)	1	Type: Float32 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0
Unités d'étude à 0 % (la plage inférieure du paramètre d'objet associé)	2	Type: Float32 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0
Index des unités pour les unités SI et les unités traditionnelles (non SI) [a] – plage 1000..1999 – autres codes réservés	3	Type: Unsigned16 Classification: Static Accessibilité: Lecture/écriture
Emplacement de la virgule décimale / du signe décimal (représente le nombre de chiffres à la droite de la virgule décimale/du signe décimal, à savoir, la signification de la partie fractionnaire de la valeur associée)	4	Type: Unsigned8 Classification: Static Accessibilité: Lecture/écriture Valeur par défaut: 0
[a] Telles que spécifiées dans *Standard Units Codes Table*, édité dans *Handbook of Measurement Equations and Tables* de l'ISA, 2nde Edition, ISBN 978 1 55617 946 4. Cet index est également édité par la Fieldbus Foundation sous TN-016:2007, Table 3.1.		

12.21 Tables complémentaires

12.21.1 Objets normalisés de profils de contrôle de processus

Le Tableau 305 énumère les objets normalisés de profils de contrôle de processus.

Tableau 305 – Objets normalisés de contrôle de processus

Type d'objet	Défini par	Identificateur du type d'objet normalisé
Analog input	12.19.7.3	99
Analog output	12.19.7.4	98
Binary input	12.19.7.5	97
Binary output	12.19.7.6	96

12.21.2 Services

Le Tableau 306 donne une liste de services.

Tableau 306 – Services

Service	Utilisation
Read	Lire la valeur d'un ou plusieurs attributs dans un ou plusieurs objets d'un UAP
Write	Ecrire la valeur dans un ou plusieurs attributs d'un ou plusieurs objets d'un UAP
Execute	Exécuter un ensemble de fonctions sur des instances d'objets d'un UAP
Publish	Editer périodiquement des données vers les abonnés
AlertReport	Rapporter une ou plusieurs conditions d'alerte
AlertAcknowledge	Acquitter un AlertReport
Tunnel	Passer la charge utile

12.22 Codage

12.22.1 Généralités

Les conditions pour coder des APDU sans fil dans la présente norme incluent les considérations suivantes:

- Certains messages se produisent souvent, comme les publications périodiques.
- Il convient que les messages soient courts, pour préserver l'énergie des batteries.
- Il convient d'avoir une sélection minimale de types de services d'ASL.

La taille maximale d'une APDU (qui est une TSDU) est déterminée en soustrayant (la taille des informations de TL s'ajoute à la TSDU pour former la TPDU) de (Assigned_Max_NSDU_Size), où Assigned_Max_NSDU_Size est un paramètre de sortie de la méthode utilisée pour établir un contrat de communication. A savoir:

maxAPDUSize = Assigned_Max_NSDU_Size – sizeOF(TLInfoAddedtoAPDU)

Voir 6.3.11.2.5 pour plus de détails relatifs à l'établissement de contrat de communication.

Le codage d'ASL doit assurer que la taille d'APDU maximale n'est pas dépassée.

NOTE L'IETF RFC 2348 fournit des recommandations relatives à la taille maximale des NPDU.

12.22.2 Règles de codage pour unités de données de protocole d'application

12.22.2.1 Généralités

Les règles de codage définies en 12.22.2 représentent le bit 0 comme étant le bit de poids faible (LSB) dans la valeur représentée.

Toutes les APDU contiennent un en-tête d'AL et un contenu d'APDU spécifique à un type de service. Le Tableau 307 indique la construction de codage générale d'une APDU.

Tableau 307 – Format de messagerie d'application

Peut être de 1 octet, 2 octets, 3 octets, ou 5 octets (voir 12.22.2.3)	***N* octets**
En-tête d'ASDU (assure le routage vers les objets corrects; fournit l'identification de type de service)	Contenu spécifique à un service

12.22.2.2 Concaténation

Les APDU peuvent être concaténées ensemble, et la concaténation d'APDU individuelles peut être donnée à la TL comme étant une seule TSDU. La taille de cette TSDU ne doit pas dépasser la taille d'APDU maximale pour des communications relativement au contrat de communication correspondant entre les applications expéditrice et réceptrice.

Le Tableau 308 décrit le format d'APDU concaténées en une seule TSDU.

Tableau 308 – APDU concaténées en une seule TSDU

APDU_1	**...**	**APDU_n**

La concaténation peut être utilisée pour s'assurer que lorsque l'une des APDU concaténées est reçue, toutes ont été reçues, ce qui fournit une base pour les actions multicomposants qui sont atomiques dans le cadre des communications inter-appareils.

NOTE La façon dont l'ASL détermine quand et quoi concaténer relève d'une initiative locale.

12.22.2.3 En-tête d'AL

L'en-tête d'AL prend en charge quatre modes d'adressage d'identificateur d'objet qui déterminent la construction d'en-tête au-delà du premier octet. Les modes d'adressage d'identificateur d'objet sont:

- mode d'adressage d'identificateur d'objet à quatre bits;
- mode d'adressage d'identificateur d'objet à huit bits (1 octet);
- mode d'adressage d'identificateur d'objet à seize bits (2 octets); et
- mode d'adressage inféré, qui peut être utilisé seulement dans la seconde APDU et les APDU suivantes d'une TSDU qui contient plusieurs APDU concaténées.

L'identification de l'UAP contenant l'objet est une fonction de la TL.

Le mode d'adressage d'identificateur d'objet en utilisation pour l'interprétation des APDU est indiqué dans des bits 5 et 6 du premier octet de l'en-tête d'APDU. Le Tableau 309 représente le codage de ce premier octet d'en-tête d'APDU.

Tableau 309 – Adressage d'objet

Octets	Bits							
	7	6	5	4	3	2	1	0
1	Type de primitive de service (.req = 0 .resp = 1)	Mode d'adressage d'identificateur d'objet Valeurs nommées: 00: mode à 4 bits 01: mode à 8 bits 10: mode à 16 bits 11: mode inféré		Type de service d'ASL				

12.22.2.4 Code d'identificateur d'objet

12.22.2.4.1 Généralités

Dans toutes les constructions d'en-tête, l'identificateur d'objet source représente l'identificateur d'objet dans l'application qui initie la primitive de service d'ASL (c'est-à-dire, l'initiateur d'une primitive .request ou d'une primitive .response), et l'identificateur d'objet de destination représente l'identificateur d'objet dans l'application qui reçoit la primitive de service d'ASL (c'est-à-dire, le destinataire d'une primitive .indication ou d'une primitive .confirmation).

12.22.2.4.2 Mode d'adressage d'identificateur d'objet à quatre bits

Le mode d'adressage d'identificateur d'objet à quatre bits indique que l'identificateur d'objet source et l'identificateur d'objet de destination peuvent être exprimés chacun sous la forme d'un nombre entier non signé de 4 bits. Ce mode d'adressage permet la prise en charge du compactage d'en-tête optimale pour les processus d'application avec un petit nombre d'objets. Ce mode est décrit en Tableau 310.

Tableau 310 – Construction d'en-tête d'APDU de mode d'adressage à quatre bits

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Type de primitive de service	0	0	Type de service d'ASL				
1	Source object identifier				Destination object identifier			

12.22.2.4.3 Mode d'adressage d'identificateur d'objet à huit bits

Le mode d'adressage d'identificateur d'objet à huit bits indique que l'identificateur d'objet source et l'identificateur d'objet de destination peuvent être exprimés chacun sous la forme d'un nombre entier non signé de 8 bits, et en outre qu'au moins l'un des identificateurs d'objet ne peut pas être exprimé sous la forme d'un nombre entier non signé de 4 bits. Ce mode est décrit en Tableau 311.

Tableau 311 – Construction d'en-tête d'APDU de mode d'adressage à huit bits

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Type de primitive de service	0	1	Type de service d'ASL				
1	Source object identifier							
1	Destination object identifier							

12.22.2.4.4 Mode d'adressage d'identificateur d'objet à seize bits

Le mode d'adressage d'identificateur d'objet à seize bits indique que l'identificateur d'objet source et l'identificateur d'objet de destination peuvent être exprimés chacun sous la forme d'un nombre entier non signé de 16 bits et en outre qu'au moins l'un des identificateurs d'objet ne peut pas être exprimé sous la forme d'un nombre entier non signé de 8 bits. Ce mode est décrit en Tableau 312.

Tableau 312 – Construction d'en-tête d'APDU de mode d'adressage à seize bits

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Type de primitive de service	1	0	Type de service d'ASL				
2	Source object identifier							
2	Destination object identifier							

12.22.2.4.5 Mode d'adressage d'identificateur d'objet inféré pour des concaténations optimisées

Le mode d'adressage d'identificateur d'objet inféré est une technique d'optimisation utilisée seulement au sein d'une APDU concaténée. L'intention de cette technique est de sauvegarder des octets émis en éliminant les identificateurs redondants de source et d'objet, qui peuvent être déterminés à partir de l'APDU la plus récemment analysée contenue au sein de la même concaténation d'APDU.

L'adressage d'objet inféré ne doit pas être indiqué dans la première APDU d'une concaténation.

NOTE Toute APDU indiquant le mode d'adressage d'objet inféré dans la première APDU rencontrée dans l'analyse d'ASL est considérée comme étant une APDU mal formée.

Un exemple est inclus dans le Tableau 313.

Tableau 313 – Exemple de cas d'utilisation d'adressage inféré

APDU_1	APDU_2	APDU_3	APDU_4	APDU_5
00 mode d'adressage d'identificateur d'objet	11 mode d'adressage d'identificateur d'objet (indique l'utilisation des OID source et destination issus de l'APDU_1)	11 mode d'adressage d'identificateur d'objet (indique l'utilisation des OID source et destination issus de l'APDU_2, qui utilise les OID source et destination issus de l'APDU_1)	01 mode d'adressage d'identificateur d'objet	11 mode d'adressage d'identificateur d'objet (indique l'utilisation des OID source et destination issus de l'APDU_4)
APDU_1 inclut: - 00 mode d'adressage; - type de service; - identificateur d'objet source de 4 bits; - identificateur d'objet de destination de 4 bits; charge utile spécifique à un service	APDU_2 inclut: - 11 mode d'adressage; - type de service; - charge utile spécifique à un service	APDU_3 inclut: - 11 mode d'adressage; - type de service; - charge utile spécifique à un service	APDU_4 inclut: - 01 mode d'adressage; - type de service; - identificateur d'objet source de 8 bits; - identificateur d'objet de destination de 8 bits; charge utile spécifique à un service	APDU_5 inclut: - 11 mode d'adressage; - type de service; - charge utile spécifique à un service

Le Tableau 314 décrit la construction de l'en-tête d'APDU en mode d'adressage inféré.

Tableau 314 – Construction d'en-tête d'APDU de mode d'adressage inféré

Nombre d'octets	Bits							
	7	6	5	4	3	2	1	0
1	Type de primitive de service	1	1	Type de service d'ASL				

12.22.2.5 Codage d'attribut d'objet

12.22.2.5.1 Généralités

Le codage d'attribut d'objet est déterminé par un format d'identificateur d'attribut. Le format peut indiquer:

- Six bits, non indexé: L'attribut s'inscrit dans un entier Unsigned6 et n'est pas indexé.
- Six bits, à un seul indice: L'attribut s'inscrit dans un entier Unsigned6 et exige un seul indice. L'indice de l'attribut est extensible, comme indiqué par le premier bit de l'indice. Si le premier bit de l'indice est 0, l'indice a une taille de 7 bits. Si le premier bit de l'indice est 1, l'indice a une taille de 15 bits.
- Six bits, à deux indices: L'attribut s'inscrit dans un entier Unsigned6 et exige deux indices. Les indices d'attribut sont extensibles individuellement; à savoir, le premier indice peut avoir une taille de 7 bits ou de 15 bits et le second indice peut aussi avoir une taille soit de 7 bits, soit de 15 bits. La taille de l'indice est déterminée par le premier bit de l'indice. Si le premier bit de l'indice est 0, l'indice a une taille de 7 bits. Si le premier bit de l'indice est 1, l'indice a une taille de 15 bits.
- Douze bits, non indexé: L'attribut ne s'inscrit pas dans un entier Unsigned12. L'attribut n'est pas indexé.
- Douze bits, à un seul indice: L'attribut s'inscrit dans un entier Unsigned12 et exige un seul indice. L'indice de l'attribut est extensible, comme indiqué par le premier bit de l'indice. Si le premier bit de l'indice est 0, l'indice a une taille de 7 bits. Si le premier bit de l'indice est 1, l'indice a une taille de 15 bits.
- Douze bits, à deux indices: L'attribut s'inscrit dans un entier Unsigned12 et exige deux indices. Les indices d'attribut sont extensibles individuellement; à savoir, le premier indice peut avoir une taille de 7 bits ou de 15 bits et le second indice peut aussi avoir une taille soit de 7 bits, soit de 15 bits. La taille de l'indice est déterminée par le premier bit de l'indice. Si le premier bit de l'indice est 0, l'indice a une taille de 7 bits. Si le premier bit de l'indice est 1, l'indice a une taille de 15 bits.

NOTE Se référer à 12.23.1.3 pour les définitions de Unsigned6 et de Unsigned12.

12.22.2.5.2 Identificateur d'attribut de 6 bits, non indexé

Le Tableau 315 indique le codage pour un identificateur d'attribut de 6 bits qui n'est pas un attribut indexé ou structuré.

Tableau 315 – Identificateur d'attribut de 6 bits, non indexé

Nombre d'octets	Nombre d'octets							
	7	6	5	4	3	2	1	0
1	Forme courte d'attribut (valeur = 00 binaire)		Identificateur de l'attribut					

12.22.2.5.3 Formes d'identificateur d'attribut de 6 bits, à un seul indice

Le Tableau 316 et le Tableau 317 indiquent le codage pour un identificateur d'attribut de 6 bits qui peut être accessible en utilisant un seul indice.

Tableau 316 – Identificateur d'attribut de 6 bits, à un seul indice, avec un indice de 7 bits

Nombre d'octets	Bits

12.22.2.12 Publish

Le Tableau 347 fournit les règles de codage pour un service Publish natif.

Lorsqu'il est utilisé conjointement avec un objet concentrateur, le champ Data dans la charge utile comprend les données entières communiquées, qui sont une séquence configurée des variables de contrôle de processus. Les variables de contrôle de processus incluent à la fois les informations de statut et les valeurs de processus. La structure des données est indiquée par la version du contenu d'édition. Le numéro de séquence se situe dans le domaine d'application d'un objet concentrateur particulier.

	7	6	5	4	3	2	1	0
S	SEQUENCE OF APDUs							

12.22.3 Codage des données d'application

12.22.3.1 Généralités

Le codage des éléments de données d'application uniques est toujours primitif. Dans les tableaux de 12.22.3, l'octet 1 représente l'octet de poids fort, le bit 7 représente le bit de poids fort au sein d'un octet, et le bit 0 représente le bit de poids faible au sein d'un octet.

La sémantique des données d'utilisateur est connue par:

- accord préalable (contenu de la charge utile de tunnel, par exemple);
- position dans l'APDU avec une taille de champs fixe pour le contenu; ou
- champs existants dans l'APDU.

Dans ces situations, aucune information de décodage complémentaire n'est ajoutée à l'APDU.

Les règles de codage pour les données d'application sont fournies dans le Tableau 350 et dans le Tableau 351. Si la taille est fixe, comme dans le cas du type de données OctetStringN pour une valeur fixe donnée de N, alors les informations de taille sont implicites dans la déclaration, elles ne sont pas acheminées explicitement dans l'APDU, comme indiqué dans le Tableau 350.

Tableau 350 – Règle de codage générale pour les données d'application de taille invariable

Data (taille fixe)

En contraste, si la taille peut changer, comme dans le cas du type de données (et pas OctetStringN pour n'importe quel N), la taille du champ réel est explicitement couverte dans l'APDU. Cela est souvent fait en préfixant les données avec la taille, comme illustré au Tableau 351. Dans d'autres cas, le champ size est trouvé directement dans ou est calculable depuis un champ trié précédemment dans l'APDU.

Tableau 351 – Règles de codage pour les données d'application de taille variable de 0..255 octets

Unsigned8 N, taille des données (en octets)	Data (taille N octets)

Les paragraphes 12.22.3.2 à 12.22.3.8 définissent le codage des données pour les types de données normalisés.

12.22.3.2 Valeurs booléennes

NOTE Le nom de ce type a été attribué en l'honneur du logicien George Boole.

12.22.3.2.1 Codage de valeurs booléennes

Les booléens sont codés sous la forme de valeurs égales à zéro/différentes de zéro dans un champ 1 bit pour les structures de données condensées ou 8 bits pour les structures de données relativement non condensées.

12.22.3.2.2 Boolean8

Le codage Boolean8, utilisé dans des structures de données relativement non condensées, est:

- Data type: Boolean
- Taille: 1 octet

Une valeur égale à zéro de la représentation Unsigned8 sous-jacente code la valeur false; une valeur non égale à zéro code la valeur true.

12.22.3.2.3 Boolean1

Le codage Boolean1, utilisé dans des structures de données condensées, est:

- Data type: Boolean
- Taille: 1 bit

Une valeur égale à zéro de la représentation Unsigned1 sous-jacente code la valeur false; une valeur non égale à zéro égale à un (1) code la valeur true.

12.22.3.3 Valeurs entières

12.22.3.3.1 Codage de valeurs entières signées

12.22.3.3.1.1 Généralités

Les entiers signés sont codés sous forme de nombre de complément à 2. Dans la représentation de complément à 2, les nombres négatifs sont représentés par le complément à 2 de la valeur absolue. Dans ce système, zéro a une seule représentation.

Dans la représentation de complément à 2, les nombres positifs sont représentés comme un binaire simple, et les nombres en complément à 2 négatifs sont représentés comme le nombre binaire qui, lorsqu'il est ajouté à un nombre positif de même grandeur, est égal à zéro.

Le bit de poids fort (à savoir, le bit 7 pour une valeur Integer8, le bit 15 pour un Integer16) indique le signe du nombre entier, et s'appelle donc le bit de signe. Si le bit de signe est zéro, le nombre représenté est supérieur ou égal à zéro (à savoir zéro ou un nombre positif). Si le bit de signe est un, le nombre représenté est inférieur à zéro (à savoir un nombre négatif).

NOTE Pour calculer le complément à 2 d'un nombre entier, on inverse l'équivalent binaire du nombre en changeant tous les uns en zéros et tous les zéros en uns (également appelé complément à 1) et ensuite on ajoute un.

Exemple: Formation du complément à 2 de la valeur 17.

0x 0001 000 1 (17 en binaire)

Pour former le complément à 2:

En premier lieu: NOT (0x 0001 000 1) = 0x 1110 111 0, où l'opération NOT provoque l'inversion des bits.

Ensuite, on ajoute 1: (0x 1110 111 0) + (0x 0000 0001) = 0x 1110 1111 (complément à deux = -17).

12.22.3.3.1.2 Integer8

Le codage d'un Integer8 est:

- Data type: Integer8
- Plage: $-2^7 \leq k \leq 2^7 -1$ (c'est-à-dire, $-128 \leq k \leq 127$)
- Taille: 1 octet

12.22.3.3.1.3 Integer16

Le codage d'un Integer16 est:

- Data type: Integer16
- Plage: $-2^{15} \leq k \leq 2^{15} -1$ (c'est-à-dire, $-32\,768 \leq k \leq 32\,767$)
- Taille: 2 octets

12.22.3.3.1.4 Integer32

Le codage d'un Integer32 est:

- Data type: Integer32
- Plage: $-2^{31} \leq k \leq 2^{31} -1$ (c'est-à-dire, $-2\,147\,483\,648 < k < 2\,147\,483\,647$)
- Taille: 4 octets

12.22.3.3.1.5 IntegerN

Le codage IntegerN, utilisé dans des structures de données condensées, est:

- Data type: IntegerN
- Plage: $-2^{-(N-1)} \leq k \leq 2^{(N-1)}-1$
- Taille: N bits

12.22.3.3.2 Codage de valeurs entières non signées

12.22.3.3.2.1 Unsigned8

Le codage d'un Unsigned8 est:

- Data type: Unsigned8
- Plage: $0 \leq k \leq 2^8 -1$ (c'est-à-dire, $0 \leq k \leq 255$)
- Taille: 1 octet

Le Tableau 352 fournit les règles de codage pour les données Unsigned8.

Tableau 352 – Règles de codage pour Unsigned8

Octet	Bits							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**
1	2^7	2^6	2^5	2^4	2^3	2^2	2^1	2^0

12.22.3.3.2.2 Unsigned16

Le codage d'un Unsigned16 est:

- Data type: Unsigned16
- Plage: $0 \leq k \leq 2^{16}$ -1 (c'est-à-dire, $0 \leq k \leq 65\,535$)
- Taille: 2 octets

Le Tableau 353 fournit les règles de codage pour les données Unsigned16.

Tableau 353 – Règles de codage pour Unsigned16

2	2^7	2^6	2^5	2^4	2^3	2^2	2^1	2^0

12.22.3.3.2.3 Unsigned32

Le codage d'un Unsigned32 est:

- Data type: Unsigned32
- Plage: $0 \leq k \leq 2^{32}$ -1 (c'est-à-dire, $0 \leq k \leq 4\,294\,967\,295$)
- Taille: 4 octets

Le Tableau 354 fournit les règles de codage pour les données Unsigned32.

Tableau 354 – Règles de codage pour Unsigned32

Octet	Bits							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**
1	2^{31}	2^{30}	2^{29}	2^{28}	2^{27}	2^{26}	2^{25}	2^{24}
2	2^{23}	2^{22}	2^{21}	2^{20}	2^{19}	2^{18}	2^{17}	2^{16}
3	2^{15}	2^{14}	2^{13}	2^{12}	2^{11}	2^{10}	2^9	2^8
4	2^7	2^6	2^5	2^4	2^3	2^2	2^1	2^0

12.22.3.3.2.4 Unsigned64

Le codage d'un Unsigned64 est:

- Data type: Unsigned64
- Taille: 8 octets
- Plage: $0 \leq k \leq 2^{64}$ -1 (c'est-à-dire, $0 \leq k \leq 18\,446\,744\,073\,709\,551\,615$)

Le Tableau 355 fournit les règles de codage pour les données Unsigned64.

Tableau 355 – Règles de codage pour Unsigned64

15	2^{15}	2^{14}	2^{13}	2^{12}	2^{11}	2^{10}	2^{9}	2^{8}
16	2^{7}	2^{6}	2^{5}	2^{4}	2^{3}	2^{2}	2^{1}	2^{0}

12.22.3.3.2.6 UnsignedN

Le codage UnsignedN, utilisé dans des structures de données condensées, est:

- Data type: UnsignedN
- Plage: $0 \leq k \leq 2^{N)}$-1
- Taille: N bits

12.22.3.4 Valeurs de virgule flottante

12.22.3.4.1 Codage de valeurs en virgule flottante

La présente norme utilise le codage défini par l'ISO/IEC/IEEE 60559 (basé sur l'IEEE 754) pour les valeurs à virgule flottante normalisées et les NaN. Chaque valeur est représentée par trois champs contigus:

- S, le signe de la valeur en virgule flottante, où 0 et 1 représentent respectivement le positif et le négatif, acheminé dans un champ de 1-bit;
- E, l'exposant de la valeur, en base 2, biaisé de B, acheminé dans un champ de N_E = environ 1/4 du nombre total de bits de la représentation de la valeur à virgule flottante, où la valeur de B est $2^{(N_E-1)}$-1;
- F, la partie fractionnaire de la mantisse de la valeur, également en base 2, acheminée dans les N_F bits restants de la représentation de la valeur.

Quand E n'est pas composé que de bits égaux à zéro ou que de bits égaux à un, la valeur numérique résultante est $(-1)^S \times 2^{(E-B)} \times (1,F)$. Quand E et F sont tous deux égaux à zéro bits, la valeur représentée est un zéro signé.

Quand E ne comporte que des bits un et F que des bits zéro, la valeur représentée est un infini signé. Voir l'ISO/IEC/IEEE 60559 pour plus d'informations sur la représentation, la plage et la précision des nombres réels, y compris le codage du zéro signé, de l'infini signé (débordement), des nombres dénormalisés (soupassement) et des NaN.

12.22.3.4.2 Single-precision float (virgule flottante en simple précision)

Les valeurs en virgule flottante en simple précision sont représentées de façon contiguë comme indiqué dans le Tableau 357, où N_E = 8, B = 127 et N_F = 23. Cela permet à une valeur en virgule flottante en simple précision d'être calculée par l'équation suivante, qui s'applique lorsque E n'est pas des zéros partout ou des uns partout:

$$(-1)^S \times 2^{(E - 127)} \times (1,F)$$

Tableau 357 – Règles de codage pour single-precision float

Octet	Bits							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**
	Signe (S)	Exposant (E)						
1	+/-	2^7	2^6	2^5	2^4	2^3	2^2	2^1
	(E)	Fraction (F)						
2	2^0	2^{-1}	2^{-2}	2^{-3}	2^{-4}	2^{-5}	2^{-6}	2^{-7}
3	2^{-8}	2^{-9}	2^{-10}	2^{-11}	2^{-12}	2^{-13}	2^{-14}	2^{-15}
4	2^{-16}	2^{-17}	2^{-18}	2^{-19}	2^{-20}	2^{-21}	2^{-22}	2^{-23}

12.22.3.5 Double-precision float (virgule flottante en double précision)

Les valeurs en virgule flottante en double précision sont représentées de façon contiguë comme indiqué dans le Tableau 358, où N_E = 11, B = 1 023 et N_F = 52. Cela permet à une valeur en virgule flottante en double précision d'être calculée par l'équation suivante, qui s'applique lorsque E n'est pas des zéros partout ou des uns partout:

$(-1)^S \times 2^{(E - 1\,023)} \times (1,F)$

Tableau 358 – Règles de codage pour double-precision float

Octet	Bits							
	7	**6**	**5**	**4**	**3**	**2**	**1**	**0**

8	2^{-45}	2^{-46}	2^{-47}	2^{-48}	2^{-49}	2^{-50}	2^{-51}	2^{-52}

12.22.3.6 VisibleString

Le codage d'une chaîne visible est:

- Type: VisibleString
- Plage: Voir ISO/IEC 646 et ISO/IEC 2375: Définition de numéro d'enregistrement 2 + ESPACE
- Codage: Codage: Voir l'ISO 646

NOTE Voir l'ISO/IEC 2375 pour plus de détails.

Le Tableau 359 fournit les règles de codage pour les données VisibleString. Si la taille de la chaîne n'est pas déterminable à partir d'autres facteurs, la taille en octets est codée dans un octet qui précède immédiatement la chaîne OctetString, comme spécifié en Tableau 351.

Tableau 359 – Règles de codage pour VisibleString

12.22.3.7 OctetString

Le codage d'une chaîne octet est:

- Type: OctetString
- Codage: Binaire

Le Tableau 360 fournit les règles de codage pour les données OctetString. Si la taille de la chaîne n'est pas déterminable à partir d'autres facteurs, la taille en octets est codée dans un octet qui précède immédiatement la chaîne OctetString, comme spécifié en Tableau 351.

Tableau 360 – Règles de codage pour OctetString

Octet	Bits							
	7	6	5	4	3	2	1	0
1	Premier octet de la chaîne							
…	…							
N	Dernier octet de la chaîne							

12.22.3.8 BitString

Le codage d'une chaîne de bits qui ne fait pas partie d'une structure condensée supérieure est:

- Type: BitString
- Codage: Binaire
- Taille: Seuls les multiples de 8 bits (à savoir: les multiples d'octets) sont pris en charge pour BitString sans faire partie d'une structure condensée supérieure

Le Tableau 361 fournit les règles de codage générales pour les données BitString. Si la taille de la chaîne n'est pas déterminable à partir d'autres facteurs, la taille en octets est codée dans un octet qui précède immédiatement la chaîne BitString, comme spécifié au Tableau 351.

Tableau 361 – Règles de codage pour BitString

Octet	Bits							
	7	6	5	4	3	2	1	0
1	(8 x *N*-1)ème	(8 x *N*-2)ème	(8 x *N*-3)ème	(8 x *N*-4)ème	(8 x *N*-5)ème	(8 x *N*-6)ème	(8 x *N*-7)ème	(8 x *N*-8)ème
	(position du bit dans la chaîne)							
2	(8 x *N*-9)ème	(8 x *N*-10)ème	(8 x *N*-11)ème	(8 x *N*-12)ème	(8 x *N*-13)ème	(8 x *N*-14)ème	(8 x *N*-15)ème	(8 x *N*-16)ème
…								
N	etc.							

12.22.3.9 Clé symétrique (SymmetricKey)

Une clé symétrique est opaque. Dans cette édition de la présente norme, il s'agit d'une clé de 128 bits. En tant que telle, elle est mise en correspondance, sans interprétation, avec un Octet16 qui mesure seize octets.

12.22.4 Types de données relatives au temps

12.22.4.1 Généralités

Le temps est continu et potentiellement représenté avec une précision presque infinie dans une plage presque infinie. Ainsi, toute représentation raisonnable du temps a une résolution finie spécifique (par exemple 1 h, 1 s, 1 ns, 10^{-20} s, etc.) et une plage spécifique, telle que [0..1 j) ou (0..10 000 ans], et toute valeur temporelle doit être représentée par le modulo de ces valeurs.

Dans la présente norme, TAINetworkTime est représenté avec une résolution de 2^{-16} s et une plage de [0..2^{32}) s, modulo 2^{32} s. TAITimeRounded a la même plage mais est arrondi à la seconde la plus proche et a une résolution de 2^{0} s (c'est-à-dire 1 s).

TAITimeDifference est conçu pour représenter la différence entre deux valeurs différentes de TAINetworkTime. Cette différence est également représentée modulo 2^{32} s, de sorte que des valeurs numériques très importantes représentent des différences négatives. L'identification de la partie de la plage de 2^{32} s d'une valeur TAITimeDifference qui est interprétée comme différence positive et de la partie qui est interprétée comme différence négative est déterminée par l'utilisation qui est faite de cette différence.

EXEMPLE Lors de la différenciation de deux valeurs TAINetworkTime au cours du traitement d'un nonce TPDU, la logique indiquée adresse spécifiquement les différences comprises dans une petite plage signée et catégorise toutes les autres différences comme étant "hors plage" sans essayer de les assigner au passé ou au futur relativement éloignés du temps TAI référencé.

12.22.4.2 TAINetworkTime

TAINetworkTime représente le temps du réseau en temps TAI sous la forme d'une valeur binaire à point fixe de six octets avec une résolution of 2^{-16} s modulo 2^{32} s. Ainsi les quatre octets supérieurs représentent le temps TAI actuel en unités de 1 s tandis que les deux octets inférieurs représentent le temps TAI fractionnel en unités de 2^{-16} s.

- Data type: TAINetworkTime

NOTE 1 Cette représentation s'applique aussi à TAITimeDifference qui est une différence modulo.

- Plage valide exprimée en tant que valeur binaire à point fixe non signée
  - dont le composant intégral a la plage 0..2^{32}-1 s (modulo 2^{32} s);
  - et dont le composant fractionnel a une résolution de 2^{-16} s.

NOTE 2 Etant donné que toutes les valeurs possibles se produisent de façon répétée (cycliquement) dans une représentation modulo telle que TAINetworkTime, il n'est pas possible de coder des valeurs à signification spéciale dans cette plage comme cela peut être fait avec les extrémités d'une plage linéaire.

Tableau 362 montre la représentation de TAINetworkTime et de TAITimeDifference lors de l'interprétation comme différence modulo.

Tableau 362 – Règles de codage pour TAINetworkTime et TAITimeDifference lors de l'interprétation comme différence modulo

Octet	Bits								Interprétation
	7	6	5	4	3	2	1	0	
1	2^{31}	2^{30}	2^{29}	2^{28}	2^{27}	2^{26}	2^{25}	2^{24}	Partie intégrale du temps TAI avec une granularité de 1 s
2	2^{23}	2^{22}	2^{21}	2^{20}	2^{19}	2^{18}	2^{17}	2^{16}	
3	2^{15}	2^{14}	2^{13}	2^{12}	2^{11}	2^{10}	2^{9}	2^{8}	
4	2^{7}	2^{6}	2^{5}	2^{4}	2^{3}	2^{2}	2^{1}	2^{0}	
5	2^{-1}	2^{-2}	2^{-3}	2^{-4}	2^{-5}	2^{-6}	2^{-7}	2^{-8}	Partie fractionnelle du temps TAI avec une granularité de 2^{-16} s
6	2^{-9}	2^{-10}	2^{-11}	2^{-12}	2^{-13}	2^{-14}	2^{-15}	2^{-16}	

12.22.4.3 TAITimeDifference

Le codage pour TAITimeDifference est identique à celui de TAINetworkTime. Cependant, puisqu'il s'agit d'une valeur modulo, elle a des interprétations potentielles en tant que valeurs signées. Ces interprétations sont:

- Data type: TAITimeDifference
- Plage valide exprimée en tant que valeur binaire à point fixe non signée à 2 compléments
  - dont le composant intégral a la plage -2^{32}..2^{32}-1 s;

– dont le composant fractionnel a une résolution de 2^{-16} s; et

– qui est considérée comme "s'enroulant" des valeurs positives aux valeurs négatives à une certaine valeur Unsigned32 pour le composant intégral qui dépend du scénario d'utilisation spécifique.

12.22.4.4 TAITimeRounded

TAITimeRounded représente le temps TAI en secondes intégrales modulo la période de la représentation, arrondi à la seconde la plus proche. Son codage est:

- Data type: TAITimeRounded
- Plage valide: 0..2^{32}-1 s (modulo 2^{32} s)

Le Tableau 363 montre la représentation de TAITimeRounded.

Tableau 363 – Règles de codage pour TAITimeRounded

Octet	Bits								
	7	6	5	4	3	2	1	0	Interprétation
1	2^{31}	2^{30}	2^{29}	2^{28}	2^{27}	2^{26}	2^{25}	2^{24}	Temps TAI avec une granularité de 1 s
2	2^{23}	2^{22}	2^{21}	2^{20}	2^{19}	2^{18}	2^{17}	2^{16}	
3	2^{15}	2^{14}	2^{13}	2^{12}	2^{11}	2^{10}	2^{9}	2^{8}	
4	2^{7}	2^{6}	2^{5}	2^{4}	2^{3}	2^{2}	2^{1}	2^{0}	

12.22.4.5 Structures de données normalisées

Les structures de données normalisées sont codées en concaténant les valeurs codées pour les éléments de la structure dans l'ordre allant de l'élément de plus petit numéro à l'élément de plus grand numéro, en commençant à l'octet 1 du résultat codé.

12.22.4.6 Null

Le type de données null a une taille de zéro (0) octet. La valeur null est souvent utilisée pour la cohérence sémantique, où elle représente le potentiel pour un contenu lorsqu'aucun contenu n'a été identifié.

12.22.4.7 Packed

Le type de données condensé indique qu'un ou plusieurs éléments des types de données normalisés ont été concaténés ensemble sans trous pour maintenir l'alignement des octets. De plus, les éléments condensés de type BitString et BooleanArray peuvent ne pas occuper un nombre entier d'octets. La structure et la composition des données packed est implicitement connue par les correspondants.

NOTE Les matrices BooleanArray sont généralement représentées sous la forme de chaînes BitString condensées.

12.22.4.8 Données structurées

12.22.4.8.1 SEQUENCE

SEQUENCE est utilisé pour indiquer des données structurées de(s) même(s) ou différent(s) type(s) de données normalisé(s). Cela s'apparente à une construction enregistrement.

La présente norme ne prend pas en charge les séquences qui contiennent les membres facultativement présents. Si un tel besoin est identifié, une séquence (structure) séparée doit être définie pour chaque séquence de membres exigée de cette nature. Les correspondants

doivent avoir une connaissance préalable de la structure de la séquence; donc, aucun mécanisme n'est fourni pour acheminer explicitement sa structure.

12.22.4.8.2 SEQUENCE OF

Pour des données, SEQUENCE OF sert à indiquer une construction ARRAY (matrice). Le contenu de la matrice peut être acheminé dans son intégralité, ou un élément individuel spécifié d'une matrice peut être acheminé.

Pour l'acheminement d'un élément individuel, le type de données de l'élément est implicitement connu par les correspondants. Sachant que certains types de données ont une taille variable, la taille de l'élément est acheminée avec les données de l'élément.

Lorsque des matrices sont acheminées dans leur intégralité, elles sont codées dans l'ordre rangée d'abord. La taille de la matrice en octets doit également être incluse. Le type de données des éléments est également connu implicitement par les points d'extrémité correspondants, et n'est pas explicitement spécifié dans l'APDU. La(les) dimension(s) de la matrice est(sont) également implicitement connue(s) par les points d'extrémité correspondants, et n'est(ne sont) donc pas explicitement incluse(s) dans l'APDU.

NOTE Selon la notation matricielle normalisée, les rangées sont identifiées par le premier indice d'une matrice bidimensionnelle et les colonnes par le deuxième indice. Par exemple, pour le langage de programmation "C", une matrice bidimensionnelle composée de deux lignes et de trois colonnes, ce qui donnerait visuellement

```
1  2  3
4  5  6 '
```

peuvent être définies par

```
int A[2][3] = { {1, 2, 3}, {4, 5, 6} }
```

Le codage de la présente norme transporterait les éléments de cette matrice dans l'ordre ci-dessous: 1, 2, 3, 4, 5, 6.

12.22.4.8.3 CHOICE

CHOICE représente une sélection choisie dans une énumération prédéfinie de possibilités acceptables. Le contenu des données varie en fonction du choix sélectionné.

12.22.4.8.4 OPTIONAL

OPTIONAL indique que le composant désigné peut ne pas être inclus dans la structure contenante.

12.22.4.8.5 IMPLICIT

IMPLICIT indique que les aspects de codage qui identifient le type, la taille, la sélection et la présence ou l'absence en tant qu'élément optionnel doivent être supprimés lorsque ces informations sont déterminables autrement à partir du contexte, par exemple à partir d'autres éléments de la structure de données.

NOTE Lorsqu'une déclaration de type de données se termine avec un nombre entier explicite indiquant la taille du type atomique (par ex: Unsigned12) ou le nombre d'éléments d'un type de matrice (par ex: OctetString2), ce nombre entier est implicite dans la déclaration et n'est pas transporté dans la PDU en tant que taille explicitement acheminée dans l'élément lui-même. Ainsi, un OctetStringN ne contient pas de champ spécifiant N, tandis qu'un OctetString contient un tel champ (car la taille n'est pas implicite dans la déclaration).

12.23 Syntaxe

12.23.1 Unité de données de protocole d'application

12.23.1.1 Début du module conteneur

NOTE 1 La racine d'identificateur d'objet pour les définitions suivantes a été changée en une racine IEC pour prendre en charge la correction et l'évolution de la structure des TSDU par rapport à celle de structure ISA 100.11a TSDU d'origine.

NOTE 2 La déclaration d'extensibilité ASN.1 "..." est utilisée dans chaque production pouvant être étendue dans les éditions futures de la présente norme, ou dans des modes spécifiques à l'industrie ou au fournisseur dans le cadre de cette édition.

```
IEC62734 (1 0 62734) edition (1) TSDU (1) ) DEFINITIONS
      IMPLICIT TAGS
      EXPORTS IEC62734_TSDU;
      ::= BEGIN
```

NOTE 3 Pour cette édition de l'IEC 62734, la structure au niveau des bits de l'IEC62734_TSDU est identique à celle de l'ISA 100_TSDU dans l'ISA 100.11a:2011, 11.23; un des préfixes désigne donc une structure avec une représentation concrète identique et une sémantique associée similaire. La déclaration de préfixe équivalente pour l'ISA 100.11a était

```
--  ( ISA ( ) ISA100.11a:2011 (71) ) DEFINITIONS
--      IMPLICIT TAGS
--      EXPORTS ISA100_TSDU;
--      ::= BEGIN
```

12.23.1.2 Définitions de haut niveau

```
IEC62734_TSDU:: = IMPLICIT CHOICE (
      individualAPDU                ASLIndividualAPDU,
      concatenatedAPDU              ASLConcatenatedAPDU
)
ASLIndividualAPDU::= IMPLICIT CHOICE(
   confirmedRequestAPDU             ASLConfirmedServiceRequest,
   confirmedResponseAPDU            ASLConfirmedServicerResponse,
   unconfirmedRequestAPDU           ASLUnconfirmedServiceRequest,
   publicationAPDU                  ASLPublicationRequest
)
ASLConcatenatedAPDU::= IMPLICIT SEQUENCE (
   IMPLICIT CHOICE (
      -- implicit based on the content of the APDU header, which is common across the choices
      confirmedRequest              ASLConfirmedServiceRequest,
      confirmedResponse             ASLConfirmedServiceResponse,
      unconfirmedRequest            ASLUnconfirmedServiceRequest
   )
)
```

NOTE La concaténation fonctionne, car la taille de chaque APDU apériodique est soit déterminée par des informations explicites, soit est implicite par la définition de primitives de service.

12.23.1.3 Substitutions communes

```
Float32::= REAL (WITH COMPONENTS(, base(2)) SIZE 32)          -- single-precision binary float
Float64::= REAL (WITH COMPONENTS(, base(2)) SIZE 64)          -- double-precision binary float

Integer8::= INTEGER (-128..127)                               -- 8-bit integer
Integer16::= INTEGER(-32 768..32 767)                         -- 16-bit integer
Integer32::= INTEGER(-4 294 967 296..4 294 967 295)           -- 32-bit integer

Unsigned8::= INTEGER(0..255)                                  -- 8-bit unsigned
Unsigned16::= INTEGER(0..65 535)                              -- 16-bit unsigned
Unsigned32::= INTEGER(0..4 294 967 295)                 -- 32-bit unsigned
Unsigned64::= INTEGER(0..18 446 744 073 709 551 615)-- 64-bit unsigned
Unsigned128::= INTEGER(0..340 282 366 920 938 463 374 607 431 768 212 455) -- 128-bit unsigned

Octet1::= Unsigned8
DL16Address::= Unsigned16
EUI64Address::= Unsigned64
IPv6Address::= Unsigned128
SymmetricKey::= PACKED ARRAY [128] OF BIT   -- opaque, uninterpretable bit string
```

```
TAINetworkTime::= SEQUENCE (          -- referenced to TAI start time instant
   Seconds                            Unsigned32,
   FractionalSecond                   Unsigned16
)

TAITimeRounded::= SEQUENCE (          -- referenced to TAI start time instant
   Seconds                            Unsigned32,
)

TAITimeDifference::= SEQUENCE (       -- not referenced to TAI start time instant
   Seconds                            Unsigned32,
   FractionalSecond                   Unsigned16
)                                     -- See NOTE 1
```

NOTE 1 Comme la représentation du temps TAI dans la présente norme est modulo 2^{32} s, une valeur de type TAITimeDifference peut être interprétée comme une différence positive ou négative, avec une différente entre les deux de 2^{32} s. Des utilisations différentes de ce type imposent des limites locales différences dans la plage attendue de différence numérique, qui à leur tour déterminent la façon dont la différence modulo est interprétée. (Par exemple, -2^{31} s .. + (2^{31}-1) s ou -2^k s .. + (2^{32}-2^k-1) s pour $0 \leq k < 32$, etc.)

NOTE 2 Les éléments suivants ne sont utilisés que dans des structures de données condensées.

```
Unsigned1::= INTEGER(0..1)                          -- 1-bit unsigned
Unsigned2::= INTEGER(0..3)                          -- 2-bit unsigned
Unsigned3::= INTEGER(0..7)                          -- 3-bit unsigned
Unsigned4::= INTEGER(0..15)                         -- 4-bit unsigned
Unsigned5::= INTEGER(0..31)                         -- 5-bit unsigned
Unsigned6::= INTEGER(0..63)                         -- 6-bit unsigned
Unsigned7::= INTEGER(0..127)                        -- 7-bit unsigned

Unsigned9::= INTEGER(0..511)                        -- 9-bit unsigned
Unsigned10:= INTEGER(0..1 023)                      -- 10-bit unsigned
Unsigned11::= INTEGER(0..2 047)                     -- 11-bit unsigned
Unsigned12::= INTEGER(0..4 095)                     -- 12-bit unsigned
Unsigned13::= INTEGER(0..8 191)                     -- 13-bit unsigned
Unsigned14::= INTEGER(0..16 383)                    -- 14-bit unsigned
Unsigned15::= INTEGER(0..32 767)                    -- 15-bit unsigned

Unsigned63::= INTEGER(0..9 223 372 036 854 775 807) -- 63-bit unsigned
```

12.23.1.4 En-tête de sous-couche d'application

```

AlertPriority::= Unsigned4
```

La priorité alerte est une valeur qui indique l'importance de l'alerte. Plus la valeur est grande, plus l'alerte est importante. Les systèmes d'hôte mettent en correspondance les priorités d'appareil aux priorités d'alerte d'hôte qui comprennent habituellement les catégories:

– urgent,

– high,
– medium,
– low, et
– journal.

Le mapping recommandé des valeurs de priorité d'alerte en ces catégories est spécifié en 12.17.5.2.2.22.

```
MalformedAPDUClass::= AlertClassevent;

MalformedAPDUAlertCategory::= AlertCategorycommunicationsDiagnostic

MalformedAPDUAlertType::= AlertTypemalformedAPDUCommunicationAlert

MalformedAPDUAlertPriority = 7          -- mid-range of medium priority alerts

MalformedPDUAlertValue::= IMPLICIT SEQUENCE (  -- alert value sent by ASL to DMAP
   sourceAddress                IPv6Address,          -- 128 bits to ensure address uniqueness.
   thresholdExceeded            Unsigned16,
   TimeWindow                   TAITimeDifference
)

MalformedPDUAlertValueSize::= 24 -- sizeof(MalformedPDUAlertValue)
```

12.23.3 Service feedback code

NOTE Service feedback code sert à indiquer le statut (succès, par exemple), un avertissement (valeur limitée, par exemple) ou une erreur (mode incompatible, par exemple).

```
ServiceFeedbackCode::= Unsigned8 (      -- 1octet
   -- standard error codes, range 0..127
   success                      (0)     -- success
   failure                      (1)     -- generic failure
   other                        (2),    -- reason other than that listed in this enumeration
   invalidArgument              (3),    -- invalid attribute to a service call
   invalidObjectID              (4),    -- invalid object ID
   invalidService  (5),                 -- unsupported or illegal service
   invalidAttribute             (6),    -- invalid attribute index
   invalidElementIndex          (7),    -- invalid array or structure element index (or indices)
   readOnlyAtrribute            (8),    -- read-only attribute
   valueOutOfRange              (9),    -- value is out of permitted range
   inappropriateProcessMode     (10),   -- process is in an inappropriate mode for the request
   incompatibleMode             (11),   -- value is not acceptable in current context

   invalidValue    (12),                -- value (data) not acceptable for other reason
                                           (e.g., too large, too small, invalid engineering units code)
   internalError    (13),               -- device internal problem
   invalidSize      (14),                  -- size is not valid (may be too big or too small)
   incompatibleAttribute        (15),   -- attribute not supported in this version
   invalidMethod  (16),                 -- invalid method identifier
   objectStateConflict          (17),   -- state of object in conflict with action requested
   inconsistentContent          (18),   -- the content of the service requested is inconsistent
   invalidParameter             (19),   -- value conveyed is not legal for method invocation
   objectAccessDenied           (20),   -- object is not permitting access
   typeMismatch                 (21),   -- data not as expected (e.g., too many or too few octets)
   deviceHardwareCondition      (22),   -- device specific hardware condition prevented request from
                                           succeeding (e.g., memory defect problem)
   deviceSensorCondition        (23),   -- problem with sensor detected
deviceSoftwareCondition         (24),   -- device specific software condition prevented request from
                                           succeeding (e.g., local lockout, local write protection,
                                        -- simulating in progress)
   fieldOperationCondition      (25),   -- field specific condition prevented request from succeeding
                                           (e.g., lockout, or environmental condition not in range)
   configurationMismatch        (26),   -- a configuration conflict was detected
   insufficientDeviceResources  (27),   -- e.g., queue full, buffers/memory unavailable
   valueLimited                 (28),   -- e.g., value limited by device
   dataWarning                  (29),   -- e.g., value has been modified due to a device specific reason
   invalidFunctionReference     (30),   -- function referenced for execution is invalid
   functionProcessError         (31),   -- function referenced could not be performed due to a device
                                           specific reason
```

```
   warning                          (32),   -- successful, but there is additional information that may be of
                                            interest to the user which may, for example be conveyed via
                                            accessing an attribute or by sending an alert
writeOnlyAttribute                  (33),   -- write-only attribute (e.g., a command attribute)

12.24 Exemples de codage détaillés (informative)

12.24.1 Read

Scénario: L'objet client 11 souhaite lire des données dans l'objet serveur 12, attribut 3. La réponse indique que la lecture a réussi et retourne une valeur de longueur deux octets.

Le Tableau 364 montre un exemple d'une demande de lire plusieurs valeurs.

Tableau 364 – Exemple de codage: Demande Read pour un attribut sans indice

Codage des octets en hexadécimal	Sémantique
03	Demande de lecture
BC	Client (source) object ID = 11_{10} Server (destination) object ID = 12_{10}
XX	Identificateur de demande
03	ID d'attribut = 3 (l'attribut est scalaire)

Le Tableau 365 montre un exemple d'une réponse à une demande de lire plusieurs valeurs.

Tableau 365 – Exemple de codage: Réponse Read pour un attribut sans indice

Codage des octets en hexadécimal	Sémantique
83	Réponse Read
CB	Server (source) object iD = 12_{10} Client (destination) object ID = 11_{10}
XX	Identificateur Request (même valeur que pour l'identificateur Request qui était inclus dans la demande de service correspondante)
00	Succès
02	La valeur a une longueur de deux octets
YY YY	Valeur

12.24.2 Tunnel

Scénario: L'objet 16 dans le client envoie un message à l'objet 20 dans le serveur. Le contenu du message doit être passé à l'objet serveur.

Le Tableau 366 montre un exemple d'une demande de service Tunnel qui a la taille de charge utile de 9 octets.

Tableau 366 – Exemple de codage: Demande de service Tunnel

Codage des octets en hexadécimal	Sémantique
06	Demande de Tunnel
09	Taille
(9 octets de données tunnellisées)	Données tunnellisées

13 Configuration

13.1 Généralités

Un appareil conforme à la présente norme est considéré comme étant configuré lorsque l'appareil a les informations exigées pour communiquer avec un réseau cible et pour initier une demande de rattachement au gestionnaire de système/sécurité du réseau cible. Dans le présent document, un réseau cible est défini comme étant un réseau que l'appareil est configuré pour rejoindre. Les informations exigées pour initier la demande de rattachement comprennent à la fois les informations (relatives à la confiance) de sécurité et les informations relatives à un réseau. L'Article 13 spécifie la procédure de configuration par liaison radio et le format de message dans lequel le moyen de terrain de Type A est utilisé, et les formats de message hors bande dans lesquels le moyen de terrain de Type A n'est pas utilisé pour configurer les informations relatives à la sécurité et relatives à un réseau.

La configuration par liaison radio utilise le processus de rattachement de sous-réseau pour établir une connexion entre l'appareil de configuration et l'appareil configuré. Le processus de rattachement de sous-réseau est décrit en 6.3.9.2 et suit deux chemins facultatifs, l'un défini pour un appareil se rattachant avec des informations relatives à la confiance basées sur une clé symétrique, et l'autre défini pour un appareil se joignant avec des informations relatives à la confiance basées sur une clé asymétrique. La configuration hors bande peut ne pas utiliser le processus de rattachement de sous-réseau; à la place, il peut configurer les informations par l'intermédiaire d'autres moyens câbles ou sans fil.

Le but du processus de configuration est de fournir assez d'informations afin que l'un de ces chemins puisse être pris par l'appareil.

Le processus de configuration implique un appareil qui met en œuvre le rôle de configuration en fournissant les informations relatives à un réseau et les informations relatives à la confiance au nouvel appareil. Pendant la configuration, l'opérateur peut utiliser l'appareil de configuration, agissant comme un proxy pour le gestionnaire de système, pour décider si, oui ou non, il convient de connecter un nouvel appareil au réseau, avec des informations issues du gestionnaire de sécurité. Dans un autre exemple, une copie de la liste d'appareils autorisés peut être obtenue auprès du gestionnaire de sécurité, permettant à l'appareil de configuration de prendre une décision locale. Lorsque le réseau cible est un réseau sécurisé, il est nécessaire de configurer des informations tant relatives à la confiance que relatives à un réseau; pour les réseaux non sécurisés, la clé par défaut (K_global) est utilisée comme information relative à la confiance. Une fois qu'un appareil est configuré, il est prêt à rejoindre le réseau cible. Par la suite, habituellement sans intervention humaine, le gestionnaire de sécurité du réseau cible peut soit accepter, soit rejeter, la demande de rattachement au réseau cible issue de l'appareil en se basant sur les informations configurées.

NOTE Dans la présente norme, divers aspects relatifs à l'installation d'informations relatives à la confiance et relatives à un réseau dans un appareil, l'acheminement de ces informations vers le gestionnaire de sécurité, et l'établissement de la confiance sont décrits dans différents articles. L'installation d'informations relatives à la confiance et relatives à un réseau est décrite à l'Article 13. L'acheminement d'informations vers le gestionnaire de sécurité est décrit à l'Article 9 et à l'Article 10. L'établissement de la confiance est décrit en 7.4.4.3.2.

13.2 Termes et définitions pour les appareils ayant divers rôles ou états

Les termes suivants sont définis pour les appareils ayant divers rôles ou états:

- **Appareil configuré**: Un appareil qui a besoin d'être configuré ou qui est en train d'être configuré. L'appareil peut manquer de tout ou partie des informations exigées pour rejoindre un réseau.

NOTE 1 Un appareil qui contient de vieilles informations relatives à un réseau est souvent mis à jour en le configurant avec de nouvelles informations.

- **Réseau cible**: Le réseau auquel le DBP est configuré pour se rattacher.
- **Appareil de configuration**: Un appareil qui met en œuvre le rôle consistant à configurer un autre appareil pour permettre à ce dernier appareil de rejoindre le réseau cible. Un PD peut ne pas être un appareil mettant en œuvre seulement le rôle de configuration; à la place, il pourrait être:
  - le gestionnaire de système/gestionnaire de sécurité du réseau cible;

    NOTE 2 Le rôle de gestionnaire de système/gestionnaire de sécurité peut être réparti, par exemple, dans un ensemble désigné d'appareils dans le réseau cible.

  - un appareil, tel qu'un appareil tenu à la main contenant un gestionnaire de système/gestionnaire de sécurité, qui utilise la suite de protocoles spécifiée par la présente norme pour configurer le DBP à travers un mini-réseau temporaire distinct; ou
  - un appareil qui utilise la communication hors bande (OOB), telle que communications en champ proche de champ (NFC) dans l'infrarouge, ou des prises, pour configurer le DBP, où la communication OOB ne relève pas du domaine d'application de la présente norme.
- **Réseau par défaut**: Le réseau dont l'identificateur de réseau est 1.
- **Réseau de configuration**: Un réseau formé entre le PD et le DBP. Si le PD est un appareil tenu à la main, le mini-réseau de configuration est le réseau formé entre l'appareil tenu à la main et le DBP. Si l'appareil de configuration est le gestionnaire de sécurité du réseau cible, le réseau de configuration peut être un réseau logique distinct séparé sur le réseau cible lui-même.
- **Clé de rattachement (K_join)**: Une clé de rattachement symétrique utilisée pour rejoindre un réseau cible sécurisé. La valeur de la clé K_join est censée être secrète, et elle est donc censée offrir la confidentialité de données. La valeur de la clé K_join

est mise à jour pendant la configuration à une nouvelle valeur qui est connue seulement par le gestionnaire de sécurité de réseau-cible et à l'appareil.[12]

- **Valeur de la clé de rattachement par défaut (K_global)**: Une clé de rattachement symétrique avec une valeur éditée. La valeur de K_global n'est pas censée être un secret; sa valeur est bien connue. Elle n'offre donc pas la confidentialité des données, mais elle aide à améliorer l'intégrité des données. Son but est d'établir la connectivité entre les appareils conformes à la présente norme qui ne partagent pas une clé de rattachement secrète. Une telle connectivité est nécessaire pour:
  - la configuration par liaison radio (OTA) des informations relatives à un réseau cible;
  - la lecture par OTA de l'identité de l'appareil et les réglages de configuration;
  - l'authentification par OTA des authentifiants de l'appareil; et
  - la mise à jour par OTA de la clé de rattachement K_join (les deux dernières étapes en utilisant la cryptographie asymétrique).

  La valeur de la clé de rattachement par défaut doit être K_global, définie en 7.2.2.2.
- **Clé de rattachement ouverte (K_join = K_open)**: Une valeur éditée non secrète pour la clé de rattachement (K_join). Cette valeur spéciale pour la clé de rattachement est utilisée pour rejoindre un réseau de configuration afin que certaines méthodes de configuration par OTA à clé symétrique seulement puissent être facilitées. La valeur réelle pour cette clé est définie en 7.2.2.2.
- **Réseaux physiques et logiques**: Un réseau physique est un ensemble d'appareils physiques qui communiquent les uns avec les autres, possiblement en plusieurs sauts. Un réseau logique est une instance de réseau qui fonctionne sur le réseau physique. Un réseau physique peut prendre en charge plusieurs réseaux logiques. Les réseaux logiques ont différentes propriétés individuelles de priorité et de sécurité. Par exemple, le réseau cible et le réseau de configuration sont deux réseaux logiques qui existent sur un réseau physique.
- **Etat inactif**: État d'appareil qui ne participe pas activement au réseau sans fil.
- **Etat de configuration**: L'appareil est dans la phase de configuration.
- **Etat "provisioned"**: L'appareil a reçu assez d'informations pour rejoindre le réseau cible, et a obtenu le DMO.Join_Command=1.
- **Valeur d'usine par défaut**: La configuration par défaut d'un appareil de terrain tel qu'il sort d'une installation de fabrication. La configuration par défaut a les valeurs de K_global et K_join égales à leurs valeurs par défaut, et la configuration par OTA permise. Un appareil opérationnel peut être réinitialisé à la valeur d'usine par défaut, soit par le gestionnaire de système lorsqu'il est une partie intégrante d'un réseau sécurisé, soit par un moyen OOB utilisant un appareil de configuration. Les valeurs d'usine par défaut pour le processus de configuration sont résumées dans le Tableau 367. Seul le gestionnaire de système doit avoir l'autorité de réinitialiser un appareil aux valeurs d'usine par défaut par l'intermédiaire du réseau.

La présente spécification n'exclut pas les appareils qui n'autorisent pas la réinitialisation aux valeurs d'usine par défaut.

---

[12] Des mécanismes appropriés sont fournis afin que la suite de protocoles définie par la présente norme ne puisse pas être utilisée pour lire dans un appareil la valeur courante de la clé de rattachement. Noter que le caractère secret des clés de rattachement ne peut pas être mis en vigueur par la présente norme.

13.3 Procédures de configuration

Tous les appareils de terrain conformes à la présente norme doivent mettre en œuvre un objet normalisé appelé objet de configuration d'appareil (DPO). Les attributs du DPO dans le DBP doivent spécifier les informations exigées pour initier une demande de rattachement au réseau cible. L'appareil doit retenir tous les attributs du DPO en cas de cycle d'alimentation en énergie ou de remplacement de batterie. L'objet de configuration d'appareil est décrit dans le détail en 13.9.1.

La présente spécification n'exclut pas que le gestionnaire de système puisse avoir le DPO, par exemple, qui stocke une adresse EUI64 du gestionnaire de sécurité.

Les PD doivent mettre en œuvre un objet de service de configuration d'appareil (DPSO) qui contient des informations destinées aux DBP qui sont desservis par le PD.

La configuration implique de positionner les attributs du DPO. Les attributs dans le DPO contiennent des informations tant relatives à un réseau que relatives à la confiance. Ces attributs peuvent être positionnés par l'intermédiaire de trois moyens différents:

- ils peuvent être préinstallés au cours de la fabrication de l'appareil; ou
- ils peuvent être positionnés en utilisant des moyens OOB; ou
- ils peuvent être positionnés par un PD utilisant un réseau de configuration, où le PD agit comme un proxy pour un gestionnaire de sécurité/gestionnaire de système d'un réseau cible pour fournir les informations relatives à la confiance et relatives à un réseau pour le réseau cible en question.

Tous les appareils conformes à la présente norme doivent prendre en charge la formation du réseau de configuration en utilisant seulement la suite complète de protocoles définie par la présente norme (PhL, DL, NL, et TL), c'est-à-dire, n'exigeant aucun autre mécanisme. Cependant, la présente norme n'interdit pas la configuration par des moyens de communication OOB.

Avec le moyen de terrain de Type A (5.2.6.4) dans le réseau de configuration, les PDU normalisées doivent être utilisées pour positionner les attributs du DPO, qui définit un ensemble d'attributs en lecture seule par défaut pour la formation du réseau de configuration ou d'un réseau non sécurisé. Les attributs par défaut incluent des clés symétriques par défaut éditées (K_join = K_global et K_join = K_open), un identificateur de sous-réseau D par défaut et un ensemble de voies par défaut. Comme cet ensemble d'attributs par défaut est connu et contenu dans le DPO de tous les appareils conformément à la présente norme, ces attributs fournissent un moyen pour tous les appareils de rejoindre un réseau de configuration.

Le DPO inclut un attribut, DPO.Allow_Provisioning, qui spécifie si l'accès aux attributs de l'objet par l'intermédiaire de l'instance ouverte par défaut est autorisé ou bloqué.

Quelques appareils peuvent mettre en œuvre un mécanisme externe (à savoir un commutateur) qui verrouillera l'état de configuration (soit vide, soit configuré) de l'appareil, pour réduire au maximum la consommation de batterie et pour réduire au maximum également la probabilité qu'un PD larron reconfigure un appareil.

13.4 Clés symétriques préinstallées

La formation d'un réseau de configuration n'est pas une étape nécessaire pour la configuration; les informations relatives à la confiance peuvent être préinstallées dans un appareil. Par exemple, il est possible qu'un utilisateur délègue (en partie) la configuration d'appareils à un fabricant d'appareil ou à un tiers. Un fabricant d'appareil peut préprogrammer des clés de rattachement symétriques secrètes et il peut fournir les données de clés de rattachement symétriques secrètes à l'utilisateur afin que les données puissent être chargées dans le gestionnaire de système/gestionnaire de sécurité du réseau cible. En variante, l'utilisateur peut stipuler au fabricant d'appareil la clé symétrique qui doit être chargée. Dans

ce cas, le DPO d'un appareil doit être préinstallé avec des informations relatives à un réseau cible et avec la clé de rattachement symétrique cible K_join. En fonction de l'application, deux ou plus de deux appareils peuvent partager les mêmes informations secrètes. Les appareils avec préinstallation d'informations relatives à la confiance et d'informations relatives à un réseau-cible peuvent passer directement au processus de rattachement de sous-réseau.

Lorsqu'un appareil a des informations relatives à la confiance qui sont préinstallées, mais pas d'informations relatives à un réseau-cible, il doit être possible de configurer l'appareil avec les informations nécessaires relatives au réseau. Cela facilite le fait d'avoir l'appareil qui reçoit des annonces issues du réseau-cible sur les voies prévues, en accélérant le processus de rattachement et les demandes de rattachement de sous-réseau présentes seulement vers le réseau-cible. Si les informations relatives à un réseau ne sont pas configurées, un appareil peut utiliser les réglages de réseau par défaut pour rechercher par balayage les annonces issues de tous les réseaux dans son voisinage (y compris ceux des concurrents de l'organisation propriétaire de l'appareil).

13.5 Configuration utilisant des mécanismes hors bande

Des appareils sans clés symétriques préinstallées ont besoin d'être authentifiés et ensuite configurés avec des informations de confiance. Comme noté plus haut, cela peut être accompli soit par le moyen de terrain de Type A de réseau de configuration par liaison radio, soit pas des mécanismes OOB.

Les moyens de communication OOB comprennent, sans s'y limiter, les connecteurs câblés en infrarouge, les cartes mémoire, les claviers sur des appareils, les NFC, et les prises. Le mécanisme des communications OOB ne relève pas du domaine d'application de la présente norme. Il convient que les attributs du DPO qui spécifient le rattachement au réseau-cible soient mis aux mêmes valeurs quel que soit le moyen utilisé (liaison radio ou OOB).

13.6 Réseaux de configuration

13.6.1 Généralités

Outre la configuration OOB et la préconfiguration en usine, la présente norme définit la formation d'un réseau normalisé pour configurer des appareils par liaison radio (OTA) en utilisant le moyen de terrain de Type A. La clé de rattachement symétrique par défaut (K_global) ou la clé de rattachement symétrique ouverte (K_join = K_open) peut être utilisée comme étant les informations relatives à la confiance pour la formation du réseau de configuration par OTA. La clé de rattachement par défaut (K_global) est utilisée pour la formation du réseau de configuration pour obtenir des informations relatives à un réseau cible et la clé de rattachement à un réseau cible et pour des appareils avec une capacité cryptographique asymétrique. La clé de rattachement (K_join = K_open) est utilisée pour la formation d'un réseau de configuration où les informations relatives à la confiance et relatives à un réseau sont configurées par liaison radio. Cette forme de configuration est peu sûre et, par défaut, les gestionnaires de système et les appareils de configuration ne doivent pas permettre le rattachement avec cette clé de rattachement.

Un PD qui a des capacités cryptographiques asymétriques distingue la méthode avec la clé utilisée pour générer le MIC dans la primitive Security_Sym_Join().request. Dans le PD, le MIC généré par l'appareil rejoignant le réseau par défaut a besoin d'être validé un maximum de deux fois – une fois pour K_open et l'autre pour K_global. Si le gestionnaire de sécurité détecte que K_global est utilisée pour le MIC, le DBP doit être configuré en utilisant la cryptographie asymétrique. Autrement, le DBP doit être configuré en utilisant la clé symétrique K_open.

Le réseau de configuration peut soit être un mini-réseau isolé formé avec un appareil tenu à la main, soit être un réseau logique distinct sur le réseau cible lui-même. Dans le dernier cas, la connectivité allant du DBP au routeur d'annonce est ouverte, mais la connectivité allant plus loin, de ce routeur d'annonce vers le gestionnaire de système, est protégée par une session existante et elle est donc sécurisée. Si le réseau de configuration logique est sur le

réseau cible, les objets d'application des gestionnaires de système/de sécurité sur le réseau cible et le réseau de configuration logique (par exemple, DPSO) peuvent communiquer les uns avec les autres au sein du même appareil.

La Figure 135 montre le (mini-)réseau de configuration.

Figure 135 – Le réseau de configuration

La configuration par OTA utilise un PD qui peut être soit:

- un configurateur tenu à la main qui forme un mini-réseau isolé avec le DBP. Cet appareil tenu à la main a son propre gestionnaire de système/gestionnaire de sécurité et une fonctionnalité de routeur d'annonce; soit
- le gestionnaire de système/gestionnaire de sécurité du réseau de configuration logique sur le réseau cible.

NOTE Lorsqu'un PD est utilisé pour la configuration par OTA, il forme temporairement un mini-réseau et fonctionne comme étant à la fois le gestionnaire de système et le gestionnaire de sécurité pour le DBP.

13.6.2 Configuration par liaison radio utilisant la cryptographie asymétrique

Les DBP qui sont capables d'accomplir des calculs cryptographiques asymétriques doivent utiliser la clé de rattachement par défaut (K_global) pour rejoindre un réseau de configuration. Le DBP reçoit des annonces dont l'ID de sous-réseau D = 1 de routeurs d'annonce limitrophes et initie une demande de rattachement en utilisant la clé symétrique par défaut. Un processus de rattachement de sous-réseau réussi se traduit par le fait que le PD et le DBP ont établi un contrat pour une communication plus approfondie. Le PD utilise alors les primitives d'AL normalisées (telles que read et write) pour transférer les informations relatives à un réseau contenues dans son DPSO vers le DPO du DBP.

Pour configurer les informations relatives à la confiance, le PD interroge le DBP, à savoir., il lit ses authentifiants (par exemple: DPO.PKI_Certificate ou plusieurs DPO.PKI_Certificates, voir Annexe G), et envoie ces authentifiants vers le gestionnaire de sécurité. Le gestionnaire de sécurité du réseau de configuration vérifie les authentifiants du DBP et valide l'authenticité du DBP par un mécanisme de défi-réponse. Le gestionnaire de sécurité/gestionnaire de système peut demander une confirmation complémentaire de l'utilisateur par une GUI pour configurer le DBP. Une fois accepté, le gestionnaire de système fournit au DBP la clé de rattachement secrète, K_join, afin que le DBP puisse rejoindre le réseau cible soit immédiatement, soit plus tard, en utilisant la clé de rattachement en question. Lorsque cette nouvelle clé est émise par liaison radio, elle doit être chiffrée par la clé asymétrique du DBP, qui est une partie intégrante de son certificat, afin qu'elle ne puisse pas être récupérée par un auditeur frauduleux pendant qu'elle est en transit.

Des gestionnaires de sécurité conformes à la présente norme ne sont pas tenus d'avoir des capacités cryptographiques asymétriques; par conséquent, certains gestionnaires de sécurité peuvent ne pas être capables d'accepter ou de configurer des appareils en utilisant des capacités cryptographiques asymétriques. Lorsque le DBP rejoint le réseau de configuration en utilisant K_global, les gestionnaires de sécurité et les PD incapables d'accomplir des calculs cryptographiques asymétriques ne doivent pas émettre les informations relatives à la confiance vers le DBP.

En plus d'un niveau élevé de sécurité, les modules cryptographiques asymétriques et les certificats fournissent un moyen commode facile pour que les appareils établissent la communication avec le gestionnaire de sécurité du réseau-cible et soient configurés sans utilisation d'outils supplémentaires. Il est recommandé que les fabricants des gestionnaires de sécurité qui ne prennent pas en charge la cryptographie asymétrique fournissent des moyens adéquats (par exemple: mémoire, puissance de traitement ou périphériques complémentaires, etc.) pour mettre à niveau de tels gestionnaires de sécurité, à la demande d'utilisateur, pour prendre en charge la cryptographie asymétrique.

13.6.3 Configuration par liaison radio utilisant une clé de rattachement symétrique ouverte

La présente norme permet à des PD de configurer des appareils qui n'ont pas de capacités cryptographiques asymétriques d'être configurés par liaison radio. À cette fin, une clé de rattachement symétrique ouverte bien connue (K_join = K_open) est utilisée. Par défaut, le gestionnaire de sécurité dans le PD ne doit pas permettre la configuration par OTA avec la clé symétrique ouverte, K_open. Le réseau de configuration n'est pas sécurisé de lui-même, car il utilise une clé ouverte éditée et une clé de rattachement pour le réseau cible, et exige

donc des mesures de compensation, telles qu'une connexion physique sécurisée ou l'utilisation de la cryptographie asymétrique, pour la sécurité.

NOTE 1 Dans la configuration par OTA avec K_global, les informations de sécurité (à savoir la clé de rattachement) sont chiffrées avec une clé asymétrique pendant l'émission.

NOTE 2 L'utilisation d'une clé de rattachement symétrique ouverte pour la configuration n'est pas une procédure sécurisée. Un appareil d'écoute frauduleuse peut être capable d'obtenir les clés de rattachement au réseau cible et poser un risque de sécurité lorsque cette procédure de configuration est utilisée. Cette procédure de configuration peut seulement être utilisée dans des applications où le risque de sécurité est minimal et l'utilisateur n'est pas concerné ou a pris des mesures suffisantes pour éviter l'écoute frauduleuse. Une telle exposition peut être évitée en utilisant la configuration à chiffrement asymétrique ou la configuration OOB.

L'utilisation de la clé de rattachement symétrique K_open pour la configuration est une option de configuration. Les DBP peuvent être préconfigurés pour ne pas utiliser la configuration par OTA avec cette clé. Par défaut, les gestionnaires de sécurité et le PDS doivent rejeter les demandes de rattachement issues de tous les appareils qui envoient des demandes de rattachement en utilisant la clé de rattachement symétrique K_open. Les gestionnaires de sécurité et les PD ont besoin d'être configurés pour accepter des demandes de rattachement utilisant la clé de rattachement K_open. Il est admissible que des gestionnaires de sécurité et des PDS ne permettent pas une telle configuration.

Un appareil qui rejoint un réseau de configuration en utilisant la clé de rattachement K_open peut être configuré par le PD avec la clé de rattachement pour un réseau cible. Cependant, une fois configuré avec une nouvelle clé de rattachement pour le réseau cible, l'appareil ne doit être pas autorisé à utiliser la clé de rattachement symétrique K_open, à moins que l'appareil ne soit réinitialisé aux valeurs d'usine par défaut. Donc, le seul moyen admissible pour que l'appareil réutilise cette clé pour la configuration est de réinitialiser l'appareil aux valeurs d'usine par défaut.

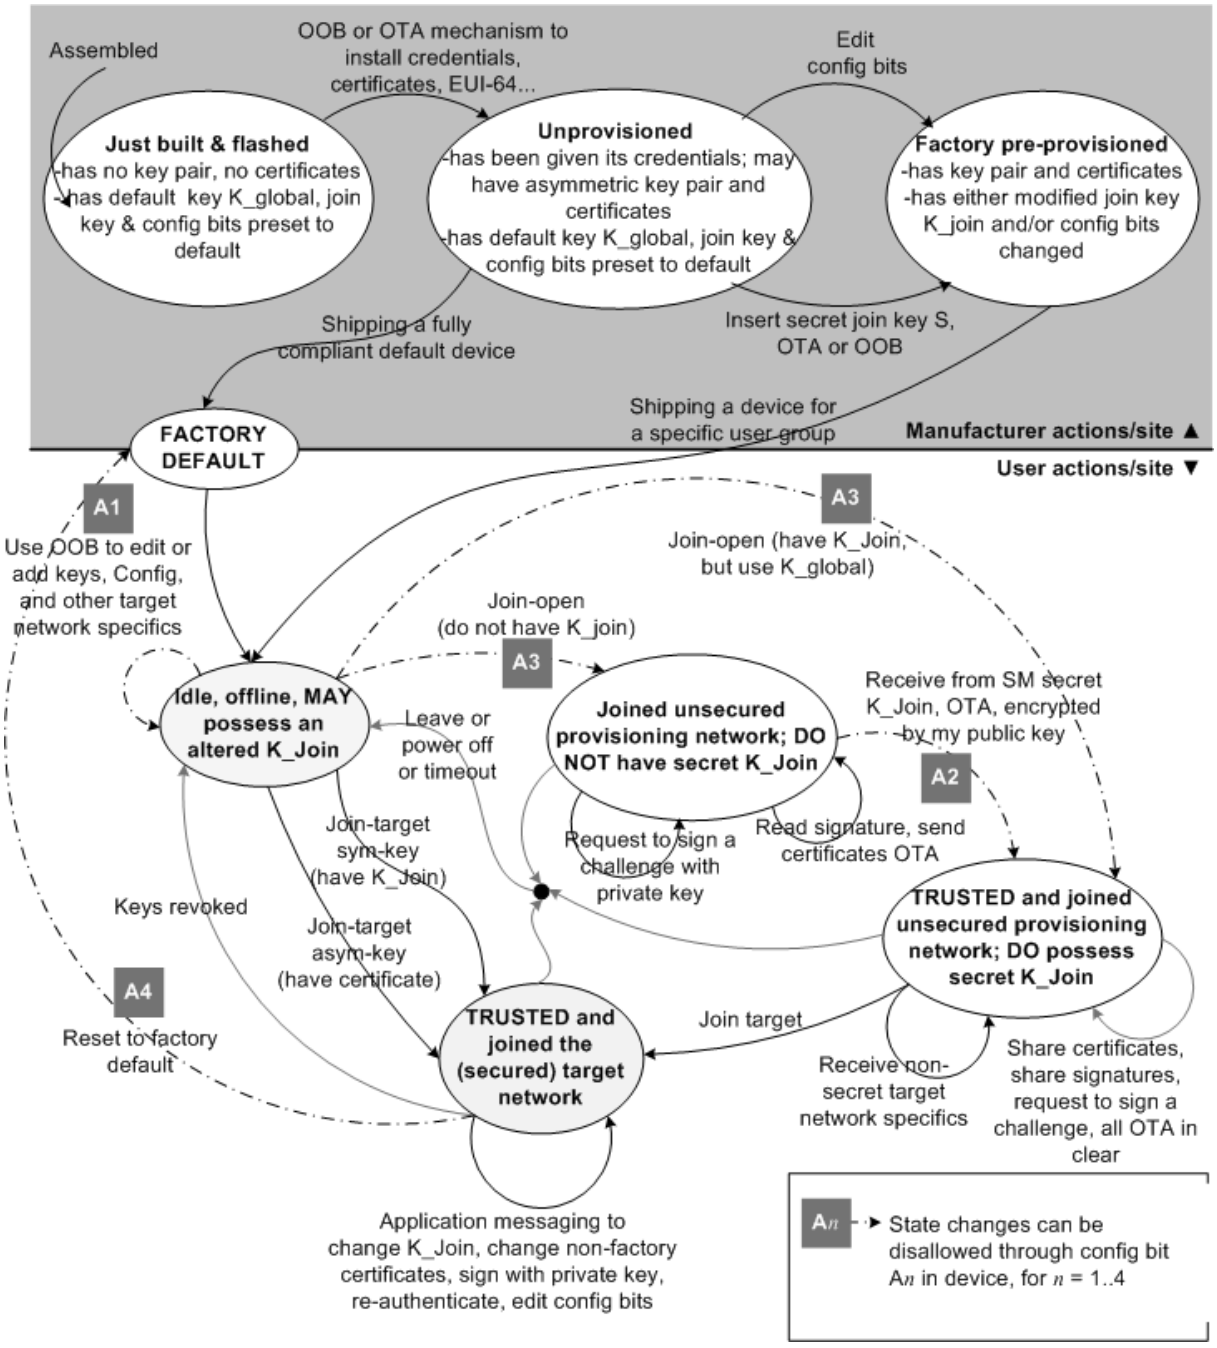
Le procédure de configuration utilisant la clé de rattachement symétrique K_open peut être utilisée dans le (mini-)réseau de configuration ou par l'intermédiaire d'un réseau logique distinct sur le réseau cible. Le DBP reçoit une annonce issue d'un réseau de configuration et une demande de rattachement normalisée est envoyée en utilisant une clé symétrique (K_join = K_open). Si la demande est acceptée, le DBP rejoint le réseau de configuration et un contrat est établi entre le DBP et le PD. Les primitives et les méthodes read/write à un niveau application sont disponibles au PD pour configurer les informations relatives à la confiance et relatives à un réseau; cela inclut, par exemple, de configurer la clé de rattachement à la cible en utilisant la méthode de DPO.Write_Join_Key.

Le (mini-)réseau de configuration peut également être utilisé pour la configuration d'appareil. Sachant qu'un contrat a déjà été établi, le PD peut également utiliser le réseau (soit OTA ou OOB) pour configurer le DBP.

13.7 Diagrammes de transition d'état

Les options débattues jusqu'ici pour la configuration sont montrées ci-dessous dans des diagrammes de transition d'états.

La Figure 136 décrit les transitions d'état pertinentes pour la configuration pendant le cycle de vie d'un appareil de terrain. Le diagramme décrit des états en un site de fabrication et en un site utilisateur.



Légende

Anglais	Français
Assembled	Assemblé
OOB or OTA mechanism to install credentials, certificates, EUI-64	Mécanisme OOB ou OTA pour installer les authentifiants, les certificats, EUI-64
Edit config bits	Modifier les bits de configuration
Just built & flashed -has no key pair, no certificates -has default key K_global, join key & config bits preset to default	Juste construit et flashé - n'a aucune paire de clés, aucun certificat - a la clé de rattachement par défaut K_global et les bits de configuration préréglés aux valeurs par défaut

Anglais	Français
Un-provisioned -has been given its credentials; may have asymetric key pair and certificates -has default key K_global, join key & config bits preset to default	Non configuré - a reçu des authentifiants, peut avoir une paire de clés asymétriques et des certificats - a la clé de rattachement par défaut K_global et les bits de configuration préréglés aux valeurs par défaut
Factory pre-provisioned -has key pair and certificates -has either modified join key K_join and/or config bits changed	Préconfiguré en usine - a une paire de clés et des certificats -a soit la clé de rattachement K_join modifiée et/ou les bits de configuration changés
Shipping a fully compliant default device	Expédition d'un appareil par défaut totalement conforme
Insert secret join key S, OTA or OOB	Insérer clé de rattachement secrète S, OTA ou OOB
Shipping a device for a specific user group	Expédition d'un appareil pour un groupe spécifique d'utilisateurs
Manufacturer actions/site	Actions/site du fabricant
User actions/site	Actions/site de l'utilisateur
FACTORY DEFAULT	VALEURS D'USINE PAR DEFAUT
A1 Use OOB to edit or add keys, config, and other target network specifics	A1 Utiliser OOB pour modifier ou ajouter des clés, la configuration, et autres spécificités de réseau-cible
A3 Join-open (have K_join, but use K_global)	A3 Rattachement ouvert (a K_join, mais utilise K_global)
A3 Join-open (do not have K_join)	A3 Rattachement ouvert (n'a pas de K_join)
Idle, offline, MAY possess an altered K_Join	Inactif, hors ligne, PEUT posséder une K_Join altérée
Leave or power off or timeout	Quitter ou éteindre ou temporiser
Joined unsecured provisioning network; DO NOT have secret K_Join	A rejoint un réseau de configuration non sécurisé, N'A PAS de K_Join secrète
A2 Receive from SM secret K_Join, OTA, encrypted by my public key	A2 Recevoir du SM la K_Join secrète, OTA, chiffrée par ma clé publique
Join-target sym-key (have K_Join)	Clé symétrique de rattachement cible (posséder K_Join)
Request to sign a challenge with private key	Demande de signer un défi avec clé privée
Read signature, send certificates OTA	Lire signature, envoyer certificats OTA
Keys revoked	Clés révoquées
Join-target asym-key (have certificate)	Clé asymétrique de rattachement cible (posséder certificat)
TRUSTED and joined unsecured provisioning network; DO possess secret K_Join	FIABLE et a rejoint un réseau de configuration non sécurisé; possède EFFECTIVEMENT K_Join secrète
Reset to factory default	Réinitialisation aux valeurs d'usine par défaut
TRUSTED and joined the (secured) target network	APPROUVE et a rejoint le réseau cible (sécurisé)
Join target	Rejoindre cible
Receive non-secret target network specifics	Recevoir spécificités non secrètes de réseau-cible

Anglais	Français
Share certificates, share signatures, request to sign a challenge, all OTA in clear	Partager certificats, partager signatures, demander de signer un défi, tout cela par OTA en clair
Application messaging to change K_Join, change non-factory certificates, sign with private key, re-authenticate, edit config bits	Messagerie d'application pour changer K_Join, changer certificats autres que d'usine, signer avec clé privée, authentifier de nouveau, modifier les bits de configuration
State change can be disallowed through config bit A*n* in device, for *n* = 1..4	Le changement d'état peut être interdit par config bit A*n* dans l'appareil, pour *n* = 1..4

Figure 136 – Diagramme de transition d'états montrant les grandes lignes des étapes de configuration au cours du cycle de vie d'un appareil

Un appareil de terrain qui est nouvellement fabriqué passe à l'état "un-provisoned" lorsque son identité (par exemple, son adresse EUI64) et ses authentifiants lui sont fournis. Dans cet état, l'appareil a les valeurs de réglage par défaut telles que définies dans le Tableau 367.

Tableau 367 – Valeurs de réglage en usine par défaut

Attribut	Description	Valeur par défaut
Default symmetric join key K_global	La clé de rattachement symétrique utilisée pour rejoindre un réseau par défaut	Spécifié en 7.2.2.2.
Open symmetric join key (K_join = K_open)	La clé de rattachement symétrique de 128 bits ouverte utilisée pour rejoindre un réseau de configuration, puis pour recevoir de nouvelles clés de rattachements à une cible	Spécifié en 7.2.2.2
Allow OOB provisioning (A1)	Ce bit de configuration permet l'utilisation de mécanismes OOB pour configurer l'appareil. Ce bit n'est pas pertinent si l'appareil n'a aucun moyen OOB pour la configuration	1 = autorisé
Allow asymmetric-key-based provisioning (A2)	Ce bit de configuration permet l'utilisation de chiffrement asymétrique pour la configuration par OTA de K_join. Ce bit n'est pas pertinent si l'appareil ne prend pas en charge la cryptographie asymétrique	1 = autorisé
Allow default join (A3)	Ce bit de configuration permet à l'appareil de rejoindre un réseau par défaut. Certains appareils peuvent choisir de ne pas permettre du tout un rattachement par défaut	1 = autorisé
Allow reset to factory defaults (A4)	Ce bit de configuration permet l'exécution de commandes OTA qui réinitialise l'appareil à la configuration en usine par défaut	1 = autorisé

Le fabricant peut expédier des appareils avec ces valeurs de réglage par défaut.

En variante, l'appareil peut être préconfiguré pour un utilisateur particulier au site de fabrication. Lorsqu'un appareil est préconfiguré, les réglages par défaut de l'appareil sont changés. L'appareil peut avoir reçu une clé de rattachement symétrique à une cible qui est spécifique à un réseau cible au site utilisateur. En outre, n'importe lesquels des bits de configuration (A1, A2, A3 et A4) peuvent être changés. Par exemple, le rattachement au réseau par défaut et la réinitialisation aux valeurs d'usine par défaut peuvent être désactivés (A3, A4 = 0). Un tel appareil ne doit pas être capable d'être configuré par l'intermédiaire de la clé de rattachement symétrique ouverte (K_join= K_open).

L'appareil arrive au site utilisateur soit préconfiguré, soit avec les valeurs d'usine par défaut et il est dans l'état "idle".

Au site utilisateur, un appareil peut être configuré à l'aide des mécanismes d'OOB (A1 activé) avec une clé de rattachement symétrique et les informations relatives à un réseau pour rejoindre le réseau-cible. En variante, l'appareil peut avoir des clés de rattachement préinstallées et/ou les informations relatives à un réseau établies par le fabricant d'appareil. Si les informations relatives à un réseau ne sont pas configurées dans l'appareil à la fabrication, l'appareil peut rejoindre un réseau de configuration avec la clé de rattachement symétrique par défaut K_global spécifiée en 7.2.2.2 (si A3 est activé) et peut être configuré avec les informations relatives à un réseau en utilisant des mécanismes par liaison radio.

Les appareils qui échouent à rejoindre le réseau cible en utilisant leurs informations configurées peuvent chercher à rejoindre un réseau de configuration (si A3 est activé) en utilisant K_global. Après s'être joint en utilisant la clé de rattachement par défaut (K_global), le PD peut utiliser la méthode Write_Symmetric_Join_Key pour mettre à jour la K_join seulement si elle est envoyée chiffrée avec la clé de asymétrique du DBP.

Si l'appareil dans un état "idle" n'a pas une clé de rattachement symétrique installée valide et est autorisé à rejoindre un réseau par défaut, et A4 est activé, l'appareil doit lancer une recherche par balayage d'annonces afin d'atteindre un gestionnaire de sécurité/gestionnaire de système d'un réseau par défaut dans son voisinage.

Si une annonce est trouvée et l'appareil a des capacités cryptographiques asymétriques et des certificats PKI, il doit transmettre ses authentifiants au gestionnaire de sécurité associé au routeur d'annonce. Les routeurs d'annonce doivent transmettre des demandes de rattachement vers leurs gestionnaires de sécurité en utilisant un contrat établi que le routeur de publicité a conclu avec le gestionnaire de sécurité/gestionnaire de système.

Lorsque le gestionnaire de sécurité reçoit de nouveaux authentifiants d'appareil, il vérifie d'abord si, oui ou non, les appareils avec ces authentifiants sont attendus et autorisés pour le réseau cible. Cela peut être accompli par l'intermédiaire de la consultation dans les listes blanches pré-peuplées avec l'adresse EUI64I de l'appareil individuel. Les authentifiants d'appareil sont utilisés par le gestionnaire de système pour décider de la CA (et sa clé de rattachement asymétrique) à utiliser dans des étapes d'authentification ultérieures.

Si l'appareil est autorisé, l'authenticité des authentifiants est vérifiée par le gestionnaire de système. Les authentifiants d'appareil comprennent les certificats de l'appareil. En utilisant plusieurs certificats, le contrôle sur des données d'appareil peut[13] être constitué de deux cryptographiques asymétriques, l'une en utilisant la clé publique de la CA qui est déjà présente à l'intérieur du gestionnaire de sécurité (le PD) pour lire le premier certificat (appelé le certificat d'émetteur) et donc la clé publique de l'émetteur, suivie du deuxième certificat (appelé le certificat d'appareil) et donc la clé publique de l'appareil, en utilisant la clé de publique de l'émetteur. Une fois que la clé publique de l'appareil est obtenue, un mécanisme de défi/réponse (voir 7.4.6) est utilisé par le PD pour établir l'authenticité du DBP.

Une copie des données échangées dans les étapes précédentes peut être journalisée dans des dossiers publics dans le PD pour des besoins d'audit futur.

L'entrée d'utilisateur pour accepter l'appareil peut être sollicitée avant que l'appareil ne soit accepté. Une fenêtre de dialogue sur une interface homme-machine (IHM) connecté au gestionnaire de système peut chercher la confirmation qu'il convient d'autoriser l'appareil digne de confiance à rejoindre le réseau cible. Cela peut être un dialogue oui/non qui demande s'il convient qu'un appareil spécifique, avec une identité authentifiée spécifique, qui est un membre d'une famille d'appareils attendus et jugés bienvenus, soit en effet maintenant préparé pour rattachement sécurisé au réseau cible sécurisé. Lorsque cette étape d'entrée utilisateur est mise en œuvre, et la réponse d'utilisateur n'est pas reçue et aucune réponse n'est envoyée au cours de la période de temporisation de la réponse de rattachement, la demande de rattachement doit être considérée comme ayant échoué.

Si l'appareil est autorisé (présent dans la liste blanche) et authentique, le PD génère une nouvelle clé pour le DBP, la chiffre avec la clé asymétrique de DBP et l'émet vers le DBP. Une copie peut être journalisée dans des dossiers dans le PD pour des besoins d'audit futur.

L'échec dans l'une des étapes ci-dessus peut être dû à la perte de connectivité, aux temporisations, ou au déni de demande de rattachement provenant du DBP. Les exemples du dernier cas comprennent un statut négatif sur des listes blanches, une discordance pendant l'authentification, ou un rejet issu d'une fenêtre de dialogue sur une IHM. Lorsqu'il est clair

---

13 La chaîne à deux certificats décrite ici est seulement l'une des nombreuses topologies de certificats possibles avec plusieurs certificats. Le DPO fournit des attributs pour inclure plusieurs certificats.

qu'il convient de rejeter un DBP pour n'importe lesquelles de ces raisons, une alerte est générée par le gestionnaire de sécurité. Aucune réponse de rattachement ne doit être renvoyée à l'appareil indiquant un échec de rattachement à l'appareil.

Si le DBP n'a pas les modules cryptographiques asymétriques, mais il a la clé de rattachement symétrique ouverte, il peut rejoindre un réseau de configuration avec la clé de rattachement symétrique ouverte (K_join = K_open). Le droit d'accepter ou de rejeter la configuration des DBP qui utilisent les clés de rattachement symétrique ouvertes (K_join = K_open) est du ressort du PD. Par défaut, le PD ne doit pas configurer les appareils qui s'attachent avec la clé de rattachement ouverte; le PD peut toutefois être configuré pour configurer ces appareils. Si le PD est configuré pour permettre la configuration OTA ouverte, le DBP sera configuré avec une nouvelle clé de rattachement K_join pour rejoindre le réseau cible. Une fois qu'il est configuré, l'appareil ne doit pas réutiliser la clé ouverte à moins qu'il n'ait été réinitialisé aux valeurs d'usine par défaut (A4 est activé).

Une fois configuré, l'appareil peut continuer à rejoindre le réseau cible avec ses informations configurées. Comme partie intégrante du processus de rattachement de sous-réseau, l'appareil reçoit une clé principale, des clés T et des clés D, en plus d'établir un contrat avec le gestionnaire de système/sécurité du réseau-cible; le fonctionnement normal du réseau sécurisé normalisé suit.

Comme partie intégrante du fonctionnement normal d'un réseau, le gestionnaire de système du réseau peut configurer l'appareil avec des informations suffisantes pour rejoindre un autre réseau lorsque l'appareil quitte le réseau courant. Ce processus permet à un appareil de rejoindre et quitter plusieurs réseaux. La configuration pour un autre réseau en utilisant un réseau cible courant est accomplie comme suit.

a) Le DPSO dans le gestionnaire de système courant récupère des informations de réseau et des clés de sécurité de réseau issues du gestionnaire de système/gestionnaire de sécurité de l'autre réseau.

   NOTE L'interface pour une telle communication entre gestionnaires ne relève pas du domaine d'application de la présente norme.

b) Le DPSO dans le gestionnaire de système courant installe les informations dans le DPO de l'appareil.

c) Le DBP quitte le réseau courant.

d) Lorsque l'appareil quitte le réseau courant, il rejoint le prochain réseau avec l'information de réseau et de sécurité installée dans son DPO.

Comme décrit dans le présent document, il y a plusieurs chemins (et transitions d'états) disponibles pour un appareil non configuré pour être configuré et pour rejoindre finalement un réseau sécurisé. Ces chemins sont montrés par l'intermédiaire du diagramme de transitions d'états à la Figure 137. La Figure 137 est reliée (et équivalente) à la Figure 136; toutefois, la Figure 137 est décrite du point de vue d'un état interne d'appareil.

Keys revoked; device set to default (certificate present)	Clés révoquées, appareil mis aux valeurs par défaut (certificat présent)
Keys revoked; device set to default (no certificate)	Clés révoquées, appareil mis aux valeurs par défaut (aucun certificat)
[1] Will transition to S1.1 if no network information[1] [2] Will transition to S2.1 if no network information[2]	[1] Passera à S1.1 si aucune information réseau[1] [2] Passera à S2.1 si aucune information réseau[2]
Provision (or update) join key and network information for next join (update certificate)	Configurer (ou mettre à jour) la clé de rattachement et les informations réseau pour le prochain rattachement (mise à jour de certificat)

Figure 137 – Diagramme de transitions d'états montrant divers chemins pour rejoindre un réseau sécurisé

Les transitions et les chemins adressés à la Figure 137 comprennent:

a) Configuration OOB de clé symétrique et d'informations de réseau:

   1) Transitions d'états: S0 → S2.1 → S2.2 → S4.

   2) Synopsis: Des mécanismes OOB sont utilisés pour configurer un appareil avec la clé de rattachement à un réseau-cible (S0 –> S2.1) et des informations de réseau (S2.1 → S2.2). Ensuite, l'appareil utilise la procédure de rattachement symétrique (S2.2 → S4) pour rejoindre le réseau sécurisé.

b) Préconfiguré en usine (OOB ou autrement): Clés asymétriques et certificats et configuration OOB d'informations de réseau:

   1) Transitions d'états: S0 → S1.1 → S1.2 → S4.

   2) Synopsis: Un appareil est préconfiguré en usine avec des clés asymétriques et des certificats (S0 → S1.1). L'appareil a les informations nécessaires pour initier une

procédure de rattachement à clés asymétriques. Cependant, il n'a pas assez d'informations relatives à un réseau. Ces informations sont configurées en utilisant le mécanisme OOB (S1.1 → S1.2). Ensuite, l'appareil utilise la procédure de rattachement asymétrique pour rejoindre le réseau sécurisé (S1.2 → S4).

c) Configuration OOB d'informations de clés symétriques et configuration par OTA des informations de réseau:

   1) Transitions d'états: S0 → S2.1 → S3.2 → S2.2 → S4.

   2) Synopsis: Un appareil est configuré en utilisant un mécanisme OOB (ou préconfiguré) avec la clé de rattachement symétrique pour le réseau-cible (S0 → S2.1). L'appareil rejoint alors un réseau de configuration par défaut en utilisant la clé de rattachement par défaut, K_global (S2.1 → S3.2). Le PD dans le réseau de configuration fournit les informations de réseau pour le réseau cible. L'appareil quitte le réseau de configuration (S3.2 → S2.2) et rejoint le réseau sécurisé (S2.2 → S4) en utilisant la procédure de rattachement symétrique.

d) Clés asymétriques et certificats préconfigurés en usine (OOB ou autrement) et configuration par OTA des clés symétriques:

   1) Transitions d'états: S0 → S1.1 → S3.1 → S3.2 → S2.2 → S4.

   2) Synopsis: Un appareil est préconfiguré en usine avec des clés asymétriques et des certificats (S0 → S1.1). L'appareil a les informations nécessaires pour initier une procédure de rattachement à clés asymétriques. Cependant, il ne peut pas rejoindre un réseau-cible qui ne prend pas en charge le processus de rattachement de sous-réseau asymétrique. L'appareil rejoint alors un réseau de configuration par défaut qui est différent du réseau cible en utilisant la clé de rattachement par défaut, K_global (S1.1 → S3.1). Comme partie intégrante de ce réseau de configuration, l'appareil échange ses authentifiants, passe avec succès par un mécanisme défi-réponse, et reçoit du PD la clé de rattachement au réseau cible, chiffrée avec la clé publique de l'appareil (S3.1 → S3.2). L'appareil est alors configuré avec les informations de réseau par OTA. Ensuite, l'appareil quitte le réseau de configuration (S3.2 → S2.2) et rejoint le réseau sécurisé (S2.2 → S4) en utilisant la procédure de rattachement symétrique.

e) Configuration basée sur clé de rattachement ouverte en clair:

   1) Transitions d'états: S0 → S2.1 → S2.2 → S4(1) → S2.2 → S4(2).

   2) Synopsis: Un appareil qui a la clé de rattachement symétrique ouverte par défaut. Il utilise la procédure à clé de rattachement symétrique pour rejoindre un réseau de configuration (S2.2. → S4(1)). Comme partie intégrante de ce réseau de configuration, l'appareil est configuré avec la clé de rattachement au réseau cible et les informations de réseau. L'appareil quitte ensuite le réseau de configuration (S4(1) → S2.2). L'appareil est maintenant configuré pour rejoindre le réseau-cible; il rejoint le réseau-cible sécurisé en utilisant le processus de rattachement de sous-réseau à clé symétrique (S2.2 → S4(2)). Dans cette transition, la première fois que l'appareil a rejoint un réseau de configuration est indiquée par l'état S4(1), et la deuxième fois qu'il est rattaché au réseau cible est indiquée par l'état S4(2). Après que l'appareil a atteint S4(2), l'appareil ne peut pas utiliser la clé de rattachement symétrique ouverte, à moins qu'il soit réinitialisé aux valeurs d'usine par défaut.

13.8 Objets de protocole d'application de gestion d'appareil utilisés au cours de la configuration

La présente norme utilise un objet de DMAP et un objet SMAP au cours de la configuration. L'objet de configuration d'appareil (DPO) détient les réglages de configuration. La Figure 138 montre des objets de configuration et les interactions entre eux.

Figure 138 – Objets de configuration et interactions

Qu'il soit le gestionnaire de système/gestionnaire de sécurité dans un appareil tenu à la main ou le gestionnaire de système du réseau cible, le PD doit mettre en œuvre un objet de service de configuration d'appareil (DPSO) avec des attributs et des méthodes pour configurer le DBP. Le DPSO peut avoir une liste de clés symétriques, utilisée pour configurer des appareils qui n'ont pas de clés préinstallées.

La liste blanche, les informations de clés symétriques, et les informations de réseau-cible dans le DPSO peuvent être maintenues avec des informations spécifiques à un appareil dans l'attribut White_List_Array dans le Tableau 372. En variante, un groupe de clés symétriques valides peut être maintenue.

Lorsque le DBP rejoint le réseau de configuration en utilisant K_global, un contrat est établi entre le PD et le DBP. Le DPSO dans le PD peut utiliser le contrat établi pour communiquer avec le DPO dans le DBP. Les primitives des services read et write sont utilisées pour accéder aux attributs du DPO et les positionner. Un sous-ensemble d'informations de réseau et de confiance peut maintenant être configuré dans le DPO en utilisant le DPSO. Pour écrire la nouvelle clé de rattachement symétrique dans l'appareil, le DPSO invoque la méthode de Write_Join_key du DPO. Cette méthode est permise si la nouvelle valeur de clé a été reçue sous la protection de la cryptographie asymétrique. Les attributs dans le DPO comprennent des informations tant relatives à un réseau que relatives à la confiance.

Il convient que les utilisateurs qui désirent plus de sécurité pendant la configuration utilisent l'authentification par cryptographie asymétrique et la technique de chargement de clés sécurisées pendant les étapes relatives à la confiance. En variante, des mécanismes hors bande peuvent être utilisés pour configurer des clés de rattachement.

Une fois que les informations appropriées relatives à la confiance et à un réseau ont été configurées dans le DPO, l'appareil est prêt à rejoindre le réseau cible. Le réseau de configuration peut également être utilisé pour la configuration d'appareil. Sachant qu'un contrat a été déjà établi, le PD peut également utiliser le réseau (ou des moyens OOB) pour configurer les objets UAP et DMAP appropriés du DBP.

L'objet de configuration d'appareil (DPO) fournit un attribut appelé le Target_DL_Config dans le format de DL_Config_Info. DL_Config_Info est décrit à l'Article 9 (voir Tableau 102) pour configurer divers attributs de la DL. Une fois qu'il est configuré avec cet attribut, le DPO fournit à la DL un OctetString encapsulant DL_Config_Info qui inclut au moins une supertrame, et au moins une liaison, qui peuvent être utilisées par la DL pour rechercher des annonces. Des modèles d'intervalles de temps spécifiques à un réseau cible (par exemple, autres que par défaut), des profils de sauts de voies, des supertrames et des liaisons peuvent également être fournis au DBP par l'attribut Target_DL_Config. Une telle configuration aide à réduire la quantité d'informations (supertrames de rattachement, par exemple) qui autrement seraient tenues d'être annoncées par les routeurs d'annonce de réseau cible.

La DL de l'appareil joue un rôle majeur au cours de la configuration et du rattachement de l'appareil. Le diagramme d'états de la DL lorsqu'elle passe par le processus de configuration est décrit en 9.1.14.2.

Si le processus de configuration est réussi, le DPO fournit à la DL le jeu d'attributs, y compris les informations relatives au sous-réseau D, les supertrames, et les liaisons, que la DL peut utiliser pour rechercher le réseau cible et le(s) sous-réseau(x) D correspondants. Dans l'état "provisoned", la DL actionne son diagramme d'états tel qu'il est configuré dans les supertrames et les liaisons qui ont été fournies par le DPO. Le fonctionnement de la supertrame peut être retardé ou désactivé en positionnant le champ IdleTimer dans la supertrame.

Sachant que l'appareil retient les informations utilisées pour configurer la DL (tous les attributs du DPO), cela assure un moyen de réinitialiser la DL à son état "provisioned" en mettant la DL dans son état par défaut et en ajoutant ensuite les attributs configurés.

Le DPO doit être accessible au gestionnaire de système du réseau cible après s'être rattaché avec Key_Join. Une fois que l'appareil rejoint un réseau cible, le gestionnaire de système du réseau cible a la capacité de changer les attributs du DPO. Le gestionnaire de système du réseau cible a la capacité d'ordonner à l'appareil de rejoindre un autre réseau cible en fournissant des informations de réseau et de confiance de l'autre réseau. Selon la valeur du bit de configuration A4, le gestionnaire de système du réseau cible a la capacité d'invoquer une méthode DPO.Reset_To_Defaults pour retirer de l'appareil les informations de confiance.

NOTE Dans la phase de configuration, le DPO dans le DBP est accessible par la fonctionnalité de gestionnaire de système/gestionnaire de sécurité dans le PD.

13.9 Objets de gestion

13.9.1 Objet de configuration d'appareil

Le Tableau 368 décrit les attributs du DPO. Le type de données, la valeur par défaut, et une courte description sont fournis pour chaque attribut. Chaque attribut a également l'accessibilité de lecture seule ou de lecture/écriture. Les attributs du DPO sont accessibles seulement au gestionnaire de système/gestionnaire de sécurité. La valeur d'un attribut en lecture seule peut être positionnée seulement au moment de la fabrication d'appareil (à savoir à un moment avant que l'appareil soit certifié) ou en interne par l'appareil; aucune entité externe à l'appareil ne peut changer cet attribut. L'accessibilité en lecture/écriture implique que les entités externes à l'appareil peuvent changer la valeur de l'attribut. Les attributs du DPSO sont seulement accessibles (lecture/écriture) au gestionnaire de système.

La valeur des attributs constants n'est pas changée pendant le cycle de vie de l'appareil, ni intérieurement ni extérieurement. La définition de la classification est donnée en 12.6.3.

Tableau 368 – Objet de configuration d'appareil *(1 de 7)*

Nom du type d'objet normalisé: Device provisioning object (DPO, objet de configuration d'appareil)				
Identificateur du type d'objet normalisé: 120				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Default_NWK_ID	1	Une identification réseau publiée pour le réseau par défaut	Type: Unsigned16 Classification: Constant Accessibilité: Lecture seule (Read Only) Valeur par défaut: 0x0001	Il s'agit de l'identification réseau pour le réseau par défaut. Le réseau par défaut peut être utilisé pour former le mini-réseau de configuration
Default_SYM_Join_Key	2	Une clé de rattachement publiée du réseau par défaut	Type: Clé symétrique (SymmetricKey) Classification: Constant Accessibilité: Lecture seule (Read Only) Valeur par défaut: K_global, 7.2.2.2	Cette clé est utilisée par des appareils pour rejoindre le réseau par défaut. Les clés par défaut peuvent être utilisées pour former le mini-réseau de configuration
Open_SYM_Join_Key	3	Une clé de rattachement publiée du réseau par défaut	Type: Clé symétrique (SymmetricKey) Classification: Constant Accessibilité: Lecture seule (Read Only) Valeur par défaut: K_open, 7.2.2.2	Cette clé est utilisée par des appareils pour rejoindre le réseau de configuration non sécurisé

Tableau 368 *(2 de 7)*

Nom du type d'objet normalisé: Device provisioning object (DPO, objet de configuration d'appareil)				
Identificateur du type d'objet normalisé: 120				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Default_Channel_List	4	La liste des voies 2,4 GHz utilisées par le réseau par défaut. L'attribut est codé comme un matriciel de 16 bits pour représenter les 16 fréquences	Type: Unsigned16 Classification: Constant Accessibilité: Lecture seule (Read Only) Valeur par défaut: 0x7FFF	La liste des voies utilisées par les routeurs d'annonce du réseau par défaut. Pour rejoindre le réseau par défaut, l'appareil peut recevoir des annonces sur n'importe laquelle des fréquences
Join_Method_Capability	5	Les capacités d'attachement de l'appareil	Type: Unsigned2 Classification: Constant Accessibilité: Lecture/écriture Valeur par défaut: 00 Valeurs nommées: 00= rattachement par défaut seulement 01= rattachement à clés symétriques seulement 10= rattachement à clés asymétriques seulement 11= tout rattachement à clés	Cet attribut définit les capacités d'attachement d'un appareil. L'appareil peut utiliser soit les clés symétriques, soit l'infrastructure à clés asymétriques pour rejoindre un réseau cible. Cet attribut définit simplement les capacités de l'appareil. La véritable méthode utilisée pour rejoindre le réseau cible doit être définie par le PD
Allow_Provisioning	6	Une valeur booléenne définie pour indiquer si un appareil peut ou non être configuré	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: vrai	Cet indicateur est utilisé pour verrouiller l'état d'un appareil déjà configuré. Si cette valeur est mise, l'appareil n'acceptera aucune lecture ou écriture dans les attributs de réseau cible

Tableau 368 *(3 de 7)*

Nom du type d'objet normalisé: Device provisioning object (DPO, objet de configuration d'appareil)				
Identificateur du type d'objet normalisé: 120				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Allow_Over_The_Air_ Provisioning	7	Une valeur booléenne définie pour indiquer si un appareil peut ou non être configuré	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: vrai	Ce booléen indique si la configuration par liaison radio est activée ou désactivée. Si la configuration par liaison radio est désactivée, l'appareil doit être configuré avec une méthode hors bande. Cette valeur doit être définie sur false pour les appareils dorsaux. Dans tous les cas, la configuration n'est autorisée que si l'attribut Allow_Provisioning est activé
Allow_OOB_Provisioning	8	Une valeur booléenne définie pour indiquer si un appareil peut ou non être configuré à l'aide de moyens OOB	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: vrai	Le booléen permet d'empêcher les appareils d'accepter des informations de configuration par des moyens OOB
Allow_Reset_to_Factory_ Defaults	9	Une valeur booléenne définie pour indiquer si un appareil peut ou non être réinitialisé à ses valeurs d'usine par défaut	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: vrai	Ce booléen permet de bloquer la réinitialisation des appareils à leurs valeurs par défaut d'usine par un gestionnaire de système
Allow_Default_Join	10	Une valeur booléenne définie pour indiquer si un appareil peut s'attacher à un réseau à l'aide des clés par défaut	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: vrai	Ce booléen est utilisé pour forcer les appareils à s'attacher à un réseau cible en particulier et à ne pas s'attacher à n'importe quel réseau par défaut. Les appareils qui choisissent de ne pas s'attacher à un réseau par défaut peuvent définir cet attribut sur false

Tableau 368 *(4 de 7)*

Nom du type d'objet normalisé: Device provisioning object (DPO, objet de configuration d'appareil)				
Identificateur du type d'objet normalisé: 120				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Target_NWK_ID	11	L'ID réseau du réseau cible auquel cet appareil est configuré pour s'attacher	Type: Unsigned16 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: 0	Cet attribut indique le réseau cible que cet appareil doit rejoindre [a]
Target_NWK_BitMask	12	Bitmask pour la correspondance des bits de l'ID du réseau cible	Type: Unsigned16 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: 0xFFFF	Le bitmask est utile pour la correspondance de plusieurs réseaux cibles. Si la valeur d'un bit dans le bitmask est 1, le bit doit avoir une correspondance exacte avec le bit correspondant dans le réseau cible. La valeur par défaut des 1 partout indique que tous les bits de l'ID de réseau ont besoin de concorder
Target_Join_Method	13	Indique s'il convient que l'appareil utilise le mécanisme d'attachement de clé symétrique ou de clé asymétrique pour s'attacher au réseau cible	Type: Unsigned1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: 1 Valeurs nommées: 0: clé symétrique 1: clé asymétrique	Le paragraphe 7.4.4 définit deux méthodes différentes pour le rattachement en fonction de l'utilisation soit de clés symétriques, soit de certificats à clés asymétriques. Cet attribut établit la méthode devant être utilisée pour rejoindre un réseau cible
Target_Security_Manager_EUI	14	L'adresse EUI64 du gestionnaire de sécurité dans le réseau cible que l'appareil est censé rejoindre	Type: AdresseEUI64 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: 0xFF…FF (all 0xFF)	Définit sur EUI64Address pour le gestionnaire de sécurité que l'appareil est configuré à rejoindre

Tableau 368 *(5 de 7)*

Nom du type d'objet normalisé: Device provisioning object (DPO, objet de configuration d'appareil)				
Identificateur du type d'objet normalisé: 120				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Target_System_Manager_Address	15	L'adresse IPv6 du gestionnaire de sécurité/système dans le réseau cible que l'appareil est censé rejoindre	Type: IPv6Address Classification: Statique Accessibilité: Lecture/écriture	L'adresse IPv6 est exigée pour que des appareils dorsaux rejoignent le réseau. Les appareils dorsaux n'ont pas un routeur d'annonce – donc, une demande de rattachement est envoyée à l'adresse IPv6 du gestionnaire de système/gestionnaire de sécurité pour commencer le processus de rattachement. Les appareils E/S et les appareils de routage peuvent ne pas être configurés avec cet attribut
Target_Channel_List	16	La liste des voies utilisées par le réseau cible. L'attribut est codé comme un matriciel de 16 bits pour représenter les 16 fréquences	Type: BitArray16 Classification: Statique Accessibilité: Lecture/écriture	Le réseau cible peut être en train d'utiliser seulement un sous-ensemble de voies pour des annonces par les routeurs de rattachement. En utilisant seulement un sous-ensemble des fréquences, les appareils alimentés par batteries peuvent rapidement rejoindre le réseau cible en se mettant à l'écoute dans ce sous-ensemble de fréquences seulement
Target_DL_Config	17	Les informations de configuration de DL pour cet appareil	Type: OctetString Classification: Statique Accessibilité: Lecture / Ecriture	Cet attribut indique les différents paramètres de configuration pour le DL de l'appareil. La structure de cet attribut est définie dans DL_Config_Info définie à l'Article 9

Tableau 368 *(6 de 7)*

			Classification: Statique	
			Accessibilité: Lecture/écriture	
			Valeur par défaut: 35	

[a] Si Target_NWK_BitMask (attribut 12) est défini sur 0xFFFF, l'appareil doit ignorer les annonces des routeurs qui appartiennent à un autre réseau que le réseau cible indiqué. Dans le cas contraire, une combinaison d'ID réseau et de bitmask doit être utilisée. (Voir la description de l'attribut 12 sur la façon dont le NetworkID et le bitmask sont combinés.) Cela aide avec les rattachements rapides et empêche également des appareils d'essayer de rejoindre tous les réseaux dans leur voisinage. Cette valeur peut être mise à 0 pour permettre des réponses à n'importe quel routeur d'annonce.

13.9.2 Méthodes et alertes d'objet de configuration d'appareil

Plusieurs méthodes et alertes sont disponibles dans le DPO. Le Tableau 369 décrit la méthode Reset_To_Default.

Tableau 369 – Méthode Reset_To_Default

Nom du type d'objet normalisé: Device provisioning object (DPO, objet de configuration d'appareil)				
Identificateur du type d'objet normalisé: 120				
Nom de méthode	**ID de méthode**	**Description de la méthode:**		
Reset_To_Default	1	Cette méthode est utilisée pour réinitialiser aux valeurs de réglage par défaut pour la configuration. Cette méthode ne doit être exécutée que quand Allow_Provisioning est activé		
	Input arguments (aucun)			
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Etat	Unsigned8	Valeurs nommées: 0: réussite; autre: échec

Le Tableau 370 décrit la méthode pour écrire une clé de rattachement symétrique. La clé de rattachement ne doit être pas exposée à un appareil distant, et peut être exposée à un processus interne limité. La méthode DPO.Write_Symmetric_Join_Key() installe une clé de rattachement dans une zone de mémoire qui n'est pas utilisée pour des attributs (stockage sécurisé, par exemple).

Tableau 370 – Méthode d'écriture de clé de rattachement symétrique

13.10 Objet service de configuration d'appareil

13.10.1 Attributs de l'objet service de configuration d'appareil

Le Tableau 371 décrit les attributs du DPSO.

Le gestionnaire de système peut choisir soit les informations de configuration particulières pour chaque adresse EUI64, soit un jeu de clés de rattachement pour un ensemble d'adresses EUI64 sans mapping biunivoque. L'attribut Boolean1 DPSO.Enable_White_List_Array est utilisé pour spécifier quelle méthode est utilisée.

Dans le DPSO.Enable_White_List_Array mis, DPSO.White_List_Array est utilisé pour installer des informations de configuration particulières pour chaque adresse EUI64 du DBP.

Si DPSO.Enable_White_List_Array n'est pas mis, le PD doit vérifier s'il y a au moins autant d'entrées dans DPSO.SYM_Key_List que d'entrées dans DPSO.White_List. La présente norme ne spécifie pas comment chaque entrée dans DPSO.SYM_Key_List et DPSO.White_List est mise en mapping.

Tableau 371 – Objet service de configuration d'appareil *(1 de 4)*

Nom du type d'objet normalisé: Device provisioning service object (DPSO, objet service de configuration d'appareil ()				
Identificateur du type d'objet normalisé: 106				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
White_List	1	Une liste d'appareils autorisés à être configurés par cet objet	Type: Array of EUI64Address Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: [ ] -- empty	Cette liste contient les adresses EUI64 de l'appareil en cours de configuration. Cette liste peut être utilisée pour limiter un appareil de configuration à configurer seulement un ensemble d'appareils dont les adresses EUI64 sont dans cette liste. Si cette liste est vide, l'appareil de configuration peut configurer n'importe quel appareil
Symmetric_Key_List	2	Une liste de clés de rattachement valides avec lesquelles un appareil peut être configuré	Type: Array of SymmetricKey Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: {K_global] -- 7.2.2.2	Cette clé est utilisée par des appareils pour rejoindre le réseau cible avec une entropie suffisante
Symmetric_Key_Expiry_Times	3	Le temps d'expiration pour chaque clé	Type: Array of TAITimeRounded Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: [0xFFFF FFFF] [a]	Cet attribut établit le temps d'expiration de chacune des clés symétriques. La clé est seulement utilisée pour la configuration si elle n'a pas expiré
Target_NWK_ID	4	L'ID de réseau du réseau-cible que les appareils configurés par cet objet sont censés rejoindre	Type: Unsigned16 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: 0	Cet attribut indique le réseau cible (ID de sous-réseau) qu'un appareil configuré doit rejoindre

Tableau 371 *(2 de 4)*

Nom du type d'objet normalisé: Device provisioning service object (DPSO, objet service de configuration d'appareil ()				
Identificateur du type d'objet normalisé: 106				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Target_Join_Method	5	Valeur booléenne pour indiquer s'il convient que les appareils configurés par cet objet utilisent le mécanisme d'attachement de clé symétrique ou de clé asymétrique pour s'attacher au réseau cible	Type: Unsigned8 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: 0	L'Article 7 définit deux méthodes différentes pour le rattachement en fonction de l'utilisation de clés symétriques ou asymétriques. Cet attribut établit la méthode devant être utilisée pour rejoindre un réseau cible. Valeurs nommées: 0: clé symétrique; 1: clé asymétrique
Target_Security_Manager_EUI	6	L'adresse EUI64 du gestionnaire de sécurité dans le réseau cible que l'appareil configuré par cet objet est censé rejoindre	Type: AdresseEUI64 Classification: Statique Accessibilité: Lecture/écriture	Définit sur EUI64Address pour le gestionnaire de sécurité que l'appareil est configuré à rejoindre
Target_System_Manager_Address	7	L'adresse IPv6 du gestionnaire de sécurité/système dans le réseau cible que l'appareil configuré par cet objet est censé rejoindre	Type: IPv6Address Classification: Statique Accessibilité: Lecture/écriture Plage valide: toutes les valeurs avec réglage sur bit le plus élevé	L'adresse IPv6 est exigée pour que des appareils dorsaux rejoignent le réseau
Target_Channel_List	8	La liste des voies utilisées par le réseau par défaut. L'attribut est codé comme un matriciel de 16 bits pour représenter les 16 fréquences	Type: BitArray16 Classification: Statique Accessibilité: Lecture/écriture	Le réseau cible peut être en train d'utiliser seulement un sous-ensemble de voies pour des annonces par les routeurs de rattachement
Target_DL_Config	9	Les informations de configuration de DL pour que l'appareil soit configuré par cet objet	Type: OctetString Classification: Statique Accessibilité: Lecture / écriture	Cet attribut indique les différents paramètres de configuration pour le DL de l'appareil. La structure de cet attribut est définie dans DL_Config_Info définie à l'Article 9, dans le Tableau 102

Tableau 371 *(3 de 4)*

Nom du type d'objet normalisé: Device provisioning service object (DPSO, objet service de configuration d'appareil ()				
Identificateur du type d'objet normalisé: 106				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
Allow_Provisioning	10	Une valeur booléenne définie pour indiquer si un appareil peut ou non être à nouveau configuré	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: vrai	Cet indicateur est utilisé pour verrouiller l'état futur d'un appareil configuré
Allow_Default_Join	11	Une valeur booléenne définie pour indiquer si un appareil configuré par cet objet peut s'attacher à un réseau à l'aide des clés par défaut	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: Not_allowed (0)	Cet indicateur est utilisé pour forcer les appareils configurés à s'attacher à un réseau cible en particulier et à ne pas s'attacher à un réseau par défaut. Une fois configuré, il convient que l'appareil s'attache au réseau cible
Enable_White_List_Array	12	Une valeur booléenne définie pour indiquer si l'objet de configuration est conçu pour définir des informations de configuration spécifiques pour l'appareil	Type: Boolean1 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: faux	SI ce fanion est mis, le DPSO est capable de configurer des appareils différents (sur la base de l'adresse EUI 64) avec des informations de configuration différentes. Cela peut être utilisé pour configurer un appareil particulier, avec un gestionnaire de sécurité particulier et un Target_Join_Time particulier, par exemple
White_List_Array	13	Une matrice des adresses au format EUI que le DPSO vise à configurer avec les informations de configuration correspondantes pour l'appareil en question	Type: Array of DPSOWhiteListTbl Classification: Statique Accessibilité: Lecture/écriture	Cet attribut ne doit être utilisé que si Device_specific_provisioning_flag est défini. Il contient les informations de configuration spécifiques à l'appareil comme des clés de rattachement spécifiques à un appareil, un gestionnaire de sécurité cible spécifique à un appareil, etc.
White_List_Array_Meta	14	Métadonnées pour White List Array (Attribut 13) ou ensemble de White_List (Attribut 1) et SYM_Key_List (Attribut 2)	Type: Metadata_attribute Classification: Statique Accessibilité: Lecture seule (Read only)	Métadonnées contenant un compte du nombre d'entrées et la capacité (le nombre total de rangées autorisé) de la table White_List_Array ou de l'ensemble de White_List [b]

Tableau 371 *(4 de 4)*

Nom du type d'objet normalisé: Device provisioning service object (DPSO, objet service de configuration d'appareil ()				
Identificateur du type d'objet normalisé: 106				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
DPSO_Alerts_AlertDescriptor	15	Utilisé pour changer la priorité des alertes de DPSO qui appartiennent à la catégorie de sécurité; ces événements peuvent également être activés ou désactivés	Type: Alert report descriptor (descripteur de rapports d'alertes) Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: [faux, 6]	Voir la description des alertes au Tableau 374 et au Tableau 375
Current_UTC_Adjustment	16	La valeur actuelle de l'ajustement de seconde intercalaire accumulée de l'UTC	Type: Integer16 Classification: Statique Accessibilité: Lecture/écriture Valeur par défaut: 35	Voir le Tableau 25, l'attribut 1 et la note de pied de page

[a] Lorsqu'un délai d'expiration de clé calculé donne la valeur 0xFFFF FFFF comme résultat, il est augmenté (circulairement) à la valeur modulo 0x0000 0000, ainsi la valeur 0xFFFF FFFF peut être utilisée pour désigner une clé qui n'expire jamais.

[b] Si Enable_White_List_Array est activé, cet attribut spécifie un compte du nombre d'entrées et de la capacité pour White_List_Array. Si Enable_White_List_Array est désactivé, cet attribut spécifie un compte du nombre d'entrées et de la capacité pour l'ensemble de White_List et de SYM_Key_List.

13.10.2 Attributs structurés de l'objet service de configuration d'appareil

Le Tableau 372 décrit les attributs structurés du DPSO. White_List_Array est utilisé lorsque le PD a des informations spécifiques à un appareil, c'est-à-dire, si le PD a des clés de rattachement symétriques et d'autres attributs qui sont spécifiques à un appareil. Dans ce cas, il est exigé une matrice structurée qui stocke les informations de configuration indexées par l'identificateur d'adresse EUI64 du DBP. Cette matrice indexée est décrite dans le Tableau 372.

Après que le PD a reçu l'attribut Device_SYM_Key provenant du gestionnaire de sécurité, le PD ne doit pas dévoiler l'attribut Device_SYM_Key à l'extérieur.

NOTE L'interface entre le PD et le gestionnaire de sécurité ne relève pas du domaine d'application de la présente norme.

Tableau 372 –Structure de données DPSOWhiteListTbl

Nom du type de données normalisé: DPSOWhiteListTbl		
Code du type de données normalisé: 440		
Nom de l'élément	**Identificateur de l'élément**	**Type de l'élément scalaire**
Device_EUI	1	Type: Array of EUI64Address
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
		Valeur par défaut: [ ] -- empty
Device_Tag	2	Type: Array of VisibleString
		Classification: Statique
		Accessibilité: Lecture/écriture
		Valeur par défaut: [""]
Symmetric_Key_List	3	Type: Array of SymmetricKey
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
		Valeur par défaut: {K_global] -- 7.2.2.2
Symmetric_Key_Expiry_Times	4	Type: Array of TAIRounded
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
		Valeur par défaut: [0xFFFF FFFF] [a]
Target_NWK_ID	5	Type: Unsigned16
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
		Valeur par défaut: 0
Target_Join_Method	6	Type: Unsigned8
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
		Valeur par défaut: 1
		Valeurs nommées: 0: clé symétrique; 1: clé asymétrique
Target_Security_Manager_EUI	7	Type: AdresseEUI64
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
Target_System_Manager_Address	8	Type: IPv6Address
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
		Plage valide: toutes les valeurs avec réglage sur bit le plus élevé
Target_Channel_List	9	Type: Array of Unsigned8
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
Target_DL_Config	10	Type: OctetString (voir DL_Config_Info pour le format)
		Classification: Statique
		Accessibilité: Lecture seule (Read only)
Allow_Provisioning	11	Type: Boolean1
		Classification: Statique
		Accessibilité: Lecture/écriture
		Valeur par défaut: vrai
Allow_Default_Join	12	Type: Boolean1
		Classification: Statique
		Accessibilité: Lecture/écriture
		Valeur par défaut: vrai

[a] Lorsqu'un délai d'expiration de clé calculé donne la valeur 0xFFFF FFFF comme résultat, il est augmenté (circulairement) à la valeur modulo 0x0000 0000, ainsi la valeur 0xFFFF FFFF peut être utilisée pour désigner une clé qui n'expire jamais.

Quand il n'est pas égal à null, Device_Tag spécifie un Tag_Name affecté à l'appareil par un utilisateur. Cette valeur doit être écrite dans l'attribut Tag_Name du DMO (voir 6.2.8).

13.10.3 Méthode de l'objet service de configuration d'appareil

Plusieurs méthodes sont disponibles pour manipuler le DPSO. Les méthodes normalisées telles que read et write peuvent être utilisées pour les MIB (SMIB) scalaires ou structurées

dans leur intégralité. Les méthodes décrites dans le présent document sont utilisées pour manipuler des tables. Ces méthodes permettent l'accès à une rangée particulière d'une SMIB structurée en fonction d'un champ clé unique.

Il est supposé que les tables ont un champ clé unique, qui peut être soit un seul élément, soit la concaténation de plusieurs éléments. Le champ clé est supposé être le(s) (quelques) premier(s) élément(s) de la table ou la concaténation des quelques premiers éléments de la table.

Le Tableau 373 décrit les méthodes pour la manipulation des MIB structurées. Ces méthodes sont basées sur les modèles Read_Row, Write_Row, et Delete_Row définis en Annexe J.

Tableau 373 – Table de manipulation de matrice

Nom du type d'objet normalisé: Device provisioning service object (DPSO, objet service de configuration d'appareil)		
Identificateur du type d'objet normalisé: 106		
Nom de méthode	**ID de méthode**	**Description de la méthode**
Setrow_WhiteListTbl	1	Méthode pour établir (soit écrire, soit modifier) la valeur d'une seule rangée de la matrice de liste blanche. La méthode utilise le modèle de méthode Write_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID:14 (White_List_Array) Index 1: 1 (Device_EUI)
Getrow_WhiteListTbl	2	Méthode pour obtenir la valeur d'une seule rangée de la matrice de liste blanche. La méthode utilise le modèle de méthode Read_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID:14 (White_List_Array) Index 1: 1 (Device_EUI)
Deleterow_WhiteListTbl	3	Méthode pour supprimer la valeur d'une seule rangée de la matrice de liste blanche. La méthode utilise le modèle de méthode Delete_Row défini à l'Annexe J avec les arguments suivants: Attribute_ID:14 (White_List_Array) Index 1: 1 (Device_EUI)

13.10.4 Alertes de l'objet service de configuration d'appareil

Le Tableau 374 décrit une alerte pour indiquer une tentative de rattachement effectuée par un appareil qui n'est pas sur la liste blanche.

Tableau 374 – Alerte de DPSO pour indiquer le rattachement par un appareil ne figurant pas sur la WhiteList

Nom du type d'objet normalisé: Device provisioning service object (DPSO, objet service de configuration d'appareil)					
Identificateur du type d'objet normalisé: 106					
Description de l'alerte: Alerte pour indiquer la demande de rattachement par un appareil ne figurant pas sur la liste blanche					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alertes (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: haut, moyen, faible, journal seulement)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = événement	2 = sécurité	0 = Not_On_ Whitelist_Alert	6 = Moyen	Type: AdresseEUI64	Adresse EUI64 d'un appareil pas dans la liste blanche

Le Tableau 375 décrit une alerte pour indiquer qu'une capacité inadéquate est disponible pour qu'un appareil rejoigne le réseau.

Tableau 375 – Alerte de DPSO pour indiquer une capacité inadéquate de rattachement d'un appareil

Nom du type d'objet normalisé: Device provisioning service object (DPSO, objet service de configuration d'appareil)					
Identificateur du type d'objet normalisé: 106					
Description de l'alerte: Alerte pour indiquer une capacité inadéquate de rattachement d'un appareil					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alertes (Enumerated: en fonction de la catégorie d'alertes)**	**Priorité d'alertes (Enumerated: haut, moyen, faible, journal seulement)**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
0 = événement	2 = sécurité	1 = Inadequate_Join_ Capability_Alert	6 = Moyen	Type: struct { reason: Unsigned8; rejectedDevice: EUI64Address}	Le champ reason fournit un code de diagnostic. Valeurs nommées: 1: mauvaise clé de rattachement; 2: clé de rattachement expirée; 3: authentification échouée Le champ rejectedDevice spécifie l'adresse EUI64 de l'appareil qui a tenté de s'attacher

13.10.5 Résumé des attributs qui peuvent être configurés

Ce qui suit est un résumé des attributs qui sont configurés par le PD afin qu'un nouvel appareil puisse rejoindre un réseau cible. Ces attributs peuvent être configurés en utilisant

des méthodes par liaison radio (OTA) ou des méthodes OOB. La liste d'attributs configurés comporte les éléments suivants. La liste complète est définie par le Tableau 368, le Tableau 371 et le Tableau 372.

- Informations relatives à la confiance:
  - clé de rattachement symétrique (K_join);
  - Adresse EUI64 du gestionnaire de sécurité;
  - méthode de rattachement au réseau.
- Informations relatives à un réseau:
  - network ID et bitmask;
  - Adresse IPv6 du gestionnaire de sécurité;
  - configuration de DL (contient les supertrames, TsTemplate de liaison, informations de voies, etc., exigé pour rejoindre le réseau cible).

En outre, les bits de configuration (attributs 6..10 du DPO), décrivant le comportement de l'appareil, peuvent être mis par l'appareil de configuration.

13.11 Fonctions de configuration (informative)

13.11.1 Généralités

L'interface et les procédures de configuration décrites dans le présent document ne décrivent pas une interface homme-machine (IHM). La présente norme ne spécifie pas une IHM spécifique, mais elle décrit comment de tels outils peuvent être conçus pour configurer des appareils conformes à la présente norme. Dans des opérations en installation, un utilisateur peut saisir des données de configuration et accepter ou rejeter des appareils souhaitant être configurés, en utilisant un appareil tenu à la main ou une interface en un certain emplacement central.

Les scénarios de configuration à l'Article 13 sont des exemples de configuration en utilisant des méthodes décrites par la présente norme.

13.11.2 Exemples de méthodes de configuration

13.11.2.1 Généralités

Des exemples sont débattus dans le présent document concernant la façon dont les objets et les procédures de gestion décrits peuvent être utilisés pour configurer un appareil. Ces exemples utilisent les méthodes de configuration suivantes:

- configuration par liaison radio utilisant des clés de rattachement préinstallées;
- configuration utilisant des mécanismes hors bande;
- configuration par liaison radio utilisant des certificats à clés asymétriques (PKI, par exemple);
- configuration par liaison radio utilisant des routeurs d'annonce à double rôle; et
- configuration de routeurs dorsaux.

13.11.2.2 Configuration par liaison radio utilisant des clés de rattachement préinstallées

Les étapes pour configurer un appareil avec des informations de confiance préinstallées peuvent notamment être:

a) L'appareil arrive au site de déploiement avec des clés préinstallées. Les clés sont des clés de rattachement symétriques.

b) Une WhiteList d'adresses d'appareil et de leurs clés symétriques correspondantes est installée dans le gestionnaire de sécurité du réseau-cible. Le mécanisme par lequel ces clés sont installées dans le gestionnaire de sécurité ne relève pas du domaine d'application de la présente norme. La WhiteList et les clés symétriques correspondantes peuvent être envoyées par courrier électronique sécurisé, envoyées sur des CD, remises à la main et saisies au clavier, ou livrées en utilisant n'importe quel autre outil approprié.

c) Le réseau-cible peut utiliser un sous-ensemble de fréquences autorisées et peut fonctionner dans le voisinage (à savoir dans la gamme d'interférence) de plusieurs réseaux distincts conformes à la présente norme. Dans ce cas, les informations relatives à un réseau peuvent être configurées dans l'appareil. Ces informations permettent à l'appareil de répondre à des annonces issues de réseaux-cibles seulement, et également de se mettre à l'écoute pour détecter des annonces aux fréquences correctes et au temps correct, diminuant ainsi les interférences et les temps de rattachement. Les informations relatives à un réseau peuvent être configurées en utilisant un PD par l'intermédiaire d'un mécanisme de communication hors bande ou par l'intermédiaire de mécanismes par liaison radio. Lorsqu'il n'est pas configuré avec des informations spécifiques de réseau cible, l'appareil peut essayer toutes les voies et tenter de rejoindre tous les réseaux dans son voisinage.

d) L'appareil se met à l'écoute pour détecter des annonces issues d'un routeur d'annonce dans le réseau-cible. Une fois qu'une annonce est entendue, l'appareil envoie une demande de rattachement au gestionnaire de système/gestionnaire de sécurité du réseau cible. (Le processus de rattachement de sous-réseau est décrit en 7.4.)

e) Le gestionnaire de système/gestionnaire de sécurité vérifie sa WhiteList et puis vérifie pour voir si la clé de rattachement de l'appareil concorde avec la clé de rattachement pour l'appareil fournie au gestionnaire de sécurité. Si les clés de rattachement concordent, le gestionnaire de sécurité fournit à l'appareil une clé principale qui est une clé secrète partagée entre le gestionnaire de sécurité et l'appareil. En outre, des clés T et des clés D sont fournies, et un contrat est établi avec le nouvel appareil pour parachever le processus de rattachement de sous-réseau.

13.11.2.3 Configuration utilisant des mécanismes hors bande

Les étapes pour configurer un appareil en utilisant un appareil de configuration OOB pourrait notamment être:

a) Un appareil frais arrive au site utilisateur. L'appareil a des réglages par défaut et n'a pas des clés préinstallées.

b) Un PD (par exemple, un appareil tenu à la main) obtient une liste de clés symétriques générées par le gestionnaire de sécurité/gestionnaire de système du réseau-cible. Les clés symétriques sont limitées dans le temps. Les clés peuvent être un éventail de clés ou des paires clé/adresse EUI64 spécifiques à un appareil, à la discrétion du gestionnaire de sécurité/du gestionnaire de système. Ces informations sont stockées dans le PD.

c) L'appareil tenu à la main, chargé avec les clés symétriques, est apporté à proximité du nouvel appareil ou relié au nouvel appareil et il est établi une connexion OOB entre l'appareil tenu à la main et le DBP. L'appareil tenu à la main utilise alors l'interface de communication OOB pour peupler les attributs du DPO dans le nouvel appareil. La communication OOB peut se produire en infrarouge, par connexion physique, par communication de champ proche ou d'autres moyens.

d) L'appareil est maintenant prêt à rejoindre le réseau-cible et se met à l'écoute pour détecter des annonces issues du réseau-cible. L'appareil répond aux annonces en envoyant une demande de rattachement, par l'intermédiaire du routeur d'annonce, au gestionnaire de système cible. Le gestionnaire de sécurité vérifie sa WhiteList, le cas échéant. Le gestionnaire de sécurité vérifie également la validité de la clé de rattachement et vérifie que la clé n'a pas expiré. Si la clé est valide, le gestionnaire de sécurité accepte la demande de rattachement et fournit à l'appareil une clé principale qui est une clé secrète partagée entre le gestionnaire de sécurité et l'appareil. En outre, des clés T et des clés D sont également fournies, et un contrat est établi avec le nouvel appareil pour parachever le processus de rattachement de sous-réseau.

13.11.2.4 Configuration par liaison radio utilisant des certificats d'infrastructure à clés asymétriques

Les étapes pour configurer un appareil qui a des informations de confiance préinstallées pourraient notamment être:

a) L'appareil arrive au site de déploiement avec un module de sécurité installé. Le module contient un certificat signé en usine et une paire de clés publique/privée. Une autorité de certification (CA) a signé la clé d'émetteur de l'usine.

b) Une WhiteList d'adresses d'appareil et une liste de clés asymétriques des autorités de certification sont installées dans le gestionnaire de sécurité du réseau-cible. Le mécanisme par lequel ces clés sont installées dans le gestionnaire de sécurité ne relève pas du domaine d'application de la présente norme. La WhiteList peut être envoyée par courrier électronique sécurisé, envoyée sur des CD, remise à la main et saisie au clavier, ou livrée en utilisant n'importe quel autre outil approprié.

c) Le réseau-cible peut utiliser un sous-ensemble de voies autorisées, parce qu'il peut fonctionner dans le voisinage (à savoir au sein de la gamme d'interférence) de plusieurs réseaux. Dans un tel cas, des informations relatives à un réseau peuvent être configurées à l'appareil, permettant à l'appareil de répondre aux annonces seulement issues des réseaux-cibles et de se mettre à l'écoute pour détecter des annonces sur les voies prévues, aux instants appropriés, diminuant ainsi les interférences et augmentant les fréquences de rattachement. Si l'appareil n'est pas configuré avec des informations spécifiques de réseau cible, l'appareil peut essayer toutes les voies et essayer de rejoindre tous les réseaux dans son voisinage. Les informations relatives à un réseau sont configurées en utilisant un appareil de configuration par l'intermédiaire d'un mécanisme de communication OOB ou par l'intermédiaire de mécanismes par liaison radio.

d) L'appareil se met maintenant à l'écoute pour détecter les annonces issues du routeur d'annonce dans le réseau-cible. Une fois qu'une annonce est entendue, l'appareil partage ses certificats avec le gestionnaire de sécurité. Avec le certificat public de la CA, le gestionnaire de sécurité décode le certificat d'appareil et vérifie qu'il est valide. La procédure implique également un mécanisme de défi-réponse de la part du gestionnaire de système/gestionnaire de sécurité pour confirmer l'identité de l'appareil se joignant. Le gestionnaire de sécurité vérifie sa WhiteList pour confirmer que l'appareil est censé rejoindre le réseau. L'étape de confirmation peut impliquer un menu contextuel sur une GUI du gestionnaire de sécurité pour une confirmation manuelle par un utilisateur. Une fois confirmé, le gestionnaire de sécurité peut émettre des clés T pour l'appareil si l'appareil souhaite rejoindre immédiatement le réseau. En variante, le gestionnaire de sécurité peut émettre des clés de rattachement symétrique pour que l'appareil rejoigne le réseau à un moment ultérieur. Dans un cas comme dans l'autre, les clés émises sont retournées à l'appareil, chiffrées avec la clé publique de l'appareil.

13.11.2.5 Configuration par liaison radio utilisant des routeurs d'annonce à double rôle

Les étapes pour configurer un appareil par liaison radio en utilisant un routeur d'annonce à double rôle pourraient notamment être:

a) L'appareil arrive avec des réglages d'usine par défaut en un site utilisateur. Le site utilisateur requiert de très faibles niveaux de sécurité.

b) Certains des routeurs d'annonce au site utilisateur ont un double rôle et fonctionnent comme des appareils de configuration. En utilisant la clé de rattachement symétrique ouverte (K_join = K_open), le routeur d'annonce à double rôle (à savoir le côté PD logique du routeur d'annonce à double rôle) forme un mini-réseau avec le nouvel appareil et fournit au nouvel appareil les valeurs de réglage réseau et la clé de rattachement pour le réseau cible. Ces valeurs de réglage, y compris les clés, sont envoyées en clair par liaison radio. L'appareil à double rôle peut aussi informer le gestionnaire de sécurité du réseau cible de mettre à jour sa liste blanche en ajoutant l'appareil qui vient juste d'être configuré. L'appareil de configuration à double rôle peut être opérationnel dans un endroit où l'utilisateur a une confiance certaine que l'émission de clés de rattachement par liaison radio présente un faible risque. (Cette étape pose le risque similaire à celui qui est pris en liant les ouvre-portes de garage à des télécommandes.)

c) Le DPO du nouvel appareil a maintenant les informations relatives à la confiance et les informations relatives à un réseau pour rejoindre le réseau-cible. Il peut utiliser les routeurs d'annonce (soit le même routeur d'annonce à double rôle qui l'a configuré, ou un autre routeur d'annonce du réseau cible si l'appareil a été déplacé) et envoie une demande de rattachement au gestionnaire de système du réseau cible.

d) Le gestionnaire de système du réseau-cible accepte la demande de rattachement et fournit un contrat au nouvel appareil.

13.11.2.6 Configuration de routeurs dorsaux

Les étapes pour configurer des appareils dorsaux pourraient notamment être:

a) Un appareil frais arrive au site utilisateur. L'appareil a des réglages par défaut et n'a pas de clés préinstallées.

b) Un PD (par exemple, un appareil tenu à la main ou un appareil connecté par l'intermédiaire de l'interface de dorsale au DBP) obtient une liste de clés symétriques générées par le gestionnaire de sécurité/gestionnaire de système du réseau-cible. Les clés symétriques sont limitées dans le temps. Les clés peuvent être un éventail de clés ou des paires clé/adresse EUI64 spécifiques à un appareil, à la discrétion du gestionnaire de sécurité/du gestionnaire de système. Ces informations sont stockées dans le DPSO du PD.

c) Le PD, chargé avec les clés symétriques, est apporté à proximité du nouvel appareil ou relié au nouvel appareil et il est établi une connexion OOB (qui peut, dans ce cas, être la dorsale) entre l'appareil tenu à la main et le DBP. Le PD utilise alors l'interface de communication OOB (plus probablement l'interface de dorsale) pour peupler les attributs du DPO dans le nouvel appareil.

d) L'appareil est maintenant prêt à rejoindre le réseau-cible. Cependant, à la différence d'un appareil de terrain, un appareil dorsal peut ne pas avoir une interface de DL. Par exemple, l'appareil peut être une passerelle résidant sur la dorsale. En variante, l'appareil dorsal peut être le premier routeur d'annonce connecté au réseau. Par exemple, l'appareil peut être un routeur dorsal avec la fonctionnalité de routeur d'annonce sur l'interface de couche physique IEEE 802.15.4:2011. Cependant, l'appareil a besoin d'être configuré sur la dorsale et pas par l'intermédiaire de la PhL, car, dans ce cas, il n'y a pas de routeurs d'annonce qui peuvent transmettre sa demande de rattachement au gestionnaire de système.

Pour parler au gestionnaire de système sur la dorsale sans l'aide d'un routeur d'annonce, le routeur dorsal envoie une demande de rattachement au gestionnaire de système directement sur la dorsale; l'appareil dorsal peut former l'en-tête de réseau nécessaire pour envoyer ce message. Il peut le faire parce qu'il a été configuré avec l'adresse IPv6 du gestionnaire de système (DPO.Target_System_Manager_Address). La suite de la procédure au niveau du gestionnaire de système est la même que celle en 13.11.2.3.

Annexe A
(informative)

Couche d'utilisateur/profils d'application

A.1 Vue d'ensemble

L'Annexe A décrit ce que signifient les termes "couche d'utilisateur" et "profil d'application" et elle décrit également comment ces termes se rapportent l'un à l'autre et à la présente norme.

A.2 Couche d'utilisateur

La couche d'utilisateur correspond au terme souvent appliqué à une huitième couche inexistante placée au sommet du modèle de mise en réseau d'ordinateurs à sept couches de l'OSI. L'intention de la couche d'utilisateur est d'accomplir des fonctions spécifiques à un but qui ne sont pas liées à des communications réseau. En ce qui concerne l'automation industrielle, le terme "couche d'utilisateur" est parfois appliqué pour décrire le matériel et/ou le logiciel qui n'est pas relié à la communication réseau, tel qu'un capteur de terrain ou un bloc fonctionnel de contrôle de processus. Il est possible qu'une telle couche d'utilisateur ait des informations qui doivent être communiquées sur un autre réseau qui se conforme à l'ISO/IEC 7498, le modèle de référence de base de l'OSI.

La communication réseau pour prendre en charge la fonction de couche d'utilisateur est initiée par la couche d'utilisateur en utilisant les méthodes et les protocoles définis par la 7ème couche du modèle OSI, qui s'appelle Application Layer (AL).

La présente norme vise à prendre en charge une diversité de fonctions de l'industrie d'automation qui ne sont pas directement liées à la communication réseau. À ce titre, elle définit une pile de communication d'usage général compatible avec le modèle de mise en réseau d'ordinateurs de l'OSI et inclut la définition des services normalisés de l'AL.

La présente norme définit également des objets normalisés extensibles génériques, qui peuvent être utilisés par des applications d'automation industrielle. La présente norme permet la spécialisation de ces objets normalisés, tout comme la définition à la fois de nouveaux objets normalisés spécifiques à une industrie et d'objets définis par un fournisseur. La définition d'objets normalisés spécifiques à une industrie ne relève pas du domaine d'application de la présente norme; elle est laissée à chaque organisation industrielle qui promeut l'utilisation de la présente norme pour leur industrie. La présente norme ne limite pas la portée de la fonctionnalité de couche d'utilisateur par rapport à un besoin quelconque de communication non liée à un réseau.

NOTE L'ISA 100 Wireless Compliance Institute (WCI) est un exemple d'une telle organisation pour les industries d'automation de processus.

A.3 Profil d'application

Un profil d'application définit les propriétés spécifiques à une application devant être mises en œuvre d'une manière qui promeut l'interopérabilité parmi les entités en communication. Un profil d'application peut également définir des politiques de mise en œuvre, et peut suggérer des lignes directives de mise en œuvre. Toute couche d'utilisateur au sein d'un appareil peut mettre en œuvre un ou plusieurs profils d'application.

Certaines propriétés spécifiques à un profil d'application peuvent être obligatoires pour toutes les instances des applications conformes au profil d'application particulier. D'autres propriétés spécifiques à un profil d'application peuvent être des propriétés de pratique courante qui sont des options de construction. Toutes ces propriétés sont représentées sous la forme d'attributs

d'objet, si bien que la communication de leurs valeurs peut se produire par l'utilisation des services de base de couche d'application selon la présente norme.

La portée d'un profil d'application est souvent délibérément limitée, afin de promouvoir une plus grande adoption et une plus grande utilisation du profil d'application particulier. Un exemple d'un tel profil d'application limité est un profil d'application pour des capteurs de température.

Dans un système faiblement couplé, la liaison des appareils qui prennent en charge des profils d'application avec des applications de système hôte qui utilisent ces profils est habituellement accomplie par l'intermédiaire de l'utilisation d'un fichier de caractérisation d'appareil fourni par le fournisseur de l'appareil, dont le contenu est souvent basé sur une technologie descriptive normalisée.

Un exemple d'une norme qui peut être utilisée pour décrire le contenu de profil est l'IEC 61804-3, qui peut être utilisée par les fournisseurs d'appareils pour l'industrie d'automation industrielle pour créer le fichier qui peut être utilisé avec les outils appropriés d'accompagnement de système hôte, permettant à l'hôte de représenter des fonctions d'appareil, des paramètres (attributs) et leurs dépendances, les représentations graphiques appropriées à la représentation de données, ainsi que des interactions prises en charge avec d'autres appareils.

Un appareil peut mettre en œuvre un profil d'application ou un ensemble de profils et peut utiliser les méthodes d'AL natives et les protocoles de la présente norme pour communiquer sur des réseaux sans fil conformes à la présente norme.

Sachant que la présente norme est censée prendre en charge une diversité de fonctions d'industrie d'automation industrielle qui ne sont pas liées à la communication réseau, la présente norme ne définit pas ou ne limite pas la définition ou l'utilisation des profils d'application, des langues ou des fichiers qui représentent de tels appareils, ou des outils utilisés pour représenter de tels appareils. La définition de profils normalisés spécifiques à une industrie ne relève donc pas du domaine d'application de la présente norme. Elle est, au lieu de cela, déléguée aux entreprises qui promeuvent l'utilisation de la présente norme dans une industrie d'automation particulière.

NOTE Des mécanismes ISO et IEC existent pour proposer de tels profils d'application spécifiques à une industrie.

Annexe B
(normative)

Profils de rôles de communications

B.1 Vue d'ensemble

B.1.1 Généralités

Un profil de rôles est défini comme représentant les capacités de base, y compris toutes les valeurs de réglages et toutes les configurations, qui sont exigées d'un appareil pour accomplir correctement le rôle en question. Les rôles sont définis en 5.2.6.2, mais ils sont énumérés ici pour référence comme étant gestionnaire de système, gestionnaire de sécurité, routeur dorsal, routeur, entrée-sortie (E/S), passerelle, source de temps de système, et appareil de configuration.

L'Annexe B fournit le pro forma de profil de rôle pour la conformité à la présente norme.

B.1.2 Objet

Le profil de rôle définira les capacités d'appareil, telles que des valeurs de réglage et des configurations, nécessaires pour remplir chaque rôle spécifique défini en 5.2.6.2. Le but en est d'assurer que les appareils conformes à la présente norme, y compris l'Annexe B, peuvent être interopérables, selon le cas, dans le domaine couvert par le profil de rôle.

B.1.3 Taille de système

Les capacités exigées d'un appareil pour mettre en œuvre un rôle peuvent dépendre du nombre d'appareils dans le système prévu. La taille minimale de système est définie à l'Article 5, mais il n'y a aucune taille maximale de système. Pour permettre aux exigences de l'Annexe B de servir une large plage de tailles de système, ces exigences dépendant de la taille de système doivent utiliser une formule pour spécifier les capacités minimales. Pour les besoins de l'Annexe B, le nombre d'appareils du système est appelé NSD (number of system devices).

B.1.4 Abréviations et symboles spéciaux

Les abréviations et les symboles utilisés comprennent:

- Notations pour le statut d'exigence:
  - O: obligatoire;
  - F: facultative;
  - O.n: facultative, mais la prise en charge d'au moins l'un des groupes d'options étiquetées "O.n" est exigée;
  - N/A: non applicable;
  - X: interdit.
- Élément: Conditionnelle, statut dépendant de la prise en charge marquée pour l'élément.

Par exemple, un statut de FD1:O.1 et FD2:O.1 indique que le statut est facultatif, mais au moins une des caractéristiques décrites dans FD1 et FD2 est exigée.

B.1.5 Profils de rôles

Le Tableau B.1 décrit les couches de protocoles et les exigences relatives aux supports pour tous les profils de rôles. Si un appareil est déclaré prendre en charge plus d'un rôle, cet appareil doit remplir les capacités minimales pour chaque rôle déclaré.

Tableau B.1 – Rôles des appareils de couche de protocoles

Numéro d'élément	Rôle de l'appareil	Etat					Référence	Support		
		Couches de protocole			Moyenne					
		AL	TL	NL	Type A	Squelette		N/A	Oui	Non
DR1	E/S	M	M	M	M	N/A	5.2.6.6			
DR2	Routeur	M	M	M	M	N/A	5.2.6.7			
DR3	Routeur dorsal	M	M	M	M DR4: O DR7: O	M	5.2.6.9 5.2.6.9 5.2.6.9			
DR4	Passerelle	M	M	M	DR2:O.1	DR3:O.1	5.2.6.10			
DR5	Source de temps système	N/A	N/A	N/A	N/A	N/A	5.2.6.13			
DR6	Configuration	M	M	M	M	N/A	5.2.6.8			
DR7	Gestionnaire de système	M	M	M	DR2:O.2	DR3:O.2	5.2.6.11			
DR8	Gestionnaire de sécurité	N/A	N/A	N/A	N/A	N/A	5.2.6.12			

B.2 Système

Le protocole de WISN prend en charge la capacité de mettre à niveau des appareils par liaison radio, conformément au Tableau B.2.

Tableau B.2 – Mises à niveau par liaison radio

Numéro d'élément	Types de rôles affectés	Référence	Etat	Support		
				N/A	Oui	Non
OTAR1	E/S		M			
OTAR2	Routeur		M			
OTAR3	Routeur dorsal		N/A			
OTAR4	Passerelle		N/A			
OTAR5	Gestionnaire de système		N/A			
OTAR6	Appareil de configuration		O			

B.3 Gestionnaire de système

Le gestionnaire de système alloue la capacité des appareils pour communiquer en générant, distribuant et maintenant des contrats qui définissent les ressources nécessaires pour ce besoin de communication. Sachant que chaque appareil doit stocker ses contrats, la capacité d'un appareil pour le stockage de contrats est critique. Alors que les capacités nécessaires des appareils E/S, routeurs et routeurs dorsaux dépendent du nombre d'objets d'application au sein des appareils en question, la passerelle et le gestionnaire de système dépendent du

nombre d'appareils dans le système, défini dans l'Annexe B comme étant NSD. Le NSD n'inclut pas le gestionnaire de système dans son compte d'appareils.

Les contrats exigent des sessions de communication pour la communication, établies par le gestionnaire de sécurité conjointement avec le gestionnaire de système. Plusieurs contrats, communiquant vers les mêmes points d'extrémité, peuvent partager une seule session. Les capacités minimales décrites ici supposent que chaque session est appariée à un seul contrat, en admettant que plus de contrats peuvent être nécessaires selon la nature des applications de l'appareil.

B.4 Gestionnaire de sécurité

Le gestionnaire de sécurité établit des sessions entre les processus d'application. Par exemple, lorsqu'un appareil rejoint le réseau, il a besoin d'une session DMAP-SMAP. Le nombre de sessions qu'un appareil mettant en œuvre un rôle doit être capable de maintenir est défini dans le Tableau B.3. Le nombre de sessions prises en charge par un gestionnaire de système dépend de NSD. Le nombre de clés prises en charge par une passerelle dépend du nombre de connexions Gateway-UAP que la passerelle est conçue pour prendre en charge, appelé GUC (gateway-UAP connection) dans le Tableau B.3.

Un appareil E/S est présumé requérir la capacité pour prendre en charge les sessions suivante:

- Une session entre le DMAP de l'appareil et le SMAP, établie lorsque l'appareil rejoint le réseau.
- Une session entre l'UAP de l'appareil et un premier appareil tel qu'une passerelle.
- Une session entre le DMAP de l'appareil et le premier appareil, pour rapporter des alertes de processus.
- Une session entre l'UAP de l'appareil et l'UP du second appareil, telle que dans le cas d'une communication peer-to-peer.

Tableau B.3 – Profils de prise en charge de sessions

Numéro d'élément	Types de rôles affectés	Nombre minimal de sessions prise en charge	Commentaires	Etat	Support		
					N/A	Oui	Non
NCS1	E/S	4	DMAP-SMAP UAP-Gateway DMAP-Gateway UAP-Peer	M			
NCS2	Routeur	1	DMAP-SMAP	M			
NCS3	Routeur dorsal	1	DMAP-SMAP	M			
NCS4	Passerelle	(2 x GUC) + 1	DMAP-SMAP GUC x (Gateway-UAP) GUC x (Gateway-DMAP)	M			
NCS5	Gestionnaire de système	NSD	NSD x (SMAP-DMAP)	M			

Le gestionnaire de sécurité assigne les clés de sécurité qui sont exigées pour la communication entre appareils. Le nombre de clés qu'un appareil mettant en œuvre un rôle doit être capable de maintenir est défini dans le Tableau B.4. Le nombre de clés prises en charge pour un appareil dépend du nombre de sessions prises en charge, avec les capacités minimales montrées dans le Tableau B.3. En outre, chaque appareil a besoin de la capacité

pour une clé de rattachement, une clé principale, et une clé D si une DL est incluse sur l'appareil. Des comptes de clé ont besoin d'être doublés, parce que toutes les clés excepté la clé de rattachement peuvent être dans le processus de changement.

Tableau B.4 – Profils de base

Numéro d'élément	Types de rôles affectés	Nombre minimal de clés prise en charge	Commentaires	Référence	Etat	Support

NKS7	Gestionnaire de sécurité	–N/A		7.2.2	N/A			

B.5 Physical layer, couche physique

Sachant que la PhL cite les spécifications issues de l'IEEE 802.15.4, les capacités de rôle pour la PhL font référence à l'IEEE 802.15.4.

Le Tableau B.5 décrit les rôles de couche physique.

Tableau B.5 – Rôles de PhL

Numéro d'élément	Descriptif de l'élément		Référence IEEE 802.15.4:2011	Etat	Support		
					N/A	Oui	Non
PLR1	E/S	L'appareil est un appareil à fonction réduite	5.1	O.1			
		L'appareil est un appareil à fonction complète	5.1	O.1			
PLR2	Routeur	L'appareil est un appareil à fonction complète	5.1	M			
PLR3	Routeur dorsal	L'appareil est un appareil à fonction complète	5.1	M			
PLR4	Appareil de configuration	L'appareil est un appareil à fonction complète	5.1	M			
O.1: au moins une option doit être sélectionnée.							

B.6 Data-link layer, couche de liaison de données

B.6.1 Généralités

La DL affecte quatre profils de rôles, conformément au Tableau B.6.

Tableau B.6 – DL exigée pour rôles énumérées

Numéro d'élément	Types de rôles	Référence	Etat	Support		
				N/A	Oui	Non
DLR1	E/S	5.2.6.6	M			
DLR2	Routeur	5.2.6.7	M			
DLR3	Routeur dorsal	5.2.6.9	M			
DLR4	Configuration	5.2.6.8	M			

B.6.2 Profils de rôles

B.6.2.1 Généralités

Un profil de rôles de DL décrit un ensemble de capacités minimales qui doivent être prises en charge par chaque appareil conforme qui met en œuvre le moyen de terrain de Type A. Par exemple, un appareil remplissant le rôle de routeur doit prendre en charge 8 voisins. Si un appareil satisfait à toutes les autres exigences d'un routeur, mais prend en charge seulement 4 voisins, il n'est pas conforme dans son rôle de routeur. Un appareil peut dépasser n'importe lesquelles des exigences de son rôle, tant que toutes les exigences minimales des rôles sont respectées.

La DL est configurée par l'intermédiaire de valeurs de réglages des attributs de l'objet de gestion de DL (DLMO), et les divers rôles sont décrits comme plages de valeurs de réglages de DLMO qu'un appareil peut prendre en charge.

B.6.2.2 Attributs d'objet de gestion de DL

Un niveau d'appareil de prise en charge pour une capacité peut être exprimé en rapport avec un ensemble d'attributs de DLMO et d'éléments de ces attributs. Chaque attribut et/ou élément dont la prise en charge varie par rôle est inclus.

Si un certain nombre ou une plage de nombres est énuméré(e), un appareil remplissant ce rôle doit prendre en charge le nombre en question. Si un seul nombre est énuméré, il doit être interprété comme étant une valeur minimale, sauf indication contraire. Par exemple, si un appareil doit prendre en charge 3 voisins, alors il peut prendre en charge 4 voisins, mais il est non conforme s'il prend en charge seulement 2 voisins. Un appareil E/S peut être capable de routage même s'il n'est pas entièrement conforme au rôle de routeur; par conséquent, certaines capacités relatives au routage sont montrées comme étant facultatives (non interdites) pour un appareil E/S.

Le Tableau B.7 décrit des attributs de DLMO simples avec un seul élément. (Les autres tableaux de l'Annexe B traitent des attributs de DLMO contenant plusieurs éléments.)

Tableau B.7 – Profils de rôles: Attributs généraux de DLMO

Attribut	Etat			Commentaires	Support		
	E/S	Routeur	BBR		N/A	Oui	Non
ActScanHostFract	O	M	M	Un appareil qui n'est pas un appareil d'alimentation n'aura pas nécessairement l'énergie pour agir comme un hôte de balayage actif pendant une période de temps prolongée. Voir Tableau B.8			
AdvJoinInfo AdvSuperframe	O	M	M	Tous les routeurs et routeurs dorsaux peuvent être configurés pour envoyer des annonces			
TaiTime TaiAdjust	M	M	M	La DL n'est pas nécessairement la source de TaiTime pour un appareil particulier et il existe des cas où la DL d'un appareil ne pourrait pas être impliquée dans la propagation de temps comme une source ou une destinataire. Par exemple, un BBR pourrait rester synchronisé en temps par l'intermédiaire d'un mécanisme de dorsale, et ne pas être impliqué dans la propagation de temps de DL			
ClockTimeout	M	M	M	Un BBR peut être configuré comme un destinataire d'horloge, mais cela n'est pas censé être typique			

Le Tableau B.8 décrit des profils de rôles de base pour l'attribut dlmo.Device_Capability. Les éléments d'appareils non mentionnés dans l'Annexe B doivent être pris en charge comme cela est décrit à l'Article 9.

Tableau B.8 – Profils de rôles: dlmo.Device_Capability

Elément	Etat			Notes de bas de tableau	Support		
	E/S	Routeur	BBR		N/A	Oui	Non
QueueCapacity	0	10	20	a			
ClockStability	100	10	10	b			
DLRoles	0000 xxx1	0000 xx1x	0000 x11x	c			
AdvRate	0 (X)	6	6	d			
ListenRate	0 (X)	36	36	e			
TransmitRate	0 (X)	30	60	f			

a Le gestionnaire de système configure la file d'attente de DL seulement dans la mesure où l'appareil transmet des messages pour le compte d'autres appareils. La file d'attente de DL dans un BBR est un sujet interne d'appareil pour les graphes qui commencent ou finissent dans la DL de l'appareil.

b Les valeurs de ClockStability, comme multiples de 1×10^{-6} sont des valeurs maximales permises sur tout intervalle continu de 30 s dans des conditions de fonctionnement industrielles. Alors que les appareils E/S à bas coût peuvent avoir des horloges avec une stabilité à court terme de seulement 100×10^{-6}, il convient que les appareils E/S industriel en général aient une meilleure stabilité. La présente norme a été conçue en admettant des horloges de 25×10^{-6} dans les appareils d'E/S ou mieux et il est anticipé que la plupart des profils d'application seront contraints en conséquence.

c Les bits indiquent tous les rôles de DL qui sont pris en charge par l'appareil. Noter que BBR doit agir comme un routeur, comme dans le cas d'une messagerie peer-to-peer dans un sous-réseau D.

d Tous les appareils desservant des rôles de routeur et de routeur dorsal doivent avoir les ressources suffisantes pour émettre une annonce toutes les 10 secondes (6 DPDU par minute), en moyenne. Voir 9.1.17.

e Tous les appareils desservant des rôles de routeur et de dorsal doivent avoir les ressources suffisantes pour exploiter leurs récepteurs pendant 36 secondes par heure (1 %) en moyenne. Un BBR alimenté par secteur sera normalement capable de faire fonctionner son récepteur de manière continue, mais certaines classes de BBR (telles que les ponts sans fil) pourraient être contraintes en énergie.

f Tous les appareils desservant des rôles de routeur et de dorsale doivent avoir les ressources suffisantes pour émettre le nombre indiqué de DSDU par minute. Voir 9.1.17.

Le Tableau B.9 décrit des profils de rôles de base pour l'attribut dlmo.Ch. Les éléments d'appareils non mentionnés dans l'Annexe B doivent être pris en charge comme cela est décrit à l'Article 9.

Informations de référence

C.1 Besoins industriels

Les besoins en sans fil pour des applications industrielles sont sensiblement différents de ceux exigés pour des applications résidentielles, commerciales, ou militaires. Ces différences découlent du classement industriel unique des priorités des caractéristiques telles que le coût d'appareil, le coût de système, le coût de cycle de vie, la fiabilité, la maintenabilité, la cohérence, la robustesse, l'extensibilité, la sécurité, la coexistence, les restrictions dues à la réglementation, l'interopérabilité et (dans les domaines adéquats) l'interfonctionnabilité ou l'interopérabilité.

Les membres de comité ISA 100 ont recueilli et analysé plus de 500 cas d'utilisation pour définir plus complètement les besoins en communication sans fil du secteur industriel. Les principales conclusions de cet effort étaient:

- Occasion: La détection sans fil inexistante est une occasion pour les utilisateurs finaux, les fournisseurs et les normes émergentes.
- Interopérable: Sachant que de multiples moyens instrumentaux de fournisseurs dominent l'environnement industriel, il convient que les normes du sans fil soient de haute valeur.
- Interopérable: Il convient que les appareils qui ciblent le même domaine d'application vaste (par ex: contrôle des processus ou gestion d'actifs) soient interopérables en ce qui concerne les fonctionnalités de base nécessaires pour une action coopérative dans ce domaine d'application.
- Intégration: De multiples chemins de communication entre les appareils sont nécessaires, particulièrement vers les instruments de système de commande distribué (DCS).
- Applications: Les applications telles que la surveillance/l'alerte sont du plus grand intérêt immédiat, car elles constituent la plus grande utilisation potentielle des appareils sans fil.
- Fiabilité et sécurité: Facteurs critiques pour les normes émergentes et les fournisseurs.
- Puissance: Les espérances de vie de batterie varient en raison de l'application, de l'environnement, des contraintes de coût, etc. Certains appareils auront l'alimentation en énergie par le secteur, alors que d'autres seront alimentés par des batteries ou récupéreront l'énergie dans l'environnement.

C.2 Classes d'utilisation

C.2.1 Généralités

Alors qu'il existe de nombreuses techniques qui peuvent être utilisées pour catégoriser les besoins en communications des applications industrielles, la présente norme utilise des classes basées sur l'utilisation. L'analyse des profils d'utilisation prévue des communications sans fil industrielles entre appareils a conduit au partitionnement de telles communications en six classes. Ces classes sont résumées dans le Tableau C.1.

Tableau C.1 – Classes d'utilisation

Sécurité	Classe 0: Action d'urgence	Toujours critique
Commande	Classe 1: Commande de réglementation à boucle fermée	Souvent critique
	Classe 2: Commande de supervision à boucle fermée	Habituellement non critique
	Classe 3: Commande à boucle ouverte	Humain dans la boucle
Contrôle	Classe 4: Alerte	Conséquence opérationnelle de court terme (maintenance événementielle, par exemple)
	Classe 5: Journalisation et téléchargement descendant/ téléchargement montant	Aucune conséquence opérationnelle immédiate (par exemple, recueil d'antécédents, séquence d'événements, maintenance préventive)
NOTE Les niveaux de lot 3 et 4 pourraient être de classe 2, de classe 1 ou même de classe 0, selon la fonction. Les niveaux de lot sont définis dans l'IEC 61512-1, où L3 = unité et L4 = cellule de processus.		

C.2.2 Exemples de classes

- Classe 0: Action d'urgence (toujours critique)

  On peut citer les exemples suivants:

  – interverrouillage de sécurité;
  – arrêt d'urgence;
  – contrôle incendie automatique.

- Classe 1: Commande de régulation en circuit fermé (souvent critique)

  On peut citer les exemples suivants:

  – commande directe d'actionneurs primaires (par exemple, disponibilité de la connexion appareil de terrain à hôte à la demande d'au moins 99,99 %, avec coupures de liaison > 500 ms intolérables, avec des fréquences de demande de 0,2 Hz ou plus);
  – boucles haute fréquence en cascade.

- Classe 2: Commande de supervision à boucle fermée (habituellement non critique)

  On peut citer les exemples suivants:

  – boucles basse fréquence en cascade;
  – commandes à plusieurs variables;
  – optimiseurs.

- Classe 3: Commande à boucle ouverte (Homme dans la boucle)

  On peut citer les exemples suivants:

  – l'opérateur initie manuellement une flamme et observe la flamme;
  – le garde ouvre à distance un portail de sécurité;
  – l'opérateur accomplit un réajustement manuel de pompe/vanne.

- Classe 4: Alerte – Conséquence opérationnelle de court terme

  On peut citer les exemples suivants:

  – maintenance événementielle;
  – temps marginal de palier conduit à envoyer un technicien sur le terrain;
  – le voyant batterie faible pour un appareil conduit à envoyer un technicien pour changer la batterie;
  – suivi de biens.

- Classe 5: Journalisation – données/messages sans conséquence opérationnelle immédiate

  On peut citer les exemples suivants:

  – recueil d'antécédents;

  – cycle de maintenance préventive;

  – chargement de séquence d'événements (SOE).

NOTE La SOE utilise une communication sans pertes, telle qu'un transfert de fichier, plutôt qu'une communication minutée telle qu'utilisée par la messagerie de commande.

C.2.3 Autres alarmes de téléchargement montant et de téléchargement descendant (action humaine ou automatisée)

Des exemples d'alarmes sont:

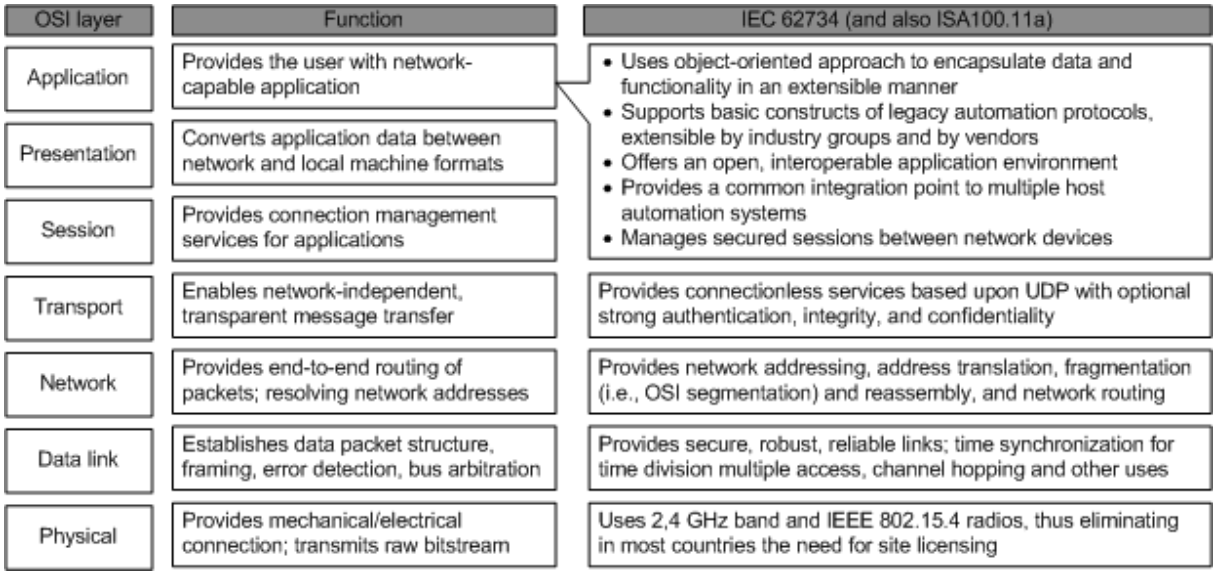
- Classe 0: détecteur de fuite pour rayonnement ou gaz mortellement toxique, réponse automatisée (par exemple, réponse de confinement automatisée).
- Classe 1: condition de processus à impact élevé, réponse automatisée (par exemple, arrêt automatisé d'une réaction).
- Classe 2: réponse automatisée à l'état du processus (par exemple, diversion automatisée de flux).
- Classe 3: état de processus avec réponse opérationnelle initiée manuellement (par exemple, décider, oui ou non, de dévier le flux vers un réacteur parallèle).
- Classe 4: état du matériel avec réponse de maintenance à courte échelle de temps (par exemple, envoyer un technicien sur le terrain).
- Classe 5: état du matériel avec action de maintenant à longue échelle de temps (par exemple, commander des pièces de rechange).

C.3 Modèle de référence de base d'interconnexion des systèmes ouverts (OSI)

C.3.1 Vue d'ensemble

La présente norme définit la suite de protocoles du réseau sans fil. Une suite de protocole est une mise en œuvre particulière de logiciel d'une suite de protocoles de mise en réseau. Dans une mise en œuvre pratique, les suites de protocoles sont souvent divisées en couches telles que celles définies dans le Modèle de référence de base de l'Interconnexion des systèmes ouverts ISO/IEC 7498-1. Le format dans la présente norme est basé sur ce modèle de référence (voir la Figure C.1), mettant en œuvre cinq des sept couches du modèle de référence de base.

NOTE Il est utile de réaliser qu'il s'agit d'un modèle virtuel, qui n'impose donc aucune exigence sur les mises en œuvre, ou même de spécifications.



Légende

Anglais	Français
OSI layer	Couche OSI
Application	Application
Presentation	Présentation
Session	Session
Transport	Transport
Network	Réseau
Data link	Liaison de données
Physical	Physique
Function	Fonction
Provides the user with network-capable application	Fournit à l'utilisateur des applications à capacité de réseau
Converts application data between network and local machine formats	Convertit les données d'application entre les formats de réseau et de machines locales
Provides connection management services for applications	Fournit des services de gestion de connexion pour les applications
Enables network-independent, transparent message transfer	Permet un transfert de messages transparent et indépendant vis-à-vis du réseau
Provides end-to-end routing of packets; resolving network addresses	Fournit un routage de bout en bout de paquets, résolvant les adresses réseau
Establishes data packet structure, framing, error detection, bus arbitration	Etablit la structure des paquets de données, le verrouillage de trame, la détection d'erreur et les contrôles d'accès aux bus
Provides mechanichal/electrical connnection; transmits raw bitstream	Fournit la connexion mécanique/électrique; émet le train de bits brut
IEC 62734 (and also ISA100.11a)	IEC 62734 (et également ISA100.11a)

Anglais	Français
Uses object-oriented approach to encapsulate data and functionality in an extensible manner Supports basic constructs of legacy automation protocols, extensible by industry groups and by vendors Offers an open, interoperable application environment Provides a common integration point to multiple host automation systems Manages secured sessions between network devices	Utilise une approche orientée objet pour encapsuler les données et la fonctionnalité de manière extensible Prend en charge les constructions de base des protocoles d'automatisation existants, extensibles par groupes d'industries et par fournisseurs Offre un environnement d'application ouvert et interopérable Gère les sessions sécurisées entre les appareils réseau
Provides connectionless services based upon UDP with optional strong authentication, integrity, and confidentiality	Fournit des services sans connexion basés sur UDP avec authentification, intégrité et confidentialité fortes facultatives
Provides network addressing, address translation, fragmentation (i.e., OSI segmentation) and reassembly, and network routing	Fournit l'adressage réseau, la traduction des adresses et la fragmentation (c'est-à-dire la segmentation OSI) ainsi que le réassemblage et le routage réseau
Provides secure, robust, reliable links; time synchronization for time division multiple access, channel hopping and other uses	Fournit des liaisons sécurisées, robustes et fiables; synchronisation temporelle pour l'accès multiple et le saut de voies par répartition dans le temps, ainsi que d'autres utilisations
Uses 2,4 GHz band, IEEE 802.15.4 radios, thus eliminating in most countries the need for site licensing	Utilise des radios de bande 2,4 GHz, IEEE 802.15.4, ce qui élimine le besoin de licence des sites dans la plupart des pays

Figure C.1 – Modèle de référence de base de l'OSI

La couche supérieure, application (AL), du Modèle de référence de base de la présente norme fournit la fonctionnalité locale pour un ou plusieurs UAP associés.

Les quatre couches, transport (TL), réseau (NL), liaison de données (DL), et physique (PhL), sont consacrées à la communication de données. Chacune a les capacités de multiplexer et de démultiplexer, et de diviser et de fusionner les flux d'informations issus des couches adjacentes. Autrement dit, les relations de messagerie entre une entité d'AL et une entité de TL, ou entre une entité de TL et une entité de NL, ou entre une entité de NL et une entité de DL, ou entre une entité de DL et une entité de PhL, peuvent ne pas être biunivoques (1:1).

Ces couches inférieures ont aussi les capacités suivantes:

- ordonnancer des unités de données de service (SDU) pour maintenir l'ordre de la présentation originale;
- exécuter une ou plusieurs des opérations ci-dessous
  - segmenter ou réassembler des SDU dans des unités de données de protocole (PDU),
  - bloquer ou débloquer des SDU dans des unités de données de protocole (PDU) et
  - concaténer ou séparer des PDU,

  afin qu'elles soient dimensionnées de manière plus appropriée pour les capacités de transport de la couche inférieure;
- diviser des PDU parmi plusieurs chemins de couche inférieure ou recombiner ces PDU à leur réception avant de les transférer sur une route de couche supérieure; et
- acquitter la réception de PDU comme une forme de contrôle d'erreur.

C.3.2 Couche d'application

L'AL est la couche qui s'interface directement aux UAP (et les inclut conceptuellement), gérant des communications avec d'autres UAP sous la supervision de l'UAP de gestion

locale. Un UAP peut accomplir une fonction individuelle ou n'importe quelle combinaison de fonctions. Les UAP peuvent être utilisés, par exemple, pour:

- traiter les matériels d'entrée et/ou de sortie;
- distribuer des communications vers un jeu d'UAP corésident au sein d'un appareil (fonction proxy);
- prendre en charge la tunnellisation d'un protocole non natif (par exemple, hérité d'un système de commande) compatible avec l'environnement réseau de la présente norme; et/ou
- accomplir une fonction de calcul.

L'AL est habituellement composée d'un ou plusieurs UAP qui partagent des éléments de services communs.

Les tâches principales d'une entité d'AL permettent de fournir:

- une place dans l'architecture de la présente norme pour les UAP;
- les moyens par lesquels les UAP gèrent les communications avec des UAP pour d'autres appareils par l'intermédiaire de la suite de protocoles, y compris:
  - identification des partenaires de communication prévus (par exemple, par le nom, par l'adresse, par la description, etc.),
  - accord sur la sécurité (par exemple, authentification, intégrité des données),
  - détermination de la qualité de service acceptable (par exemple, priorité, fenêtres de temps pour la messagerie de commande, acceptabilité de la livraison de message dans le désordre, acceptabilité de la livraison de message en des incréments partiels, etc.),
  - accord sur la responsabilité pour la correction d'erreur,
  - identification des syntaxes abstraites et
  - synchronisation des UAP coopérateurs;
- les moyens par lesquels les UAP peuvent informer l'entité d'application associée des exigences de ressource nécessaires, y compris celles applicables pour le placement en tampon des messages:
  - tailles attendues et maximales des messages et
  - nombre de salves maximal prévu de l'émission et de la réception des messages ou combien de messages peuvent être envoyés ou arriver en une courte quantité de temps en comparaison à la périodicité moyenne des messages; et
- toute fonction nécessaire de communication qui ne soit pas déjà accomplie par les couches inférieures.

C.3.3 Couche transport

La TL est la couche la plus élevée à laquelle les applications en communication sont adressables. Les tâches principales d'une entité de TL sont:

- fournir l'adressage des UAP par l'intermédiaire de la sélection d'une entité d'AL associée spécifique;
- établir les chemins de messagerie de bout en bout allant d'un UAP à un ou plusieurs autres UAP par l'intermédiaire de leurs entités d'AL associées, où ces processus sont habituellement situés dans des appareils distincts;
- acheminer et réguler le flux de messages entre ou parmi ces UAP; et
- mettre fin à ces chemins de messagerie s'il y a lieu.

C.3.4 Couche réseau

La NL est la couche la plus élevée à laquelle les appareils en communication sont adressables. Il s'agit de la plus basse couche avec une portée plus que locale, qui transmet des messages entre un groupe d'entités et d'autres, ou rejette les messages. Les tâches principales d'une entité de NL sont:

- fournir l'adressage, à l'échelle d'un réseau, des appareils;
- relayer des messages (les NPDU) entre les entités (par exemple, un routeur) par l'intermédiaire des sous-réseaux D, habituellement en changeant les adresses d'entité de DL source et destination associées à des enveloppes de message (les DPDU) dans le processus, ou rejeter les NPDU; et
- fournir la segmentation et le réassemblage de messages, selon le cas, pour correspondre aux capacités des sous-réseaux D sur lesquels des messages sont transmis.

NOTE La NL est la couche OSI où ont lieu l'adressage et le routage d'appareils de point d'extrémité. Les relais de couche inférieure peuvent transmettre des messages au sein d'un seul domaine d'adressage sans modification de message, mais ils sont incapables de réadresser des messages ou de couvrir des domaines d'adressage. Les adresses d'appareil à l'échelle d'un réseau sont les adresses IPv6.

C.3.5 Couche de liaison de données

La DL est la plus basse couche centrée sur les informations, qui coordonne les entités de PhL interagissantes et fournit la messagerie de bas niveau de base parmi des entités de DL. Les tâches principales d'une entité de DL sont:

- fournir l'adressage, local à une liaison, des entités DL homologues;
- acheminer des messages (les DPDU) d'une entité de DL donnée vers toutes les autres dont les entités de PhL sont des correspondantes (par exemple, à toutes les entités de PhL de la liaison locale), ou rejeter les DPDU;
- gérer l'utilisation de la PhL;
- fournir l'adressage de message de bas niveau, la temporisation des messages et les contrôles d'intégrité des messages;
- fournir la détection de bas niveau de la perte de message et la récupération de perte de message (par exemple, acquittement immédiat; répéter la tentative si aucun acquittement); et
- facultativement, relayer les DPDU entre les entités de DL (par exemple, un pont).

NOTE La DL est la couche OSI qui gère et compense les caractéristiques spécifiques de la technologie de communications physiques choisie. Elle fournit seulement l'adressage local, et transmet des messages au sein du domaine d'adressage local sans réadressage. Elle ne modifie pas les adresses de message. Les adresses DL16 ont seulement une portée locale et, donc, il est possible que les mêmes adresses DL16 soient dupliquées dans d'autres liaisons locales.

C.3.6 Couche physique

La PhL est la couche la plus basse du modèle OSI et la seule couche qui traite de la physique du monde réel. Toutes autres couches traitent d'informations abstraites, représentées en dernier ressort sous forme de bits; la PhL est concernée par les signaux physiques (parfois appelés bauds ou puces). Les tâches principales d'une entité de PhLE sont:

- coder les bits, séparément ou en groupes de plusieurs bits, dans les signaux physiques;
- acheminer ces signaux d'un emplacement physique vers un autre;
- décoder ces signaux en groupes d'un seul bit ou de plusieurs bits, possiblement avec correction d'erreur;
- prendre des instructions auprès du DLE associé en ce qui concerne l'installation de voie physique, l'adressage de récepteur physique et d'autres aspects de voie et de codage de communications;

- transporter au DLE localement associé les informations relatives à l'état de l'entité de PhLE, de la voie et du dernier jeu de signaux reçus; et
- facultativement, relayer les PhPDU entre les entités de PhLE (par exemple, un répétiteur).

Utilisation de réseaux dorsaux

E.1 Généralités

Le réseau dorsal peut être d'une utilisation avantageuse pour le concepteur de système, car il enlève le message du moyen de terrain de Type A, octroyant de la largeur de bande supplémentaire et une QoS plus élevée pour d'autres messages.

E.2 Caractéristiques recommandées

Bien que la dorsale elle-même ne soit pas spécifiée dans la présente norme, il est admis et recommandé que la dorsale présente les caractéristiques suivantes:

- Débit supérieur ou égal au débit du moyen de terrain de Type A (≥ 250 kbit/s).
- Capacité de prendre en charge le trafic bidirectionnel de message non sollicité.
- Qualité de service d'un niveau suffisant permettant de maintenir la synchronisation du temps de réseau. Cela peut mettre en place des méthodes spécifiques de synchronisation du temps sur la dorsale.
- Fiabilité élevée. Il convient que le fonctionnement ne charge pas le réseau avec des fréquents messages perdus et de fréquentes répétitions de tentative.
- Sécurité suffisante pour ne pas présenter une menace de sécurité pour l'application des utilisateurs finaux ou pour le réseau.
- Capacité d'encapsuler les TPDU ou TSDU de protocoles (de tunnellisation) définies par la présente norme ou de les convertir afin qu'elles puissent traverser la dorsale sans être modifiées lorsqu'elles émergent aux appareils dorsaux. Généralement, la dorsale doit être capable de prendre une TSDU conforme à la norme au point d'entrée et la livrer, inchangée, à travers la dorsale vers le point de sortie.
- Capacité de préserver les mécanismes de sécurité d'application de bout en bout.
- Prise en charge du réseautage multipoint entre les appareils.

Il est admis que de nombreux bus de terrain normalisés peuvent ne pas avoir ces caractéristiques et peuvent donc ne pas être adaptés à être utilisés comme réseau dorsal. Dans de nombreux cas, un réseau dorsal sera un réseau IP tel que selon l'ISO/IEC 8802-3 (IEEE 802.3) ou l'ISO/IEC 8802-11 (IEEE 802.11), mais il n'y a aucune exigence pour cela. Il existe beaucoup d'autres variantes sur le marché qui sont bien adaptées pour les besoins d'un réseau dorsal. Ceux-ci pourraient inclure des réseaux sans fil point à point ou bien point à multipoint.

E.3 Dorsales de protocole internet

E.3.1 Méthodes d'émission d'unités de données de protocole IPv6

Dans de nombreux cas, une dorsale disponible utilisera une NL de protocole internet (IP). Dans ce cas, il existe plusieurs manières différentes de transporter les TPDU du réseau de capteurs industriels sans fil (WISN) en utilisant le comportement de protocole normalisé:

- Encapsuler au sein de NPDU IPv4 les unités de données de protocole de transport du réseau de capteurs industriels sans fil.

  Le mécanisme utilisé pour encapsuler les TPDU du WISN au sein de NPDU IPv4 est formellement connu comme étant IPv6 sur IPv4 ou 6over4 et s'appelle parfois

Ethernet virtuel. Cette méthode est documentée dans l'ETF RFC 2529. Un routeur dorsal – l'IETF RFC 2529 les appelle hôtes IPv6 – situé sur une liaison physique qui n'a aucun routeur IPv6 directement connecté peut devenir un hôte IPv6 complètement fonctionnel en utilisant un domaine de multidiffusion IPv4 comme sa liaison locale virtuelle. Les routeurs dorsaux connectés en utilisant cette méthode n'exigent pas d'adresses compatibles IPv4 ou de tunnels configurés.

- Tunnelliser sur le réseau IPv4 les unités de données de protocole de transport du réseau de capteurs industriels sans fil.

  En suivant l'IETF RFC 4213, cette méthode encapsule des unités de données de protocole (PDU) IPv6 au sein d'en-têtes IPv4 pour les transporter sur des infrastructures de routage IPv4. Deux types de tunnellisation sont possibles, à savoir le type configuré et le type automatique. Dans la tunnellisation configurée, l'adresse de point d'extrémité de tunnel IPv4 est déterminée par les informations de configuration relatives au nœud d'encapsulation. Dans la tunnellisation automatique, l'adresse de point d'extrémité du tunnel IPv4 est déterminée à partir de l'adresse IPv4 intégrée dans l'adresse de destination compatible IPv4 de la PDU IPv6.

- Encapsuler au sein de NPDU Ethernet brutes les unités de données de protocole de transport du réseau de capteurs industriels sans fil.

  Cette méthode spécifie le format NPDU pour la transmission des PDU IPv6 à la suite de l'IETF RFC 2464. En outre, cette méthode dicte la formation d'adresses IPv6 locales à une liaison et d'adresses configurées sans états sur les réseaux Ethernet. Finalement, cette approche spécifie le contenu des adresses de couche liaison source/cible utilisées dans la sollicitation de routeur, l'annonce de routeur, la sollicitation de voisin, l'annonce de voisin, et redirige les messages lorsque ces messages sont émis sur un réseau Ethernet.

- Utiliser la dorsale IPv6 native sans la moindre encapsulation ou tunnellisation.

  Si la dorsale utilise une NL IPv6, ni l'encapsulation ni la tunnellisation ne sont nécessaires, car le mode natif d'une dorsale est de transporter des PDU IPv6.

E.3.2 Découverte d'appareils homologues d'un routeur dorsal

Pour que le routeur dorsal (BBR) fonctionne correctement et connecte des appareils de WISN sur la dorsale, il a besoin de connaître les adresses dorsales des autres BBR ou homologues dans le réseau dorsal. Au sein de chaque BBR, il convient que les informations d'adressage de ses pairs soient stockées dans une table d'homologues de routeur dorsal (BRPT). Il existe deux méthodes de base de génération de la BRPT, à savoir la configuration et la découverte.

NOTE La BRPT et le mécanisme pour découvrir des homologues ne relèvent pas du domaine d'application de la présente norme.

La configuration se produit lorsque les adresses des BBR homologues sont insérées dans la BRPT par le gestionnaire de système ou par un opérateur. Les avantages de cette méthode sont qu'elle est directe et empêche le BBR d'accéder à des appareils inappropriés sur la dorsale.

La découverte se produit lorsque le BBR recherche automatiquement des appareils homologues dans la dorsale. Il existe plusieurs techniques de découverte, telles que celles mentionnées dans l'IETF RFC 2529 et autres. Les avantages de cette méthode sont qu'elle est automatique, n'exige aucune implication d'opérateur, et peut être mise à jour facilement et souvent.

E.3.3 Sécurité

E.3.3.1 Sécurité des unités de données de protocole de transport

Les mécanismes de sécurité de la dorsale ne relèvent pas du domaine d'application de la présente norme. Les méthodes de sécurité IP typiques comprennent IPSec, SSL, et d'autres. En plus de tous les éventuels mécanismes de sécurité sur la dorsale, le mécanisme de sécurité de la TL du WISN protège la TPDU au sein de la dorsale.

E.3.3.2 Sécurité de la dorsale

Selon la perception de certains, le fait d'autoriser un WISN à accéder à une dorsale d'IP pourrait dégrader la sécurité de la dorsale. Ce souci peut être atténué en limitant l'accès de BBR aux seuls BBR homologues par l'intermédiaire d'une liste de contrôle d'accès ou par l'utilisation de pare-feu configurés pour limiter correctement l'accès à des appareils spécifiques.

Annexe F
(normative)

Concepts de sécurité de base – Notation et représentation

F.1 Chaînes et opérations sur les chaînes

Une chaîne est une séquence de symboles sur un ensemble spécifique (par exemple, l'alphabet binaire (0, 1) ou l'ensemble de tous les octets).

La taille d'une chaîne est le nombre de symboles qu'elle contient (sur le même alphabet).

La concaténation à droite de deux chaînes x et y de taille m et n respectivement (notation $x \,||\, y$) est la chaîne z de taille $m + n$ qui coïncide avec x sur ses m symboles de gauche et avec y sur ses n symboles de droite.

Un octet est une chaîne de symboles de longueur 8. Dans ce contexte, tous les octets sont des chaînes sur l'alphabet binaire.

F.2 Entiers, octets et leur représentation

Tout au long de la présente norme, la représentation des nombres entiers sous la forme de chaînes d'octets et celle des chaînes d'octets sous la forme de chaînes binaires doivent être fixe.

Tous les nombres entiers doivent être représentés sous la forme de chaînes d'octets dans l'ordre "octet de poids fort en premier". Cette représentation est conforme à la convention donnée dans l'ANSI X9.63:2011, 4.3.

Tous les octets doivent être représentés sous la forme de chaînes binaires dans l'ordre "bit de poids fort en premier".

F.3 Entités

Tout au long de la présente norme, chaque entité doit être un DEV et doit être identifié de façon univoque par son adresse EUI64. Le paramètre entityIdSize doit avoir la valeur 64.

Annexe G
(informative)

Utilisation de chaînes de certificats pour la configuration par liaison radio

La présente norme utilise le certificat implicite appelé le PublicReconstrKey (voir Annexe H pour les détails) pour la cryptographie à clés asymétriques. Connaissant l'identité d'un appareil A (ID_A) et le certificat implicite γ_A de l'appareil, la clé publique de l'appareil A peut être calculée en utilisant l'équation suivante:

$$Q_A = Hash(\gamma A||ID_A)\gamma A+Q_{CA}$$

où Q_{CA} est la clé publique de l'autorité de certification (CA).

Dans ce contexte, les étapes suivantes décrivent le processus pour la configuration par OTA en utilisant la cryptographie à clés 'asymétriques telle que présentée à la Figure 137.

1) Le CA édite Q_{CA}, sa clé publique, sur le web.
2) Le fabricant d'appareil (device manufacturer (DM)) obtient un certificat issu de la CA:

   C_DM = PublicReconstrKey(DM) || Subject(DM) || Issuer(CA) || Text

   où:

   - Subject = ID du DM
   - Issuer = ID de la CA
   - PublicReconstrKey_DM = γ_DM est utilisé pour calculer la clé publique du DM en utilisant l'équation:

     $Q_{DM} = HASH(\gamma\_DM||Subject)\gamma\_DM + Q_{CA}$
3) L'appareil individuel obtient un certificat issu du DM:

   C_DEV = PublicReconstrKey(DEV) || Subject(DEV) || Issuer(DM) || Text

   où:

   - Subject = ID de l'appareil
   - Issuer =ID du DM
   - PublicReconstrKey_DEV = γ_DEV est utilisé pour calculer la clé publique de l'appareil en utilisant l'équation:

     $Q_{DEV} = HASH(\gamma\_DEV||Subject)\gamma\_DEV + Q_{DM}$
   - C_DEV et C_DM sont remplis dans le DBP par le DM.
4) Le DBP rattache le PD dans un réseau de configuration. Le PD a le QCA.
5) Le DBP envoie un numéro aléatoire, C_DEV et C_DM au PD. Le PD calcule Q_DEV comme expliqué aux étapes 2) et 3).
6) Un mécanisme de défi/réponse est utilisé pour authentifier l'appareil, et il convient que le gestionnaire de sécurité valide le certificat implicite du fabricant à ce stade.
7) Si le défi/réponse donne un résultat positif, le PD envoie K_join chiffré avec Q_DEV.

Annexe H
(normative)

Blocs modules de base de sécurité

H.1 Blocs modules de base cryptographiques à clés symétriques

H.1.1 Vue d'ensemble

Les primitives et les éléments de données cryptographiques à clés symétriques suivants sont définis pour une utilisation avec toutes les opérations de traitement de la sécurité spécifiées dans la présente norme.

H.1.2 Paramètres de domaine des clés symétriques

La clé symétrique doit avoir la taille de clé keylen=128 (en bits).

H.1.3 Cryptage par blocs

Le chiffrement de bloc utilisé dans la présente norme doit être AES-128, comme spécifié dans l'ISO/IEC 18033-3. Ce chiffrement de bloc doit être utilisé avec des clés symétriques comme spécifié en H.1.2. Dans ce cas, la taille de clé est égale à la taille de bloc du bloc chiffrant, 128 bits.

H.1.4 Mode de fonctionnement

Le mode de fonctionnement de cryptage par blocs utilisé dans la présente norme doit être le mode de fonctionnement CCM*, tel que spécifié dans l'IEEE 802.15.4:2011, B.3.2.

H.1.5 Fonction de hachage cryptographique

La fonction de hachage cryptographique utilisée dans la présente norme doit être la fonction de hachage cryptographique à cryptage par blocs spécifiée à l'Article H.9, avec les instanciations suivantes:

- chaque entité doit utiliser le cryptage par blocs tel que spécifié en H.1.3;
- tous les nombres entiers et tous les octets doivent être représentés tels que spécifiés à l'Article F.2.

La fonction de hachage de Matyas-Meyer-Oseas (voir Article H.9) a une taille de compilation de messages hashlen qui est égale à la taille de bloc, en bits, du bloc chiffrant établi.

H.1.6 Fonction de hachage codée pour authentification de message

Le code d'authentification de message par hachage (HMAC) codé utilisé dans la présente norme doit être HMAC, tel que spécifié dans la FIPS 198, avec les instanciations suivantes:

- chaque entité doit utiliser la fonction de hachage cryptographique H telle que spécifiée en H.1.5;
- la taille de bloc B doit avoir la valeur entière B=keylen/8, où keylen est tel que spécifié en H.1.2 (à savoir, B est égal à la taille de la clé symétrique, en octets, qui est utilisée par la fonction de hachage codée);
- la taille de sortie HMAClen de la fonction de HMAC doit avoir la même valeur entière que le paramètre de compilation de messages hashlen, tel que spécifié en H.1.5.

H.1.7 Fonction de hachage codée spécialisée pour authentification de message

Le code d'authentification de message par hachage codé spécialisé[14] utilisé dans la présente norme doit être le code d'authentification de message par hachage codé, tel que spécifié en H.1.6.

H.1.8 Paramètres de domaine de défi

Les paramètres de domaine de défi utilisés dans la présente norme doivent être tels que spécifiés en H.6.2, avec l'instanciation (minchallengelen, maxchallengelen)=(keylen, keylen), où keylen est tel que spécifié en H.1.2.

Tous les défis doivent être validés en utilisant la primitive de validation de défi telle que spécifiée à l'Article H.7.

H.2 Blocs modules de base cryptographiques à clés asymétriques

H.2.1 Généralités

Les primitives et les éléments de données cryptographiques à clés asymétriques suivants sont définis pour une utilisation avec toutes les opérations de traitement de la sécurité spécifiées dans la présente norme.

NOTE Voir également l'ISO/IEC 180332 pour plus d'informations relatives à la cryptographie asymétrique.

H.2.2 Paramètres de domaine de courbe elliptique

Les paramètres de domaine de courbe elliptique utilisés dans la présente spécification doivent être ceux pour la courbe ansit283k1 telle que spécifiée dans la norme ANSI X9.63:2011, appendice J4.5, exemple 1.

Tous les points de courbe elliptique doivent être validés en utilisant la primitive de validation de clé publique telle que spécifiée dans l'ANSI X9.63:2011, 5.2.2.

H.2.3 Représentation de points de courbe elliptique

Tous les points de courbe elliptique doivent être représentés dans la notation polynomiale telle spécifiée dans l'ANSI X9.63:2011, 4.1.2.1. Tous les points de courbe elliptique doivent être émis sous forme compressée, telle que spécifiée dans l'ANSI X9.63:2011, 4.2.2.

H.2.4 Paire de clés publiques d'une courbe elliptique

Une paire de clés de courbe elliptique est constituée d'un nombre entier q et d'un point Q sur la courbe déterminée en multipliant le point générateur G de la courbe par ce nombre entier (à savoir Q=qG) comme spécifié dans la norme ANSI X9.63:2011. Ici, Q est appelé la clé publique, alors que q est appelé la clé privée; la paire (q, Q) est appelée la paire de clés publiques. Chaque clé privée doit être représentée comme spécifié dans l'ANSI X9.63:2011, 4.3.1. Chaque clé privée doit être sur la courbe comme spécifié en H.2.2 et doit être représentée comme spécifié en H.2.3.

---

14 Cela se réfère au schéma MAC où la fonction MAC a la propriété complémentaire d'être également une pré-image et résistante aux collisions pour les parties prenantes connaissant la clé (voir également la remarque 9.8 de Menezes et al.). De telles fonctions MAC permettent la dérivation de clé dans des contextes où une commande unilatérale des clés est indésirable.

H.3 Information de codage

H.3.1 Généralités

Ce qui suit spécifie le format des informations de codage à clés asymétriques utilisées dans la présente norme.

H.3.2 Certificats implicites de cryptographie sur courbe elliptique

Les certificats implicites IC_U doivent être spécifiés comme

IC_U = PublicKeyReconstrData || Subject || Issuer || Usage_Serial || KeyValidityInfo || Text

où:

- Le paramètre PublicKeyReconstrData doit représenter les données de reconstruction de clés publiques BEU telles que spécifiées dans le plan de génération de certificats implicites (voir H.5.1).
- Le paramètre Subject doit être l'entité U qui est liée aux données de reconstruction de clés publiques BEU pendant l'exécution du plan de génération de certificats implicites, à savoir l'entité qui est prétendument propriétaire de la clé privée correspondant à la clé publique qui peut être reconstruite à partir de PublicReconstrKey.
- Le paramètre Issuer doit être l'entité de l'autorité de certification (CA) qui crée le certificat implicite pendant l'exécution du plan de génération de certificats implicites.
- Le paramètre Usage_Serial est défini dans le Tableau 68.
- Le paramètre KeyValidityInfo doit indiquer la période de validité du support de codage telle qu'indiquée par les paramètres ValidNotBefore et ValidNotAfter, qui indiquent respectivement le début et la fin de la période de validité. Le KeyValidityInfo doit être formaté comme

  KeyValidityInfo = ValidNotBefore || ValidNotAfter

  où ValidNotBefore et ValidNotAfter doivent être représentés tels que spécifiés en 12.22.4.2.
- Le paramètre Text doit être la représentation d'informations complémentaires, telles que spécifiées en H.3.4.
- La chaîne I_U telle que spécifiée dans le plan de génération de certificats implicites (voir H.5.1) doit être la chaîne d'octets comprenant les chaînes Subject, Issuer, et Text, comme suit:

  I_U = Subject || Issuer || Text

H.3.3 Certificats manuels de cryptographie sur courbe elliptique

Les certificats manuels MC_U doivent être spécifiés sous la forme MC_U = PublicKey || Subject || Issuer || Text, où:

- Le paramètre PublicKey doit être la représentation en octet de la clé publique W_U telle que spécifiée dans la transformation de la génération de certificats manuels.
- Le paramètre Subject doit être l'entité U du prétendu propriétaire de la clé privée correspondant à la clé publique représentée par PublicKey.
- Le paramètre Issuer doit être l'entité de la CA qui crée le certificat manuel pendant l'exécution de la transformation de génération de certificats manuels (ladite autorité de certification).
- Le paramètre Usage_Serial est défini dans le Tableau 68.
- Le paramètre KeyValidityInfo doit indiquer la période de validité du support de codage telle qu'indiquée par les paramètres ValidNotBefore et ValidNotAfter, qui indiquent

respectivement le début et la fin de la période de validité. Le KeyValidityInfo doit être formaté comme

KeyValidityInfo = ValidNotBefore || ValidNotAfter

où ValidNotBefore et ValidNotAfter doivent être représentés tels que spécifiés en 12.22.4.2.

- Le paramètre Text doit être la représentation d'informations complémentaires, telles que spécifiées en H.3.4.
- La chaîne I_U telle que spécifiée dans le plan de génération de certificats manuels (voir l'Article H.10) doit être la chaîne d'octets comprenant les chaînes Subject, Issuer, et Text, comme suit:

  I_U = Subject || Issuer || Text

NOTE Un certificat manuel n'est pas un certificat numérique réel, car la liaison entre les paramètres PublicKey et Subject est établie et vérifiée par des moyens non cryptographiques.

H.3.4 Informations supplémentaires

Les informations complémentaires Text doivent être spécifiées comme suit:

Text = Reserved

où le paramètre Reserved permet la prise en charge de futures extensions des informations complémentaires et doit être mis à une chaîne de bits zéro partout pour la présente version de la norme.

H.4 Plan d'agrément de clés

H.4.1 Plan d'agrément de clé à clés symétriques

Le plan d'agrément de clés à clés symétriques utilisé dans la présente norme doit être le plan complet de confirmation de clé à clés symétriques tel que spécifié avec les instanciations suivantes:

- Chaque entité doit être identifiée telle que spécifiée à l'Article F.3.
- Chaque entité doit utiliser le plan HMAC tel que spécifié en H.1.5.
- Chaque entité doit utiliser la fonction de hachage cryptographique telle que spécifiée en H.1.5.
- Le paramètre keydatalen doit avoir la même valeur entière que le paramètre de taille de clé keylen tel que spécifié en H.1.2.
- Chaque entité doit utiliser les paramètres de domaine de défi tels que spécifiés en H.1.8.
- Tous les octets doivent être représentés tels que spécifiés à l'Article F.2.

H.4.2 Plan d'agrément de clé à clés asymétriques

Le plan d'agrément de clés à clés asymétriques utilisé dans la présente norme doit être le MQV complet avec plan de confirmation de clé tel que spécifié dans l'ANSI X9.63:2011, 6.11, avec les instanciations suivantes:

- Chaque entité doit être identifiée telle que spécifiée à l'Article F.3.
- Chaque entité doit utiliser le plan HMAC tel que spécifié en H.1.5.
- Chaque entité doit utiliser la fonction de hachage cryptographique telle que spécifiée en H.1.5.
- Le paramètre keydatalen doit avoir la même valeur entière que le paramètre de taille de clé keylen tel que spécifié en H.1.2.

- Le paramètre SharedData doit être la chaîne vide. Le paramètre shareddatalen doit avoir la valeur entière 0.
- Chaque entité doit utiliser les paramètres de domaine de courbe elliptique tels que spécifiés en H.2.2.
- Tous les points de courbe elliptique doivent être représentés tels que spécifiés à l'article H.2.3.
- Tous les octets doivent être représentés tels que spécifiés à l'Article F.2.

H.5 Plans d'informations de codage

H.5.1 Plan de certificats implicites

Le plan de certificats implicites utilisé dans la présente norme doit être le plan de certificats implicites ECQV tel que spécifié en SEC 4, avec les instanciations suivantes:

- Chaque entité doit être identifiée telle que spécifiée à l'Article F.3.
- Chaque entité doit utiliser la fonction de hachage cryptographique telle que spécifiée en H.1.5.
- Chaque entité doit utiliser les paramètres de domaine de courbe elliptique tels que spécifiés en H.2.2.
- Tous les points de courbe elliptique doivent être représentés tels que spécifiés à l'article H.2.3.
- Tous certificats implicites doivent être représentés tels que spécifiés en H.3.2.
- L'infrastructure des certificats implicites doit être l'un des plans spécifiés en H.3.2.
- Tous les octets doivent être représentés tels que spécifiés à l'Article F.2.

H.5.2 Plan de certificats manuels

Le plan de certificats manuels utilisé dans la présente norme doit être le plan de certificats manuels tel que spécifié à l'Article H.10, avec les instanciations suivantes:

- Chaque entité doit être identifiée telle que spécifiée à l'Article F.3.
- Chaque entité doit utiliser les paramètres de domaine de courbe elliptique tels que spécifiés en H.2.2.
- Tous les points de courbe elliptique doivent être représentés tels que spécifiés à l'article H.2.3.
- Tous certificats manuels doivent être représentés tels que spécifiés en H.3.2.
- L'infrastructure des certificats manuels doit être l'un des plans spécifiés en H.3.2.
- Tous les octets doivent être représentés tels que spécifiés à l'Article F.2.

H.6 Génération et validation des paramètres de domaine de défi

H.6.1 Vue d'ensemble

Les paramètres de domaine de défi imposent des contraintes sur la(les) taille(s) des défis de bit qu'un plan attend. A ce titre, cela détermine une limite sur l'entropie des défis et, donc, sur la sécurité des plans cryptographiques dans lesquels ces défis sont utilisés. Dans la plupart des plans, les paramètres de domaine de défi seront tels que seuls les défis d'une taille fixe seront acceptés (par exemple, défis de 128 bits). Toutefois, on peut définir les paramètres de domaine de défi tels que des défis de taille variable soient acceptés. Ce dernier cas est utile dans des contextes où les entités qui souhaitent s'engager dans des plans cryptographiques pourraient avoir un générateur de bits aléatoire défectueux ou de basse qualité. Le fait de permettre aux deux entités qui s'engagent dans un plan d'apporter comme contribution de longues entrées permet à chacune d'apporter de l'entropie suffisante au plan à proximité.

Dans la présente norme, des paramètres de domaine de défi seront partagés par un certain nombre d'entités utilisant un plan de la norme. Les paramètres de domaine de défi peuvent être publics; la sécurité du système ne repose pas sur le fait que ces paramètres soient secrets.

H.6.2 Génération de paramètres de domaine de défi

Les paramètres de domaine de défi doivent être générés en utilisant la routine suivante:

- Entrée: Cette routine ne prend aucune entrée.
- Actions: Les actions suivantes sont entreprises:
  - Choisir deux nombres entiers non négatifs minchallengelen et maxchallengelen, tels que minchallengelen ≤ maxchallengelen.
- Sortie: Paramètres de domaine de défi D=(minchallengelen, maxchallengelen).

H.6.3 Vérification de paramètres de domaine de défi

Les paramètres de domaine de défi doivent être vérifiés en utilisant la routine suivante:

- Entrée: Ensemble prétendu de paramètres de domaine de défi D = (minchallengelen, maxchallengelen).
- Actions: Les vérifications suivantes sont faites:
  - La vérification que minchallengelen et maxchallengelen sont des nombres entiers non négatifs.
  - Vérifier que minchallengelen ≤ maxchallengelen.
- Sortie: Si l'une des vérifications ci-dessus a échoué, alors produire invalide et rejeter les paramètres de domaine de défi. Autrement, produire valide et accepter les paramètres de domaine de défi.

H.7 Primitive de validation de défi

La validation de défi se réfère au processus de vérification des propriétés de taille d'un défi. Elle est utilisée pour vérifier si, oui ou non, un défi devant être utilisé par un plan dans la norme a la taille suffisante (par exemple, des messages qui sont trop courts sont rejetés, en raison d'entropie insuffisante).

La primitive de validation de défi est utilisée à l'Article H.7 et utilise la routine suivante:

- Entrée: L'entrée de la transformation de validation est un ensemble valide de paramètres de domaine de défi D = (minchallengelen, maxchallengelen), ainsi que la chaîne binaire Challenge.
- Actions: Les actions suivantes sont entreprises:
  - Calculer la longueur de bits challengelen de la chaîne de bits Challenge.
  - Vérifier que challengelen ∈ [minchallengelen, maxchallengelen]. (A savoir, vérifier que le défi a une taille appropriée.)
- Sortie: Si la vérification ci-dessus échoue, alors produire invalide et rejeter le défi. Autrement, produire valide et accepter le défi.

H.8 Primitive de génération de clés secrètes (SKG)

La primitive SKG dérive une valeur secrète partagée à partir d'un défi possédé par une entité U_1 et d'un défi possédé par une entité U_2 si tous les défis partagent les mêmes paramètres de domaine de défi. Si les deux entités exécutent correctement cette primitive avec des défis correspondants comme entrées, la même valeur secrète partagée sera produite.

La valeur secrète partagée doit être calculée comme suit:

- Conditions préalables: Ce qui suit représente les conditions préalables pour l'utilisation de la primitive SKG:
  - Chaque entité doit être liée à un identificateur unique (par exemple, noms distingués). Tous les identificateurs doivent être des chaînes de bits de la même taille, entityIdSize. L'identificateur de l'entité U_1 sera désigné par la chaîne de bits U_1. L'identificateur de l'entité U_2 sera désigné par la chaîne de bits U_2.
  - Un plan MAC spécialisé[15] doit avoir été sélectionné, avec les informations d'étiquetage telles que spécifiées dans l'ANSI X9.63:2011, 5.7.1. La taille en bits des clés utilisées par le plan MAC spécialisé est désignée par macKeySize.
- Entrée: La primitive SKG prend comme entrée:
  - Une chaîne de bits MacKey de taille macKeySize bits devant être utilisée comme la clé d'un plan MAC spécialisé établi.
  - Une chaîne de bits QEU_1 appartenant au propriétaire U_1.
  - Une chaîne de bits QEU_2 appartenant au propriétaire U_2.
- Actions: Les actions suivantes sont entreprises:
  - Former la chaîne de bits constituée de l'identificateur de U_1, de l'identificateur de U_2, la chaîne de bits QEU_1 correspondant au défi de U_1, et la chaîne de bits QEU_2 correspondant au défi de U_2:
  - MacData = $U_1 \,||\, U_2 \,||\, QEU_1 \,||\, QEU_2$.
  - Calculer l'étiquette MacTag pour MacData avec la clé MacKey en utilisant la transformation d'étiquetage du plan MAC spécialisé établi:
  - $MacTag = MAC_{MacKey}(MacData)$.
  - Si la transformation d'étiquetage produit non valide, produire également non valide et arrêter.
  - Mettre Z=MacTag.
- Sortie: La chaîne de bits Z comme la valeur secrète partagée.

H.9 Fonction de hachage cryptographique à chiffrement par blocs

La fonction de hachage de Matyas-Meyer-Oseas est une fonction de hachage cryptographique basée sur des blocs chiffrants. Cette fonction de hachage est définie pour des blocs chiffrants avec une taille de clé qui est égale à la longueur du bloc, comme l'AES-128, et avec un choix particulier pour le vecteur d'initialisation fixe IV (qui est défini ici comme étant IV=0).

NOTE Pour une définition plus générale de la fonction de hachage de Matyas-Meyer-Oseas, voir le *Handbook of applied cryptography*:1996, 9.4.1, inclus dans la Bibliographie.

La fonction de hachage est définie comme suit:

- Conditions préalables: Ce qui suit représente les conditions préalables au fonctionnement de la fonction de hachage de Matyas-Meyer-Oseas:
  - Une fonction E de chiffrement par blocs doit avoir été choisie, avec une taille de clé qui est égale à la taille de bloc. La fonction de hachage de Matyas-Meyer-Oseas a une taille de compilation de messages qui est égale à la taille de bloc de la fonction de chiffrement établie. Elle opère sur des chaînes de bits de taille inférieure à 2^n, où n est la taille de bloc, en octets, du chiffrement par blocs établi.

---

15 Cela se réfère au schéma MAC dans lequel la fonction MAC a la propriété complémentaire d'être également une pré-image et résistante aux collisions pour les parties prenantes connaissant la clé (voir également la remarque 9.8 de Menezes et al.). De telles fonctions MAC permettent la dérivation de clé dans des contextes où une commande unilatérale des clés est indésirable.

  - Une représentation fixe de nombres entiers sous la forme de chaînes de bits ou de chaînes d'octets doit avoir été choisie.

- Entrée: L'entrée à la fonction de hachage de Matyas-Meyer-Oseas est comme suit:
  - Une chaîne de bits M de taille de bits l bits, où $0 \leq l < 2^n$.
- Actions: La valeur de hachage doit être dérivée comme suit:
  - Bourrer le message M selon la méthode suivante:
  - Concaténer à droite au message M la valeur binaire constituée d'un bit de 1 suivi de k bits de 0, où k est la plus petite solution non négative à l'équation

    $l + 1 + k \equiv 7n \pmod{8n}$.
  - Former de le message bourré M en concaténant à droite à la chaîne résultante la chaîne de n bits qui est égale à la représentation binaire du nombre entier l.
  - Analyser le message bourré M comme étant $M_1 \| M_2 \| \ldots \| M_t$ où chaque bloc de message M_i est une chaîne de n octets.
  - La sortie $Hash_t$ est définie par

    $Hash_0 = 0^{8n}$; $Hash_j = E(Hash_{j-1}, M_j) \oplus M_j$ pour $j=1,\ldots,t$.

Ici, E (K, x) est le cryptogramme qui résulte du chiffrement du texte en clair x, en utilisant la fonction E de chiffrement à blocs chiffrants établie avec la clé K; la chaîne 0^{8n} est la chaîne de bits 0 partout de n octets.

- Sortie: La chaîne de bits Hasht comme la valeur de hachage.

La fonction cryptographique de hachage opère sur une force binaire de longueur inférieure à 2^n bits, où n est la taille de bloc (ou taille de clé) du chiffrement par blocs établi, en octets. Par exemple, la fonction de hachage de Matyas-Meyer-Oseas avec AES-128 opère sur les chaînes binaires de taille inférieure à 2^{16} bits. Il est supposé que tous les appels de fonction de hachage sont sur les chaînes binaires de taille inférieure à 2^n bits. Tout plan tentant d'appeler la fonction de hachage sur une chaîne de bits dépassant 2^n bits doit produire invalide et s'arrêter.

H.10 Plan de certificats manuels à cryptographie sur courbes elliptiques

H.10.1 Vue d'ensemble

Un plan de certificat manuel basé sur la cryptographie sur courbes elliptiques (ECC) qui est utilisée dans la présente norme est décrit.

Le plan de certificat manuel est utilisé par trois entités: une autorité de certification CA, un demandeur de certificat U, et un processeur de certificat V, où U souhaite obtenir un certificat manuel issu de CA afin d'acheminer vers V la clé publique associée de U.

Le plan de certificat manuel est décrit en termes d'une transformation de génération de certificat et d'une transformation de traitement de certificat. CA, U, et V utilisent ces plans lorsqu'ils souhaitent communiquer.

Avant l'utilisation du plan, U, V, et CA s'accordent sur les paramètres avec lesquels le plan doit être utilisé. En particulier, cela inclut que U et V obtiennent une copie authentique de l'identificateur unique de CA.

CA exécute la transformation de génération de certificat manuel pour calculer une paire de clés publiques sur courbe elliptique pour U et un certificat manuel MC pour cette clé publique fournie par CA. V exécute la transformation de traitement du certificat manuel, pour obtenir la clé publique statique prétendue de U à partir du certificat manuel prétendu MC de U présenté à V.

La transformation de génération de certificat manuel produit une paire de clés publiques et un certificat pour cette clé publique. Cette paire de clés publiques doit être communiquée au prétendu détenteur d'une manière sécurisée et authentique. Le mécanisme par lequel cette paire de clés publiques est communiquée ne relève pas du domaine d'application de la présente norme.

La transformation de traitement de certificat manuel produit une clé publique statique (et les informations de codage associées) destinée au détenteur revendiqué; la preuve que cette clé publique est véritablement liée à cette entité ne peut cependant pas être corroborée par l'intermédiaire du traitement du certificat manuel. Ainsi, avec les certificats manuels, la liaison d'une entité et de sa clé publique ou privée ne peut pas être vérifiée, bien qu'on puisse obtenir la preuve qu'une certaine entité qui prétend être liée à la clé publique a en effet accès à la clé privée correspondante, pendant l'utilisation cryptographique de la clé publique (par exemple, par l'intermédiaire de l'exécution d'un plan d'agrément de clé authentifié ou d'une transformation de signature impliquant cette paire de clés publiques).

La transformation de génération de certificat manuel est spécifiée en H.10.2 et la transformation de traitement de certificat manuel est spécifiée en H.10.3.

Les conditions préalables pour l'utilisation du plan sont:

- Une infrastructure doit avoir été établie pour l'opération du plan, y compris un format de certificat, des règles de traitement de certificats, et des identificateurs uniques. Pour un exemple d'une telle infrastructure, voir l'IETF RFC 3280.
- Chaque entité a une copie authentique des paramètres de domaine de courbe elliptique de systèmes D=(p,a,b,G,n,h) ou D=(m,f(x),a,b,G,n,h). Ces paramètres doivent avoir été générés en utilisant les primitives de génération de paramètre indiquées en SEC 1:2009, 3.1.1.1 ou 3.1.2.1. En outre, les paramètres doivent avoir été validés en utilisant les primitives de validation de paramètre en SEC 1:2009 3.1.1.2 ou 3.1.2.2.
- Chaque entité doit être liée à un identificateur unique (par exemple, noms distingués). Tous les identificateurs doivent être des chaînes de bits de la même taille, entityIdSize. L'identificateur de l'entité U sera désigné par la chaîne de bits U. L'identificateur de l'entité V sera désigné par la chaîne de bits V. L'identificateur de l'entité CA sera désigné par la chaîne de bits CA.
- Une fonction de hachage cryptographique Hash doit avoir été choisie pour une utilisation avec le plan de génération de certificat implicite ECQV. Soit hashlen désignant la taille en bits de la valeur de sortie de cette fonction de hachage.
- Chaque entité doit avoir décidé de la manière de représenter les points de courbe elliptique sous forme de chaînes d'octets (à savoir forme compressée, forme non compressée, ou forme hybride).
- Une représentation fixe des octets sous la forme de chaînes binaires doit avoir été choisie (par exemple, ordre "bit de poids fort en premier" ou ordre "bit de poids faible en premier").

H.10.2 Transformation de génération de certificat manuel à cryptographie sur courbes elliptiques

Une CA doit exécuter la transformation suivante pour fournir un certificat manuel pour l'utilisateur, U. La CA doit obtenir une copie authentique de l'identificateur de U.

- Entrées: Cette routine ne prend aucune entrée.
- Ingrédients: La transformation de génération de certificat utilise la primitive de génération de paire de clés donnée en SEC 1:2009, 3.2.1, et la primitive de génération de certificat manuel de l'infrastructure établie.
- Actions: La CA doit poursuivre comme suit:

  - La primitive de génération de paire de clés spécifié en SEC 1:2009, 3.2.1, doit être utilisée pour générer une paire de clés éphémères (w_U, W_U) pour les paramètres D.
  - Le point de courbe elliptique W_U doit être converti en la chaîne d'octets WE_U telle que spécifiée en SEC 1:2009, 2.3.3.
  - La chaîne d'octets I_U, qui représente les données du certificat manuel devant être acheminées. I_U doit être construite pour contenir les informations d'identification selon les procédures de l'infrastructure établie et peut également contenir d'autres informations, telles que l'utilisation prévue de la clé publique, le numéro de série du certificat manuel, et la période de validité du certificat manuel. La forme exacte de I_U dépend du format de certificat manuel spécifié pendant le procédé d'installation.
  - La chaîne d'octets MC_U, qui est le certificat manuel de U, doit être construite selon les procédures de l'infrastructure établie. MC_U doit contenir les chaînes d'octets I_U et WEU codées de manière réversible. La forme exacte de MC_U dépend du format de certificat manuel spécifié pendant le procédé d'installation.
- Sortie: MC_U, qui doit servir de certificat manuel de U fournie par CA.

H.10.3 Transformation de traitement de certificat manuel à cryptographie sur courbes elliptiques

V doit exécuter la transformation suivante pour obtenir la clé publique statique prétendue de U à partir du certificat manuel prétendu de U fourni par CA. V doit obtenir une copie authentique de l'identificateur de U et de CA.

- Entrée: Certificat manuel prétendu de U, MC_U, fourni par CA.
- Ingrédients: La transformation de traitement de certificat manuel utilise la primitive de validation de clé publique en SEC 1:2009, 3.2.2, et la primitive de validation de certificat manuel de l'infrastructure établie.
- Actions: V poursuit comme suit:
  - Vérifier le contenu de MCU selon l'infrastructure établie. Cela inclut de vérifier le contenu du certificat, tel que le nom du sujet et la période de validité. Si le nom du sujet est différent de U, produire une sortie invalide et s'arrêter.
  - Dériver I_U à partir de MCU, selon le format de certificat manuel spécifié pendant la procédure d'installation.
  - Dériver l'identificateur de CA à partir de I_U, selon le format de certificat spécifié pendant la procédure d'installation. Si l'identificateur du CA est inconnue de V, produire invalide et s'arrêter.
  - Dériver WE_U à partir de MCU, selon le format de certificat manuel spécifié pendant la procédure d'installation.
  - Convertir la chaîne d'octets WE_U en le point de courbe elliptique W_U tel que spécifié en SEC 1:2009, 2.3.4
  - Vérifier que W_U est une clé valide pour les paramètres D comme spécifié dans SEC 1:2009, 3.2.2. Si la primitive de validation rejette la clé, produire invalide et s'arrêter.
- Sortie: Si l'une quelconque des vérifications ci-dessous a échoué, produire invalide et s'arrêter; autrement, produire valide et accepter W_U comme la clé publique statique prétendue de U. (V peut accepter W_U comme U comme étant la clé publique statique authentique de U, à condition que U apporte à V la preuve de la connaissance de la clé privée correspondante w_U et à condition que V accepte que U soit la seule partie qui peut avoir accès à cette clé privée.)

Annexe I
(informative)

Modèles de définition

I.1 Modèle de type d'objet

Il convient que des objets normalisés et leurs identificateurs d'objets normalisés associés soient identifiés dans une table pour référence rapide, comme montré dans le Tableau I.1. Cela indique les informations exigées pour définir les types d'objets normalisées définis par la présente norme.

Tableau I.1 – Tableau des types d'objets normalisés

Définition de l'organisation:			
Nom du type d'objet normalisé **(transmission non attendue, taille non spécifiée – vérifier les limites DD)**	**Identificateur du type d'objet normalisé (non négatif)**	**Identificateur d'objet normalisé (non négatif), si applicable** **Utilisé pour objets obligatoires avec exactement une instance par appareil**	**Description de l'objet** **(transmission non attendue, taille non spécifiée – vérifier les limites DD)**
…	…	…	…

Les éléments de la table incluent:

- Le nom du type d'objet normalisé définit le nom de l'objet.
- L'identificateur du type d'objet normalisé non négatif est l'identificateur numérique normalisé non négatif du type d'objet; identifie uniquement ce type d'objet.
- L'identificateur d'objet normalisé, pour les types d'objets normalisés qui sont exigés par un appareil et qui peuvent être seulement instanciés une fois, représente l'identificateur numérique normalisé non négatif pour l'instance d'objet. Cet identificateur est commun à tous les appareils. Si 7 bits ne suffisent pas, le bit de poids fort du premier octet doit être mis et un autre octet doit être disponible pour étendre la valeur de l'identificateur.
- La description d'objet est une description du but et de l'intention de cet objet.

I.2 Modèles d'attributs d'objets normalisés

Le modèle montré dans le Tableau I.2 indique les informations nécessaires pour définir les attributs d'un objet normalisé.

Tableau I.2 – Modèle pour attributs d'objets normalisés

Nom du type d'objet normalisé:				
Identificateur du type d'objet normalisé:				
Définition de l'organisation:				
Nom de l'attribut	**Identificateur de l'attribut**	**Description de l'attribut**	**Informations sur les données de l'attribut**	**Description du comportement de l'attribut**
ObjectIdentifier	Identificateur de clé	Identificateur unique pour l'objet	Type: Unsigned16.	N/A
			Classification: Statique	
			Plage valide: 1..32 767	
...	...	...	Type: ...	...
			Classification: ...	
			Accessibilité: ...	
			Valeur par défaut: ...	
			Plage valide: ...	
Réservée pour un usage futur	-	-	-	-

Les éléments de la table incluent:

- Le nom du type d'objet normalisé définit le nom de l'objet.
- L'identificateur du type d'objet normalisé est l'identificateur numérique normalisé non négatif du type d'objet; identifie uniquement ce type d'objet. La valeur de cet identificateur s'inscrit dans deux octets au maximum.
- L'organisation de définition est l'organisation définissant cet objet (par exemple, norme de base, extension définie normalisée de l'objet normalisé de base, profil spécifique à une industrie (et quelle industrie), groupe d'intérêt spécial (et quel groupe d'intérêt)), ou un fournisseur d'appareil.
- Le nom d'attribut définit le nom de l'attribut.
- L'identificateur d'attribut est un identificateur numérique normalisé de l'attribut. Tous les attributs d'un objet sont identifiés de façon univoque. Si 7 bits ne suffisent pas, le bit de poids fort du premier octet doit être mis et un autre octet doit être disponible pour étendre la valeur de l'identificateur.
- Description est la description de l'attribut.
- Type est le type de données de l'attribut. Si les données peuvent changer de taille (comme dans le cas d'un OctetString de taille variable ou d'un VisibleString de taille variable), le nombre maximal d'octets de données est indiqué.
- Classification est la classification des données ("constant", "static", "static-volatile", "dynamic", "non-cacheable") de l'attribut.
- Accessibilité est la manière dont l'attribut est accessible à distance (par exemple, read only, ou read/write)
- Valeur initiale par défaut spécifie la valeur initiale par défaut.
- Ensemble de valeurs valides spécifie l'ensemble valide de valeurs pour cet attribut.

I.3 Méthodes d'objets normalisés

Le modèle montré dans le Tableau I.3 indique les informations nécessaires pour décrire les méthodes d'un objet normalisé.

Tableau I.3 – Modèle pour méthodes d'objets normalisés

<table>
<tr><td colspan="5">Nom du type d'objet normalisé:</td></tr>
<tr><td colspan="5">Identificateur du type d'objet normalisé:</td></tr>
<tr><td colspan="5">Définition de l'organisation:</td></tr>
<tr><td>Nom de méthode</td><td>ID de méthode</td><td colspan="3">Description de la méthode</td></tr>
<tr><td rowspan="6"><nom de méthode></td><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>…</td><td>…</td><td>…</td><td>…</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>…</td><td>…</td><td>…</td><td>…</td></tr>
</table>

Les éléments de la table incluent:

- Le nom du type d'objet normalisé définit le nom de l'objet.
- L'identificateur du type d'objet normalisé est l'identificateur numérique normalisé non négatif du type d'objet; identifie uniquement ce type d'objet. La valeur de cet identificateur s'inscrit dans deux octets au maximum.
- L'organisation de définition est l'organisation définissant cet objet (par exemple, norme de base, extension définie normalisée de l'objet normalisé de base, profil spécifique à une industrie (et quelle industrie), groupe d'intérêt spécial (et quel groupe d'intérêt)).
- Le nom de méthode est le nom de la méthode.
- L'ID de méthode est l'identification numérique de la méthode. Toutes les méthodes d'un objet auront des identificateurs de méthode uniques. Si 7 bits ne suffisent pas, le bit de poids fort du premier octet doit être mis et un autre octet doit être disponible pour étendre la valeur de l'identificateur.
- Description de méthode est la description de la méthode.
- La liste de paramètres d'entrée et de leurs types de données est une liste des paramètres d'entrée, de leur type et de leur taille (si elle n'est pas explicitement discernable du type), et une description d'utilisation (comment ils sont utilisés lorsqu'ils sont envoyés sur une invocation de méthode). Il convient de les énumérer dans l'ordre d'émission.

NOTE 1 Pour simplifier, tous les paramètres sont spécifiés. S'il y a des situations où les paramètres varient, des méthodes séparées sont appropriées pour prendre en charge chaque classe de variance.

- La liste de paramètres de sortie et de leurs types de données est une liste des paramètres de sortie, de leur type et de leur taille (si elle n'est pas explicitement discernable du type), et une description d'utilisation (comment ils sont utilisés lorsqu'ils sont envoyés sur une invocation de méthode). Il convient de les énumérer dans l'ordre d'émission.

NOTE 2 Voir NOTE 1.

- Description de comportement décrit le comportement de l'objet lorsque cette méthode est invoquée.

I.4 Modèles de rapports d'alerte d'objets normalisés

Le modèle montré dans le Tableau I.4 indique les informations nécessaires pour décrire le comportement de rapports d'alertes d'un objet normalisé.

Tableau I.4 – Modèles pour rapports d'alerte d'objets normalisés

Nom du type d'objet normalisé:					
Identificateur du type d'objet normalisé:					
Définition de l'organisation:					
Description de l'alerte:					
Classe d'alertes (Enumerated: alarme ou événement)	**Catégorie d'alertes (Enumerated: diagnostic d'appareil, diagnostic de comm., sécurité ou processus)**	**Type d'alerte (Enumerated: en fonction de la catégorie d'alertes)**	**Alert priority**	**Type de données de la valeur**	**Description de la valeur incluse avec l'alerte**
<nom d'alerte>	...	...	...	Type: ...	...
				Valeur par défaut: ...	...
				Plage valide: ...	...

Les éléments de la table incluent:

- Le nom du type d'objet normalisé définit le nom de l'objet.
- L'identificateur du type d'objet normalisé est l'identificateur numérique normalisé du type d'objet qui identifie de manière unique ce(s) type(s) d'objet qui peut(peuvent) rapporter cette alerte. La valeur de cet identificateur s'inscrit dans deux octets au maximum.
- L'organisation de définition est l'organisation définissant cet objet (par exemple, norme de base, profil spécifique à une industrie (et quelle industrie), groupe d'intérêt spécial (et quel groupe d'intérêt)).
- La description de l'alerte décrit la signification sémantique de l'alerte.
- Classe d'alertes indique s'il s'agit d'un type d'alerte événement (sans états) ou alarme (orientée état).
- Catégorie d'alerte indique s'il s'agit d'une alerte relative à un appareil (par exemple, diagnostic spécifique à un appareil), relative à une communication, relative à la sécurité, ou relative à un processus. Une seule catégorie s'applique. La sélection du meilleur ajustement pour une alerte peut avoir besoin d'être débattue afin d'être mieux établie.
- Le type alerte dépend de la catégorie alerte. Voir le modèle de rapports d'alertes en 12.8 pour plus de détails.
- Priorité d'alerte est la priorité de l'alerte.
- Valeur et taille représentent la taille et la valeur incluses dans le rapport d'alerte.
- La description de la valeur incluse dans le rapport d'alerte est la description de la valeur, si une valeur est incluse dans le rapport d'alerte (par exemple, pour une alarme de processus qui est une alarme "high", il peut s'agir de variable de processus (PV)).
- Accessibilité définit si l'attribut est lisible, inscriptible ou les deux.
- La valeur initiale par défaut indique la valeur initiale par défaut de l'attribut.
- Description de l'ensemble de valeurs décrit l'ensemble de valeurs qui peuvent être prises par cet attribut.
- Description du comportement décrit le comportement de cet attribut (par exemple, quand une valeur particulière est écrite ou en cas de condition d'erreur). Des restrictions à l'utilisation (par exemple, il convient que les opérateurs n'écrivent pas dans cet attribut) peuvent être notées ici.

I.5 Définition de structures de données

Le modèle pour décrire les structures de données qui sont utilisées pour définir des types de données spéciaux est donné dans le Tableau I.5.

Tableau I.5 – Modèle pour structures de données

<table>
<tr><th colspan="3">Nom du type de données normalisé:</th></tr>
<tr><th colspan="3">Définition de l'organisation:</th></tr>
<tr><th>Nom de l'élément</th><th>Identificateur de l'élément</th><th>Type de l'élément scalaire</th></tr>
<tr><td rowspan="6">...</td><td rowspan="6">...</td><td>Type: ...</td></tr>
<tr><td>Taille: ...</td></tr>
<tr><td>Classification: ...</td></tr>
<tr><td>Accessibilité: ...</td></tr>
<tr><td>Valeur par défaut: ...</td></tr>
<tr><td>Plage valide: ...</td></tr>
</table>

Opérations sur les attributs

J.1 Opérations sur les attributs

J.1.1 Généralités

La classification et l'accessibilité d'attribut dictent les opérations autorisées sur un attribut donné. La classification et l'accessibilité d'attribut sont décrites en 12.6.

J.1.2 Classification d'attributs

Pour un débat relatif à la classification d'attribut, voir 12.6.3.

J.1.3 Récupération, positionnement et réinitialisation d'attributs

J.1.3.1 Généralités

Les attributs définis dans les objets de gestion peuvent être accessibles en utilisant les services normalisés de lecture ou d'écriture fournis par l'ASL. De telles opérations permettent la configuration des couches, ainsi que la surveillance de leur statut. Elles peuvent être utilisées pour récupérer, établir/modifier, et réinitialiser les valeurs des attributs. Les primitives de service pour ces services ainsi que les codes énumérés de retour d'informations de service, sont donnés à l'Article 12.

Des attributs peuvent être réinitialisés en utilisant le service write en écrivant la valeur par défaut dans l'attribut pertinent. Si un attribut reset est défini pour un objet de gestion, il peut être utilisé pour réinitialiser tous les attributs dans l'objet de gestion en question qui appartiennent à certaines classes d'attributs.

Des méthodes plus complexes peuvent être définies s'il y a lieu, mais seulement si les résultats équivalents ne peuvent pas être obtenus en utilisant les services read/write plus directs. Une méthode complexe peut être justifiée, par exemple, pour remplacer une séquence de transactions de communication afin d'économiser de l'énergie. Une méthode complexe peut également être justifiée lorsque des questions de synchronisation peuvent résulter si des actions individuelles sont utilisées plutôt qu'un ensemble de transactions atomiques.

J.1.3.2 Opérations programmées pour activer un basculement synchronisé

Le modèle de méthode générique Scheduled_Write fourni dans le Tableau J.1 peut être utilisé pour définir une méthode pour écrire une valeur dans un attribut à un temps TAI programmé. Il peut également être utilisé pour réinitialiser un attribut à sa valeur par défaut à un temps TAI programmé.

Tableau J.1 – Modèle de méthode Scheduled_Write

<table>
<tr><th>Nom de méthode</th><th>ID de méthode</th><th colspan="3">Description de la méthode</th></tr>
<tr><td rowspan="9">Scheduled_Write</td><td><donné dans la définition de l'objet de gestion></td><td colspan="3">Méthode pour écrire une valeur dans un attribut indiqué à un temps TAI indiqué</td></tr>
<tr><td colspan="4">Arguments d'entrée</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td>1</td><td>Attribute_ID</td><td>Data type: Unsigned16 <donné dans la définition de l'objet de gestion></td><td>L'ID d'attribut dans l'objet de gestion auquel la présente méthode est appliquée</td></tr>
<tr><td>2</td><td>Scheduled_TAI_Time</td><td>Data type: TAITimeRounded</td><td>Temps TAI auquel il convient que la valeur soit écrite dans l'attribut</td></tr>
<tr><td>3</td><td>Valeur</td><td>Data type: <donné dans la définition de l'objet de gestion></td><td>La valeur qui a besoin d'être écrite dans l'attribut</td></tr>
<tr><td colspan="4">Arguments de sortie</td></tr>
<tr><td>Numéro de l'argument</td><td>Nom de l'argument</td><td>Type de l'argument (type et taille des données)</td><td>Description de l'argument</td></tr>
<tr><td colspan="4">Aucun</td></tr>
</table>

Les codes de retour d'informations de services en 12.17.4.2.2 sont censés être utilisés pour indiquer si l'exécution de la méthode a réussi ou pas. Si elle n'a pas réussi, ce code fournit des informations indiquant pourquoi elle n'a pas réussi.

J.1.4 Récupération et positionnement d'attributs structurés

Les modèles de méthode génériques Read_Row et Write_Row donnés dans le Tableau J.2 et dans le Tableau J.3 peuvent être utilisés pour définir les méthodes qui récupèrent et établissent/modifient les valeurs d'attributs structurés. Lorsque l'attribut structuré est visualisé sous la forme d'une table d'informations, ces méthodes permettent l'accès à une rangée particulière en fonction d'une ou plusieurs valeurs de champ indice unique. Il est supposé que chaque table a au moins un champ indice unique. Le champ indice peut être soit un seul élément, soit la concaténation de quelques éléments dans la rangée.

L'argument d'entrée Scheduled_TAI_Time dans le modèle de méthode Write_Row permet l'opération programmée pour une rangée particulière de l'attribut structuré. Une valeur de 0 pour cet argument indique une opération write immédiate.

Tableau J.2 – Modèle de méthode Read_Row

Nom de méthode	ID de méthode	Description de la méthode		
Read_Row	<donné dans la définition de l'objet de gestion>	Méthode pour lire la valeur d'une seule rangée d'un attribut structuré dont les données sont visualisées sous la forme d'un tableau d'informations		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Attribute_ID	Data type: Unsigned16 <donné dans la définition de l'objet de gestion>	L'ID d'attribut dans l'objet de gestion auquel la présente méthode est appliquée
	2	Index_1	Type de données du premier champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le premier champ d'index dans l'attribut structuré pour accéder à une rangée particulière
	n+1	Index_n	Type de données du $n^{ème}$ champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le $n^{ème}$ champ d'index dans l'attribut pour accéder à une rangée particulière
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Data_Value	Data type: <donné dans la définition de l'objet de gestion>	Une chaîne d'octet qui contient la valeur de données

Tableau J.3 – Modèle de méthode Write_Row

Nom de méthode	ID de méthode	Description de la méthode		
Write_Row	<donné dans la définition de l'objet de gestion>	Méthode pour définir/modifier la valeur d'une seule rangée d'un attribut OctetString indexé dont les données sont visualisées sous la forme d'un tableau d'informations		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Attribute_ID	Data type: Unsigned16 <donné dans la définition de l'objet de gestion>	L'ID d'attribut dans l'objet de gestion auquel la présente méthode est appliquée
	2	Scheduled_TAI_Time	Data type: TAITimeRounded	Temps TAI auquel il convient que la valeur soit écrite dans la rangée de l'attribut structuré
	3	Index_1	Type de données du premier champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le premier champ d'index dans l'attribut structuré pour accéder à une rangée particulière
	N+2	Index_n	Type de données du $n^{ème}$ champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le $n^{ème}$ champ d'index dans l'attribut pour accéder à une rangée particulière
	N+3	Data_Value	Data type: <donné dans la définition de l'objet de gestion>	Une chaîne d'octet qui contient la valeur de données
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	Aucun			

Les codes de retour d'informations de services en 12.17.4.2.2 sont censés être utilisés pour indiquer si l'exécution de la méthode a réussi ou pas. Si elle n'a pas réussi, ce code fournit des informations indiquant pourquoi elle n'a pas réussi.

Une méthode basée sur le modèle Write_Row peut également être utilisée pour créer une nouvelle rangée dans l'attribut structuré si le(s) champ(s) indice fourni(s) dans l'(les) argument(s) d'entrée n'existe(nt) pas.

J.1.5 Réinitialisation des valeurs d'attributs structurés

Pour un attribut structuré, le modèle de méthode générique Reset_Row donné dans Tableau J.4 peut être utilisé pour définir des méthodes qui réinitialisent/effacent certaines valeurs dans l'attribut structuré. L'argument d'entrée Scheduled_TAI_Time dans cette méthode permet une opération reset programmée. Une valeur de 0 pour cet argument indique une opération reset immédiate.

Tableau J.4 – Modèle de méthode Reset_Row

Nom de méthode	**ID de méthode**	**Description de la méthode**		
Reset_Row	<donné dans la définition de l'objet de gestion>	Méthode pour réinitialiser une seule rangée d'un attribut structuré dont les données sont visualisées sous la forme d'un tableau d'informations		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Attribute_ID	Data type: Unsigned16 <donné dans la définition de l'objet de gestion>	L'ID d'attribut dans l'objet de gestion auquel la présente méthode est appliquée
	2	Scheduled_TAI_Time	Data type: TAITimeRounded	Temps TAI auquel il convient que l'attribut structuré soit réinitialisé
	3	Index_1	Type de données du premier champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le premier champ d'index dans l'attribut structuré pour accéder à une rangée particulière
	n+2	Index_n	Type de données du $n^{ème}$ champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le $n^{ème}$ champ d'index dans l'attribut pour accéder à une rangée particulière
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	Aucun			

Les codes de retour d'informations de services en 12.17.4.2.2 sont censés être utilisés pour indiquer si l'exécution de la méthode a réussi ou pas. Si elle n'a pas réussi, ce code fournit des informations indiquant pourquoi elle n'a pas réussi.

J.1.6 Suppression de valeurs d'attributs structurés

Le modèle de méthode générique Delete_Row décrit dans Tableau J.5 peut être utilisé pour définir les méthodes qui suppriment les valeurs d'attributs structurés. L'argument d'entrée

Scheduled_TAI_Time dans cette méthode permet une opération delete (suppression) programmée. Une valeur de 0 pour cet argument indique une opération delete immédiate.

Tableau J.5 – Modèle de méthode Delete_Row

Nom de méthode	ID de méthode	Description de la méthode		
Delete_Row	<donné dans la définition de l'objet de gestion>	Méthode pour supprimer une seule rangée d'un attribut structuré dont les données sont visualisées sous la forme d'un tableau d'informations		
	Arguments d'entrée			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	1	Attribute_ID	Data type: <Unsigned16 donné dans la définition de l'objet de gestion>	L'ID d'attribut dans l'objet de gestion auquel la présente méthode est appliquée
	2	Scheduled_TAI_Time	Data type: TAITimeRounded	Temps TAI auquel il convient que l'attribut structuré soit supprimé
	3	Index_1	Type de données du premier champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le premier champ d'index dans l'attribut structuré pour accéder à une rangée particulière
	n+2	Index_n	Type de données du $n^{ème}$ champ d'index de l'attribut structuré <donné dans la définition de l'objet de gestion>	Le $n^{ème}$ champ d'index dans l'attribut pour accéder à une rangée particulière
	Arguments de sortie			
	Numéro de l'argument	**Nom de l'argument**	**Type de l'argument (type et taille des données)**	**Description de l'argument**
	Aucun			

Les codes de retour d'informations de services en 12.17.4.2.2 sont censés être utilisés pour indiquer si l'exécution de la méthode a réussi ou pas. Si elle n'a pas réussi, ce code fournit des informations indiquant pourquoi elle n'a pas réussi.

J.2 Basculement synchronisé

Une capacité synchronisée de basculement est nécessaire pour certains attributs et attributs structurés qui représentent les informations de gestion. Pour un tel attribut, des mises à jour pour la valeur d'attribut peuvent être programmées en indiquant les informations relatives au temps de basculement TAI; cette opération peut être accomplie en utilisant une des méthodes définies ci-dessus. De telles mises à jour sont envoyées à l'objet de gestion pour lequel cet attribut est défini. L'objet de gestion valide immédiatement si, oui ou non, le basculement est faisable, et, si faisable, s'arrange pour que le basculement se produise au temps programmé.

Annexe K
(normative)

Types d'objets normalisés

L'Annexe K spécifie les types d'objets normalisés définis par la présente norme. Chaque type d'objet a trois éléments d'informations pour l'identifier:

- un identificateur de type d'objet normalisé correspondant qui identifie le type d'objet de basse défini normalisé (exemple: entrée analogique);
- un identificateur de sous-type normalisé d'objet correspondant qui identifie le sous-type d'objet normalisé d'un type de base normalisé (exemple: entrée analogique spécialisée pour la température); et
- un identificateur de sous-type de fournisseur correspondant qui identifie un sous-type spécifique à un fournisseur soit d'un objet de base normalisé, soit d'un sous-type normalisé.

Les objets de base normalisés doivent avoir leur valeur d'identificateur de sous-type d'objet égale à zéro (0) et leur identificateur de sous-type de fournisseur égal à zéro (0).

Une plus récente version de la présente norme qui trouve nécessaire d'étendre la définition du type d'objet de base selon la présente norme peut maintenir la valeur d'identificateur d'objet normalisé et la valeur de sous-type de zéro (0). Cela est autorisé, car le DMO contient un attribut pour représenter la version de la norme utilisée par l'appareil, qui peut être ainsi utilisé pour établir la structure utilisée de type d'objet de base.

Les profils d'industrie IEC62734 peuvent définir un sous-type d'objet normalisé comme objet normalisé. Le faire crée ainsi un sous-type de profil normalisé. La présente norme fournit une plage de 1..255 pour représenter tous ces sous-types d'objets normalisés à travers tous les profils.

Les fournisseurs peuvent également sous-typer soit un objet de base normalisé, soit un objet de sous-type normalisé. La présente norme fournit une gamme de 1..255 pour le sous-typage spécifique à un fournisseur.

Le sous-typage d'objet a lieu quand:

- un ou plusieurs attributs sont ajoutés au type de base;
- une ou plusieurs méthodes sont ajoutées au type de base;
- une ou plusieurs alertes sont ajoutées au type de base; ou
- toute combinaison de ce qui précède.

Les exemples d'identification d'objet avec sous-typage suivent:

- Objet de bas normalisé d'entrée analogique:
  - identificateur de type d'objet = 99,
  - identificateur de sous-type normalisé d'objet = 0,
  - identificateur de sous-type de fournisseur = 0.
- Objet de sous-type de température d'entrée analogique:
  - identificateur de type d'objet = 99,
  - identificateur de sous-type normalisé d'objet = (la présente norme définit (l'équipe de profils de la présente norme), plage 1..255),
  - identificateur de sous-type de fournisseur = 0.

- Objet d'entrée analogique spécifique à un fournisseur:
  - identificateur de type normalisé d'objet = 99,
  - identificateur de sous-type normalisé d'objet = 0,
  - identificateur de sous-type spécifique à un fournisseur = (le fournisseur définit, plage 1..255).
- Objet température d'entrée analogique spécifique à un fournisseur:
  - identificateur de type normalisé d'objet = 99,
  - identificateur de sous-type normalisé d'objet = n,
  - identificateur de sous-type spécifique à un fournisseur = (le fournisseur définit, plage 1..255).

Le Tableau K.1 spécifie les types d'objets normalisés.

Tableau K.1 – Types d'objets normalisés

Annexe L
(informative)

Types de données normalisés

Le Tableau L.1 spécifie les identificateurs de types de données normalisés pour les types de données normalisés. Des types de données normalisés sont définis pour les constructions qui sont accessibles en utilisant des services d'ASL, tels que read et write.

NOTE 1 Il est possible que les structures de données ne soient pas directement accessibles en utilisant des services ASL, par exemple, une structure de données qui est utilisée comme paramètre d'une méthode, mais qui n'est pas exposée comme un attribut d'objet accessible à l'ASL.

NOTE 2 Beaucoup d'identificateurs de types dans cette tableau sont basés sur des identificateurs de types utilisés dans une norme IEC existante.

Tableau L.1 – Types de données normalisés

Type de données	Identificateur de type (Unsigned16)	Taille (octets)
Types réservés		
Non valide (type non spécifié)	0	0

Annexe M
(normative)

Identification de protocoles de bus de terrain hérités et tunnellisés

Le Tableau M.1 énumère les valeurs d'identification du protocole Unsigned8 actuellement définies pour tunnelliser des protocoles de bus de terrain câblés hérités par l'intermédiaire de l'objet tunnel.

Tableau M.1 – Identification de protocole de bus de terrain hérités tunnellisés

Valeur	Protocole
0	Aucun (exigé)
1	HART (voir IEC 61158)
2	FF-H1 (voir IEC 61158)
3	Modbus/RTU (voir IEC 61158)
4	PROFIBUS PA (voir IEC 61158)
5	CIP (voir IEC 61158)
6..255	<réservé>

NOTE Ces valeurs d'identification de protocole ont été isolées dans l'Annexe M afin de faciliter la maintenance.

Il convient que la valeur 0 pour None soit préservée ou la fonctionnalité de tunnel sera entravée.

Annexe N
(informative)

Tunnellisation et mapping d'objets natifs

N.1 Vue d'ensemble

La tunnellisation implique l'échange de PDU d'un protocole en utilisant un second protocole. Le plus souvent, ces PDU sont des PDU d'application, mais les PDU de couche inférieure peuvent aussi être échangées. La PDU est encapsulée dans le second protocole en un nœud d'origine et envoyée par le réseau à un nœud final. Avec la tunnellisation, ce qui entre dans une extrémité sort de l'autre extrémité, ni plus, ni moins.

La communication d'application de protocole étranger (FPAC) est un mécanisme d'échange de PDU plus sophistiqué. Elle implique l'utilisation de mécanismes complémentaires, y compris le placement en cache, la compression, la conversion d'adresses, et le proxy. En ce qui concerne l'application, les mêmes PDU sont encore échangées entre le nœud d'origine et le nœud de terminaison comme avec la tunnellisation. La différence est que les mécanismes complémentaires agissent pour améliorer l'efficacité énergétique et la réactivité du système hôte.

N.2 Tunnellisation

La tunnellisation transporte des messages in extenso entre les points d'extrémité d'un tunnel. La présente norme fournit la tunnellisation qui utilise l'échange C/S non tamponné de PDU étrangères entre exactement deux points d'extrémité préconfigurés du tunnel. Aucune interprétation du contenu de la PDU n'est exigée. Pour la plupart des protocoles hérités, cette méthode ne sera pas d'un haut rendement énergétique et certains protocoles peuvent ne pas fonctionner correctement en raison de temps de réponse variables ou prolongés associés aux appareils en sommeil. Indépendamment des défauts, dans de nombreux cas, ce sera la méthode la plus indiquée pour adapter des appareils et systèmes existants à la présente norme.

Une extension de tunnellisation interprète l'adressage au sein des PDU étrangères pour permettre l'échange dynamique de PDU étrangères avec plusieurs points d'extrémité.

N.3 Communication d'application de protocole étranger

La tunnellisation n'est pas un mécanisme approprié pour la plupart des applications de liaison sans fil de faible puissance. Il est habituellement nécessaire de réduire au maximum le surdébit de PhPDU et le nombre de transactions afin de conserver l'énergie emmagasinée dans des batteries ou de fonctionner dans les limites d'un budget de puissance des méthodes de récupération. En outre, les protocoles étrangers ont souvent un besoin de réponse rapide afin d'éviter des temporisations intégrées. Les appareils en fonctionnement sans fil de faible puissance sont le plus souvent en mode de sommeil et ne peuvent donc pas répondre immédiatement.

La FPAC augmente l'efficacité énergétique et traite des questions potentielles de temporisation en utilisant le transfert à changement d'état et le placement en cache pour éliminer le transfert redondant. Des améliorations de l'efficacité énergétique et des performances sont réalisées en plaçant en cache les informations dans la passerelle, en transférant les informations vers la passerelle seulement lorsqu'elles changent, et en fournissant un mécanisme de signaux de présence ("heartbeat") pour l'intégrité. Cela réduit au maximum les transferts initiés par les appareils d'extrémité (à savoir publications périodiques), et réduit également au maximum des transferts initiés par la liaison de

communication étrangère (à savoir accès de plusieurs maîtres par la passerelle. En outre, cette méthode peut traiter des exigences de temporisation de protocoles étrangers. En comparaison à la tunnellisation, un effort supplémentaire est nécessaire pour convertir le protocole étranger.

La présente norme fournit la prise en charge de la FPAC qui réduit au maximum le surdébit de PhPDU en utilisant une combinaison de techniques:

- L'encapsulation est limitée à une seule encapsulation. Les convertisseurs de protocoles fournissent l'encapsulation complémentaire à travers les liaisons étrangères selon les besoins.
- L'encapsulation est réalisée à travers un accord de configuration en transportant le protocole étranger au sein du protocole défini par la présente norme, plutôt qu'en transportant des en-têtes de protocoles supplémentaires. Le mapping se produit comme suit:
  - Relations prises en charge par le transport (P/S et C/S).
  - Adresses étrangères et adresses natives.
  - Champs taille et champs intégrité.
- La présente norme fournit un format natif de service d'application pour l'échange de messages. Les protocoles étrangers ont leurs propres formats de service et leurs propres protocoles d'échange de messages. L'objet de tunnel permet le transfert d'APDU étrangères sans surdébit extérieur imposé par le format natif de service d'application.

La présente norme fournit la prise en charge de la FPAC qui réduit au maximum le surdébit de transactions en utilisant les techniques suivantes:

- Mécanismes de placement en cache de tampon distribués pour réduire au maximum le transfert redondant des données inchangées entre les passerelles et les appareils d'extrémité.
- Mécanismes de transferts périodiques, de changement d'états (CoSt), et apériodiques.
- Temporisateurs chiens de garde pour surveiller la disponibilité de points d'extrémité et de voies de communication et assurer la qualité de données.

La présente norme fournit la prise en charge de la FPAC qui améliore les performances de temporisation d'accès d'appareils de protocoles étrangers (et réduit au maximum les transactions inutiles) par la mise à disposition d'informations d'appareil tamponnées par une interface côté haut d'une passerelle.

NOTE Le changement d'état (CoSt) est distinct de la classe de service (CoS) telle que définie par l'IEEE 802.1Q.

N.4 Mapping d'objets natifs

La présente norme prend en charge un format natif d'objets et des services de messagerie. Des objets spécifiques à l'automation peuvent être utilisés pour prendre en charge la conversion de protocole en utilisant ces objets pour accomplir un mapping du protocole étranger dans ces objets et leur messagerie. En comparaison à la tunnellisation et aux méthodes de la FPAC, un effort supplémentaire est nécessaire pour convertir le protocole étranger.

N.5 Compris entre tunnellisation et mappage d'objets natifs

Le mapping d'objets natifs a un avantage unique dans la capacité d'établir un seul appareil d'extrémité conforme à une norme avec plusieurs protocoles étrangers. Cela est notamment attrayant pour de nouveaux appareils.

La tunnellisation et la FPAC ont un avantage en la simplicité pour adapter des appareils câblés d'automation par l'intermédiaire d'un adaptateur. Très peu, voire pas du tout, de conversion peut être nécessaire à l'autre extrémité.

Utiliser la tunnellisation conjointement avec le mapping d'objets natifs est également utile. Cela permet à des fonctions héritées communes d'utiliser le mapping d'objets natifs, alors que les fonctions rarement utilisées peuvent être tunnellisées. Cela peut conduire à un moindre effort total en conversion de protocole.

Annexe O
(informative)

Conversion de protocoles générique

O.1 Vue d'ensemble

La présente norme n'inclut pas de convertisseurs de protocoles. Elle inclut des appareils pour prendre en charge la construction des convertisseurs de protocole (généralement situés au sein de passerelles) pour des protocoles communs de bus de terrain, où un tel convertisseur serait également sensible aux contraintes des réseaux d'automation sans fil de faible puissance. Sachant que des convertisseurs spécifiques de protocole ne sont pas définis dans la présente norme, tout appui pour la conversion de protocole est donc générique.

L'Annexe O fournit un exemple de la façon d'utiliser l'objet tunnel et un GIAP conceptuel pour prendre en charge des interactions communes de conversion de protocole. L'objet tunnel inclut des caractéristiques normatives pour prendre en charge la conversion de protocole.

Les convertisseurs spécifiques de protocole (pour des bus de terrain spécifiques) pourraient inclure l'Annexe O, potentiellement sous une forme modifiée. Ils pourraient également utiliser une approche différente. De tels choix ne sont pas spécifiés par la présente norme.

O.2 Publish

Une partie d'une passerelle générique est décrite à la Figure O.1, qui se rapporte à l'utilisation de la publication. Un convertisseur générique de protocole interagit avec une passerelle UAP par l'intermédiaire du GIAP. La passerelle UAP utilise l'objet TUN pour interagir avec des homologues distants par l'intermédiaire de la suite inférieure de protocole à travers le SAP de l'ASL.

Figure O.1 – Diagramme d'édition de conversion de protocoles générique

Une PDU étrangère est reçue par le convertisseur de protocole, et le filtrage spécifique à un protocole est appliqué. Selon le protocole, une combinaison de FPT-PAI, de tout autre FPT-PCI, et de FPT-PDU peut être nécessaire afin de déterminer les GS_Session_ID et GS_Lease_ID appropriés pour l'utilisation du GIAP dans un processus de liaison à un abonné. Le filtrage spécifique à un protocole détermine la partie de la PDU étrangère qui a besoin d'être émise (GS_Publish_Data) et des paramètres de transport spécifiques à un protocole étranger tels que la priorité (GS_Transfer_Mode). Les paramètres sont ensuite utilisés pour invoquer des services de GIAP.

Le GS_Session_ID et le GS_Lease_ID sont utilisés par la passerelle UAP pour identifier l'objet TUN et pour récupérer les paramètres nécessaires pour des décisions de traitement en mode différé (mise en mémoire et retransmission ultérieure). GS_Publish_Data est tamponné et transmis au moment opportun selon l'Update_Policy, la période, la phase, le Stale_Limit, et

le contenu de données antérieur et actuel. Les décisions de mise en mémoire et de transmission ultérieure sont également commandées par des événements de temporisateur basés sur la période et la phase. Le SAP de l'ASL est utilisé pour transmettre les éventuels messages.

Une publication peut être envoyée à un ou plusieurs points d'extrémité selon le nombre d'éléments contenus par la matrice de points d'extrémité de tunnel.

O.3 Subscribe

Une partie d'une passerelle générique est décrite à la Figure O.2, qui se rapporte à l'utilisation de l'abonnement. Un convertisseur générique de protocole interagit avec une passerelle UAP par l'intermédiaire du GIAP. La passerelle UAP utilise l'objet TUN pour interagir avec des homologues distants par l'intermédiaire de la suite inférieure de protocole à travers le SAP de l'ASL.

Figure O.2 – Diagramme d'abonnement de conversion de protocoles générique

Une APDU de publication arrive à la passerelle UAP par le SAP de l'ASL. L'adressage indique un objet TUN local qui est relié à l'objet TUN d'éditeur distant. Les attributs nécessaires sont récupérés à partir de l'objet TUN pour des décisions de mise en mémoire et transmission ultérieure.

Les données de publication comportent le GS_Publish_Data issu de l'éditeur. Le placement en tampon de la publication est basé sur Update_Policy, la Period, la Phase, le Stale_Limit, et les événements de temporisateurs basés sur la Period/Phase. La transmission se produit vers le convertisseur de protocole en passant par le GIAP en fonction de l'interaction interrogée et événementielle avec le convertisseur de protocole. La passerelle UAP également met en mémoire et inclut le GS_Session_ID et le GS_Lease_ID pour que le convertisseur de protocole identifie la publication. Des informations spécifiques à la publication peuvent être mises en mémoire localement et utilisées pour réduire l'émission inutile des informations. Ces informations comprennent des informations d'adressage (GS_Foreign_Source_Address et GS_Foreign_Destination_Address) et des informations spécifiques à une connexion (GS_Connection_Info).

Le convertisseur de protocole accomplit un assemblage spécifique à un protocole pour générer la PDU étrangère.

O.4 Client

Une partie d'une passerelle générique est décrite à la Figure O.3, qui se rapporte à la transmission des messages client/serveur tunnellisés. Un convertisseur générique de protocole interagit avec une passerelle UAP par l'intermédiaire du GIAP. La passerelle UAP utilise l'objet TUN pour interagir avec des homologues distants par l'intermédiaire de la suite inférieure de protocole à travers le SAP de l'ASL.

Figure O.3 – Diagramme d'émission client/serveur de conversion de protocoles générique

Une PDU étrangère est reçue par le convertisseur de protocole, et le filtrage spécifique à un protocole est appliqué. Selon le protocole, une combinaison de FPT-PAI, de tout autre FPT-PCI, et de FPT-PDU peut être nécessaire afin de déterminer les GS_Session_ID et GS_Lease_ID appropriés pour l'utilisation du GIAP. Le filtrage spécifique à un protocole détermine la partie de la PDU étrangère qui a besoin d'être émise (GS_Request_Data ou GS_Response_Data) et des paramètres de transport appropriés tels que la priorité (GS_Transfer_Mode). Pour des demandes, la SDU peut également spécifier GS_Transaction_Info qui doit être retourné au GIAP lorsqu'une réponse concordante arrive. Les paramètres sont ensuite utilisés pour invoquer des services de GIAP.

Le GS_Session_ID et le GS_Lease_ID sont utilisés par la passerelle UAP pour identifier l'objet TUN et pour récupérer les paramètres nécessaires pour des décisions de traitement en mode différé (mise en mémoire et retransmission ultérieure). Les informations de GIAP (GS_Request_Data ou GS_Response_Data) peuvent être tamponnées avant transmission, selon que le placement en tampon est demandé (GS_Buffer) ou non, selon le contenu antérieur du tampon, et selon qu'il est spécifié une demande ou une réponse. Le SAP de l'ASL est utilisé pour transmettre les éventuels messages.

Un message de demande de tunnel peut être envoyé à un ou plusieurs points d'extrémité selon le nombre d'éléments contenus par la matrice de points d'extrémité de tunnel. Un message de réponse de tunnel peut être envoyé à un seul point d'extrémités, mais plusieurs réponses peuvent être envoyées au même point d'extrémité au fil du temps.

O.5 Server

Une partie d'une passerelle générique est décrite à la Figure O.4, qui se rapporte à la réception des messages client/serveur tunnellisés. Un convertisseur générique de protocole interagit avec une passerelle UAP par l'intermédiaire du GIAP. La passerelle UAP utilise l'objet TUN pour interagir avec des homologues distants par l'intermédiaire de la suite inférieure de protocole à travers le SAP de l'ASL.

Figure O.4 – Diagramme de réception client/serveur de conversion de protocoles générique

Une APDU de demande ou de réponse de tunnel arrive à la passerelle UAP par le SAP de l'ASL. L'adressage indique un objet TUN local qui est relié à un objet TUN distant. Les attributs nécessaires sont récupérés à partir du TUN pour des décisions de mise en mémoire et transmission ultérieure.

Les données d'APDU de tunnel incluent soit GS_Request_Data, soit GS_Response_Data. Selon le mode tunnel, les données de réponse peuvent être tamponnées pour répondre à des demandes ultérieures issues de tampons locaux. La transmission se produit vers le convertisseur de protocole en passant par le GIAP en fonction de l'interaction interrogée et événementielle avec le convertisseur de protocole. La passerelle UAP également met en mémoire et inclut le GS_Session_ID et le GS_Lease_ID pour que le convertisseur de protocole identifie les données de tunnel. Des informations spécifiques à un message tunnel peuvent être mises en mémoire et utilisées pour réduire l'émission dupliquée inutile des informations. Cela inclut des informations d'adressage (GS_Foreign_Source_Address et GS_Foreign_Destination_Address), des informations spécifiques à une connexion

(GS_Connection_Info) et des informations spécifiques à une transaction (GS_Transaction_Info) devant être transportées dans les réponses.

Le convertisseur de protocole accomplit un assemblage spécifique à un protocole pour générer la PDU étrangère.

Annexe P
(informative)

Adaptations exemplaires du GIAP pour la présente norme

P.1 Généralités

La présente norme ne définit pas la fonctionnalité pour une passerelle complète. Elle inclut des exemples d'appui qui permettent la construction de passerelle par l'addition d'un convertisseur de protocole, et une interface matérielle et une pile pour un réseau étranger. L'Annexe P ne définit pas un convertisseur de protocole; cela pourrait être un sujet de future normalisation.

L'Annexe P fournit un exemple d'une interface conceptuelle qui serait interne à une passerelle – le GIAP, qui est censé être une abstraction du système sans fil sous-jacent. En particulier, il est censé fournir une abstraction pour le système sans fil décrit dans la présente norme.

L'Annexe P décrit une manière de mettre en œuvre le GIAP informatif en utilisant les objets et les services normatifs de la présente norme. Il ne s'agit pas d'une conception complète, mais c'est une référence pour aider à la compréhension.

Les passerelles spécifiques (pour les bus de terrain spécifiques) pourraient inclure l'Annexe P, la rendant donc normative. Elles pourraient également déterminer une approche différente qui était conforme.

Dans cette passerelle exemplaire, les services de GIAP sont mis en œuvre sous la forme d'un UAP spécialisé qui utilise des objets natifs tels que définis dans la présente norme.

P.2 Paramètres

GS_Network_Address est l'adresse IPv6.

P.3 Session

Le service de session du GIAP suit les ressources à la trace et libère les ressources lorsque la session se ferme ou expire. Les ressources comprennent des contrats de communication, transferts en masse en cours, des informations tamponnées, des ressources publication/édition/C/S dans les objets, et des abonnements d'alertes.

P.4 En leasing

Le service de location de GIAP permet l'allocation de ressources et la libération individuelle lorsque la location est fermée ou expire. Les ressources comprennent des contrats de communication et des ressources d'objets pour: le transfert en masse, C/S, P/S et les alertes.

Une location diffère d'un contrat de communication parce qu'une location alloue à la fois des ressources au sein d'une entité de passerelle et, lorsqu'elles sont nécessaires, les ressources correspondant à un contrat de communication connexe.

La spécification de plusieurs adresses IPv6 au sein de GS_Network_Address_List représente un groupe de multidiffusion. Le fait de spécifier plusieurs adresses conduira à une multidiffusion simulée par l'intermédiaire de plusieurs opérations en monodiffusion. Même s'il

s'agit d'une seule location, la multidiffusion simulée exige l'allocation des plusieurs contrats point à point et la gestion simultanée de ce contrat établi au sein de la passerelle.

GS_Resource spécifie l'élément transfert en masse pour une location (Destination_Port et OID). GS_Resource est également utilisé dans le processus de liaison de jeux concordants d'objets TNU et d'objets CON et DIS concordants. Un éditeur et un/des abonné(s) concordants spécifient des valeurs connexes dans la création de locations. Ces valeurs, avec le GS_Network_Address_List, permettent à la Array of Tunnel endpoint d'être remplie d'objets TUN liés et aux objets CON et DIS d'être alloués et liés.

Les locations d'abonné spécifient GS_Update_Policy, GS_Period, GS_Phase, et GS_Stale_Limit.

P.5 Rapport de liste d'appareils

Il n'y a aucune information d'adaptation spécifique pour cet élément.

P.6 Rapport de topologie

Il n'y a aucune information d'adaptation spécifique pour cet élément.

P.7 Rapport de programmation

Il n'y a aucune information d'adaptation spécifique pour cet élément.

P.8 Rapport de santé d'appareil

Il n'y a aucune information d'adaptation spécifique pour cet élément.

P.9 Rapport de santé de voisin

GS_Signal_Strength est en correspondance avec ED et GS_Signal_Quality est en correspondance avec LQI (voir définition en 9.1.15.2).

P.10 Rapport de santé de réseau

Il n'y a aucune information d'adaptation spécifique pour cet élément.

P.11 Durée

Il n'y a aucune information d'adaptation spécifique pour cet élément.

P.12 Client/server

P.12.1 Généralités

Le service C/S de GIAP utilise l'objet TUN ou l'IFO, selon l'établissement de la location.

P.12.2 Accès natif

Lorsque l'établissement de la location spécifie GS_Protocol_Type = 0, le protocole natif est configuré par l'intermédiaire d'un IFO, le GS_Network_Address_List est vide, et les

GS_Lease_Parameters spécifient seulement GS_Transfer_Mode, qui spécifie à son tour à la fois la priorité (priority) et l'éligibilité au rejet (discard eligibility), telles que définie à l'Article 12 pour les services read, write et execute.

Les charges utiles (GS_Request_Data et GS_Response_Data) se conforment aux formats d'APDU natifs et utilisent seulement les types de service de l'ASL: lire, écrire et exécuter. Les objets IFO dans des passerelles transfèrent ces charges utiles par l'intermédiaire des services lecture, écriture, et exécuter. GS_Transfer_Mode est utilisé avec chaque transfert pour indiquer la qualité de service, y compris la priorité, associée au transfert.

GS_Buffer est utilisé pour demander le comportement tamponné et non tamponné selon ce qui est approprié aux classifications d'attributs et de services de l'ASL.

GS_Transaction_Info est vide.

Le service C/S natif est utilisé pour adresser des objets natifs dans la passerelle.

P.12.3 Accès étranger

Lorsque l'établissement de location spécifie un GS_Protocol_Type, un protocole étranger est configuré par l'intermédiaire d'un objet TUN. GS_Network_Address_List est fourni pour établir les points d'extrémité TN distants. GS_Resource est utilisé pour déterminer si les services tunnel à deux parties ou à quatre parties s'appliquent et pour faire la concordance avec les points d'extrémité TUN au sein des appareils. Une location de client ou de serveur seule établit un tunnel à deux parties. Une paire de locations de client et de serveur avec le même GS_Resource établit un tunnel à quatre parties. GS_Lease_Parameters fournissent GS_Connection_Info aux services de Serveur comme approprié pour le protocole étranger et le GS_Transfer_Mode afin d'établir les valeurs par défaut de la qualité de service et de la priorité de transfert.

Les charges utiles (GS_Request_Data et GS_Response_Data) se conforment aux formats d'APDU étrangers, y compris la spécification de types de service étrangers et de champs spécifiques à un service étrangers. Les objets TUN dans des passerelles transfèrent ces charges utiles en utilisant les services de tunnel à deux parties et à quatre parties. GS_Cache est utilisé pour demander un comportement tamponné et non tamponné comme approprié à la configuration d'objet TUN et aux exigences de protocoles étrangers. GS_Transfer_Mode est utilisé avec chaque transfert pour indiquer la qualité de service, y compris la priorité, associée au transfert.

Le GS_Transfer_Mode spécifie la priorité et l'éligibilité au rejet, telles que définies à l'Article 12 pour le service tunnel.

GS_Transaction_Info est fourni sur des services client et retourné sur des services serveur comme approprié pour le protocole étranger.

P.13 Publish/Subscribe (éditer/s'abonner)

P.13.1 Généralités

Le service P/S de GIAP utilise l'objet TUN ou les objets CON et DIS selon l'établissement de la location.

P.13.2 Accès natif

Lorsque l'établissement de la location spécifie GS_Protocol_Type = 0, le protocole d'application natif sera édité par l'objet CON et souscrit par l'intermédiaire de l'objet DIS. GS_Network_Address_List est vide. GS_Lease_Parameters contiennent seulement

GS_Transfer_Mode afin d'établir les valeurs par défaut de la qualité de service et de la priorité de transfert.

GS_Network_Address_List est utilisé pour établir les points d'extrémité publish et subscribe. GS_Network_Address détermine l'adresse d'appareil distant. GS_Resource est utilisé pour déterminer l'objet DIS au sein cet appareil. Un objet CON local est sélectionné pour être relié à l'objet DIS distant. GS_Lease_Parameters fournissent GS_Update_Policy, GS_Period, GS_Phase, et GS_Stale_Limit pour établir le comportement périodique ou de changements d'état pour les objets CON et DIS. GS_Connection_Info est vide.

La charge utile de publication (GS_Publish_Data) est envoyée et reçue dans le format NativeIndividualValue ou NativeValueList. Les objets CON et DIS dans des passerelles transfèrent cette charge utile en utilisant le service Publish. GS_Transfer_Mode est fourni avec chaque transfert afin d'indiquer la qualité de service, y compris la priorité, associée au transfert.

Le GS_Transfer_Mode spécifie la priorité et l'éligibilité au rejet, telles que définies à l'Article 12 pour le service publish.

P.13.3 Accès étranger

Lorsque l'établissement de la location spécifie GS_Protocol_Type non égal à 0, GS_Protocol_Type est utilisé pour spécifier le protocole d'application étranger qui sera édité par l'intermédiaire des objets TUN. GS_Network_Address_List est utilisé pour établir les points d'extrémité TN distants. GS_Resource est utilisé pour faire la concordance avec les points d'extrémité TUN au sein des appareils. GS_Lease_Parameters fournissent GS_Update_Policy, GS_Period, GS_Phase, et GS_Stale_Limit pour établir le comportement périodique ou de changements d'état pour les services Publish et Subscribe. GS_Lease_Parameters fournissent GS_Connection_Info aux services Subscribe comme approprié pour le protocole étranger et le GS_Transfer_Mode afin d'établir les valeurs par défaut de la qualité de service et de la priorité de transfert.

La charge utile de publication (GS_Publish_Data) est envoyée et reçue dans le format non natif. Les objets TUN dans des passerelles transfèrent ces charges utiles en utilisant le service Publish. GS_Transfer_Mode est fourni avec chaque transfert afin d'indiquer le service, y compris la priorité, associé au transfert.

Le GS_Transfer_Mode spécifie la priorité (priority) et l'éligibilité au rejet (discard eligibility), telles que définies à l'Article 12 pour le service tunnel.

P.14 Transfert en masse

Le service de transfert en masse de GIAP est mis en œuvre par l'intermédiaire du protocole de transfert en masse et des objets IFO et UDO.

Le transfert en masse est utilisé pour le téléchargement montant/téléchargement descendant dans le mode semi-duplex. Un IFO agit comme un client. Les UDO agissent comme des serveurs. L'identificateur d'objet UDO représente la ressource cible pour l'opération. Une série de transferts par blocs d'AL est commandée par les objets d'extrémité s pour fournir la livraison ordonnée et exempte d'erreur de blocs complets d'une taille négociée. Il n'y a aucun appui dans un transfert fiable dans des couches inférieures. Un protocole de transfert à plusieurs phases (ouvrir, transférer et fermer) est utilisé. Une série de demandes et de réponses distinctes suit la taille totale du transfert. Des attributs de temporisation sont définis pour que l'UDO aide le client à déterminer les politiques de temporisation et de répétitions de tentative et éviter les erreurs d'encombrement. Une opération de chargement ou de téléchargement peut être fermée en raison d'erreurs sur l'une ou l'autre extrémité.

L'établissement de location pour des transferts en masse établit les ressources de communication nécessaires par l'intermédiaire d'un contrat de communication avant le transfert en masse.

La primitive de demande de G_Bulk_Open sert à initier un transfert en masse. L'appareil cible pour un transfert en masse est adressé par le GS_Network_Address, qui est une adresse IPv6. L'élément cible pour un transfert en masse est identifié par GS_Resource, qui contient le Transport_Port et l'OID pointant vers un UDO spécifique.

P.15 Alerte

Le service alerte de GIAP est mis en œuvre par des services d'alerte (alarmes et événements).

L'établissement de location pour des alertes établit les ressources de communication nécessaires par l'intermédiaire d'un contrat de communication pour permettre la réception d'alertes. GS_Alert_Source_ID spécifie Transport_Port, OID, et le type d'alerte.

P.16 Configuration de passerelle

Il n'y a aucune information d'adaptation spécifique pour cet élément.

P.17 Configuration d'appareil

Il n'y a aucune information d'adaptation spécifique pour cet élément.

Annexe Q
(informative)

Adaptations exemplaires du GIAP pour l'IEC 62591

NOTE Les informations suivantes ont été dérivées par analyse de l'IEC 62591 et peuvent contenir des erreurs. Voir la norme IEC réelle pour une pleine et correcte appréhension.

Q.1 Généralités

Q.1.1 Vue d'ensemble

La présente norme ne définit pas la fonctionnalité pour une passerelle complète. Elle inclut des exemples d'appui qui permettent la construction de passerelle par l'addition d'un convertisseur de protocole, et une interface matérielle et une pile pour un réseau étranger. Une telle addition exige un effort séparé pour définir le convertisseur de protocole.

L'Annexe Q décrit une interface exemplaire de passerelle, appelée le GIAP, qui est censée être une abstraction d'un système sous-jacent sans fil. En particulier, elle vise à fournir une abstraction pour le système sans fil décrit dans la présente norme, et également pour le système sans fil décrit dans l'IEC 62591.

L'Annexe Q décrit une manière de mettre en œuvre le GIAP informatif en utilisant le jeu de commande IEC 62591. Il ne s'agit pas d'une conception complète, mais c'est une référence pour aider à la compréhension.

Les passerelles spécifiques (pour les bus de terrain spécifiques) pourraient inclure l'Annexe Q, la rendant donc normative. Elles pourraient également adopter une approche différente.

Q.1.2 Référence

L'Annexe Q référence l'IEC 62591, l'IEC 61158-5-20, l'IEC 61158-6-20 et HCF_SPEC-183, qui spécifient certains des commandes et codages de champ de HART utilisés par l'IEC 62591.

Q.1.3 Adressage

Les informations d'identification et d'adressage d'appareil de l'IEC 62591 comprennent:

- Surnom: un court identificateur de 2 octets pour un appareil;
- Unique ID: un identificateur globalement unique de 8 octets formé par le OUI HCF= 0x00 1B1E + l'ID unique HART de 5 octets, conformes ensemble aux exigences relatives à EUI64Address;
- Long Tag: une chaîne lisible par l'homme de 32 octets.

L'interface GIAP utilise des adresses IPv6 logiques. La plupart des commandes de l'IEC 62591 utilisent des surnoms. Les passerelles IEC 62591 doivent mettre en œuvre la commande 841 (read network device identity using nickname, lire l'identité d'appareil réseau en utilisant le surnom) utilisant le surnom qui retourne un ID unique et une longue étiquette pour un surnom. La commande 832 (read network device identity using Unique ID, lire l'identité d'appareil réseau en utilisant le Unique ID) convertit l'ID unique en surnom et en longue étiquette d'un appareil.

Il convient de mettre en correspondance l'ID unique dans les octets de poids faible de l'adresse de GIAP plus longue.

Q.1.4 Interface de pile

L'IEC 62591 décrit son interface la plus haute comme étant une interface à la NL. La description d'interface de NL reçoit des paramètres qu'elle utilise pour invoquer une TL. Indépendamment de la description d'interface, le paquet par liaison radio encapsule l'en-tête de TL au sein d'une charge utile de la NL.

La charge utile de la TL encapsule une ou plusieurs commandes HART ou IEC 62591, pour les demandes et les réponses. L'Annexe Q décrit le mappage des services GIAP vers les commandes portées par le TL.

Q.1.5 Tunnellisation

Des passerelles IEC 62591 sont exigées pour tunnelliser des commandes HART. Cela signifie qu'une passerelle inclut un réseau étranger (l'interface d'hôte) connecté à la passerelle et la passerelle tunnellisera des commandes HART par l'intermédiaire du réseau étranger.

Q.1.6 Entités

La passerelle virtuelle, le gestionnaire de réseau, l'interface d'hôte (applications d'hôte) et l'interface réseau (appareils de réseau) sont toutes les entités de l'IEC 62591 qui mettent en œuvre (émettent et répondent à) des commandes HART et des commandes de l'IEC 62591. Le gestionnaire de réseau a la communication exclusive vers un gestionnaire de sécurité. Toute la communication entre le gestionnaire de réseau et les appareils de réseau et toute la communication entre les applications d'hôte et les appareils de réseau sont acheminées à travers la passerelle virtuelle, qui agit comme un hub de routage de commandes. La passerelle virtuelle elle-même met aussi en œuvre certaines commandes. La passerelle virtuelle communique avec les appareils de réseau par un ou plusieurs points d'accès réseau aussi bien qu'avec des appareils de réseau intermédiaires qui accomplissent le routage.

Q.1.7 Réponse différée

HART incorpore un mécanisme de réponse différée, dans lequel une première réponse spécifie que la commande a été reçue, mais que la réponse réelle est retardée en raison d'exigences de traitement étendu. Les services de GIAP exigent le traitement des réponses différées au sein de la passerelle. Une erreur est retournée si une commande qui attend un acquittement n'est pas acquittée.

Q.2 Paramètres

GS_Network_Address est une adresse IPv6 logique utilisée pour identifier un appareil spécifique de l'IEC 62591 au sein d'un réseau.

GS_Unique_Device_ID est un identificateur unique d'appareil au format EUI64Address utilisé pour identifier un appareil IEC 62591 unique. Toutes les passerelles partagent un ID unique de 0xF9 8100 0002.

GS_Network_ID indique un réseau IEC 62591 qui est accessible par la passerelle. L'IEC 62591 définit une ID de 16 bits. L'IEC 62591 spécifie une seule passerelle par réseau. Une passerelle à plusieurs modes spécifie plusieurs réseaux par passerelle et utilise l'ID de réseau pour identifier le réseau spécifique associé à une passerelle virtuelle de l'IEC 62591.

Q.3 Session

Plusieurs sessions peuvent être établies par l'intermédiaire d'une passerelle. Chaque session est utilisée pour communiquer avec un réseau spécifique tel qu'indiqué par GS_Network_ID qui est fourni lorsque la session est invoquée.

L'IEC 62591 inclut un concept différent qui est aussi appelé une session. Cette session fait référence à une session de sécurité de bout en bout. L'Annexe Q ne fait pas référence à la session de sécurité, mais à la session GIAP.

Le service de session libère des ressources de passerelle virtuelle IEC 62591 lorsqu'une session finit explicitement ou par expiration de temporisateur en utilisant les commandes suivantes:

- libérer toutes les locations;
- libérer les ressources de communication non utilisées;
- libérer le cache non utilisé.

Q.4 En leasing

Une location est utilisée pour allouer et libérer des ressources de communication spécifiques dans le contexte d'une session.

NOTE Les "services" IEC 62591 sont des ressources de chemin de communication allouées, d'un appareil demandeur (passerelle y compris) vers une destination. Des services sont demandés auprès du gestionnaire de réseau et identifiés par un ID de service. Les services ont des garanties de largeur de bande et de latence indépendantes, selon les demandes d'allocation de services. Le gestionnaire de réseau traite l'établissement et la gestion des ressources intermédiaires, telles que les chemins communs (partagés), en fonction des demandes.

Une location est établie avec la commande 799 (request service, demander un service). Cette commande est utilisée pour demander au gestionnaire de réseau une connexion à un autre appareil (un service) avec la largeur de bande et la latence spécifiées.

Le service est identifié par un ID de service (en mapping avec GS_Lease_ID).

GS_Lease_Period est établi par le convertisseur de protocoles.

GS_Lease_Type est défini par les fanions de demande de service et le domaine d'application de service.

GS_Protocol_Type est défini dans l'Annexe M.

Le surnom spécifie l'adresse de l'homologue de passerelle pour le service (en mapping avec GS_Network_Address_List qui inclut un seul GS_Network_Address). L'IEC 62591 inclut des mécanismes en monodiffusion, mais pas pour des services. Le peer-to-peer au niveau d'appareil est possible au sein du protocole, mais n'est pas recommandé en raison de soucis de sécurité.

GS_Resource n'est pas utilisé dans ce contexte et il est donc mis à 0.

La période/latence est en mapping avec GS_Lease_Parameters (GS_Period, GS_Phase, et GS_Stale_Limit).

La commande 801 (delete service, supprimer service) est utilisée pour notifier à un appareil la suppression d'un service spécifique (basé sur l'ID de service) en raison de la demande d'homologue ou d'une décision du gestionnaire de réseau.

Q.5 Rapport de liste d'appareils

Une passerelle de l'IEC 62591 est exigée pour mettre en œuvre la commande 814 (read device list entities, lire les entrées de liste d'appareils). Cette commande récupère une liste des ID uniques pour les appareils connus par la passerelle.

Tous les appareils retournés sont sur la liste d'appareils actifs. Les indications whitelist (liste blanche) et blacklist (liste noire) sont maintenues dans le gestionnaire de réseau et au sein de la passerelle.

GS_Network_Address, GS_Unique_Device_ID, GS_Manufacturer, GS_Model, et GS_Revision sont retournés pour chaque appareil.

Q.6 Rapport de topologie

Le rapport de topologie retourne une liste d'appareils (GS_Device_List), leur adresse (GS_Network_Address), et des informations connexes. Le rapport de liste d'appareil identifie les appareils dans un système.

Une passerelle de l'IEC 62591 est exigée pour mettre en œuvre la commande 834 (read network topology information, lire les informations de topologie de réseau). Cette commande est utilisée pour récupérer des informations relatives à un graphe (GS_Graph_List) pour un appareil spécifique. Les informations recherchées comprennent une liste d'ID de graphe (GS_Graph_ID) pour les graphes auxquels l'appareil participe et une liste de surnoms pour les voisins dans le graphe (associé à GS_Network_Address).

Une passerelle de l'IEC 62591 est exigée pour mettre en œuvre la commande 833 (read network device's neighbor health, lire la santé de voisin de l'appareil de réseau), qui retourne l'ensemble des voisins d'un appareil spécifique. Chaque élément dans la liste retourne le surnom du voisin (qui est mapping avec GS_Network_Address au sein de GS_Neighbor_List).

Q.7 Rapport de programmation

Le service de rapports de programmation renvoie des informations de programmation pour un appareil spécifique identifié par GS_Network_Address. Le rapport de liste d'appareils peut être utilisé pour identifier les appareils dans le système.

La commande 783 (read superframe list, lire liste de supertrames), normalement utilisée par le gestionnaire de réseau) est utilisée comme moyen de rechercher la liste de supertrames et leurs informations connexes issues d'un appareil spécifique. Les informations recherchées comprennent l'ID de supertrame (GS_Superframe_ID), le nombre d'intervalles de temps (GS_Num_Time_Slots) et des fanions en mode supertrame (HCF_SPEC-183:2013, Tableau 47).

GS_Slot_Size est fixé à 10 ms. GS_Start_Time est calculé à partir de SuperframeSlot = (Absolute Slot Number) % Superframe.NumSlots.

La commande 784 (read link list, lire la liste de liaisons, normalement utilisée par le gestionnaire de réseau) est utilisée pour récupérer des informations relatives à aux entrées de liaisons issues d'un appareil spécifique. Des entrées de liaison sont liées à l'utilisation d'intervalles de temps au sein des supertrames. Les informations recherchées comprennent le Superframe ID (GS_Superframe_ID), le nombre d'intervalles de temps dans la supertrame, la voie (GS_Channel), linkOptions (HCF_SPEC-183:2013, Tableau 46), linkType (HCF_SPEC-183:2013, Tableau 45) et le surnom (associé à GS_Network_Address) du voisin dans la liaison pour construire GS_Link_List.

GS_Channel_List contient une liste de canaux en liste blanche et en liste noire telles que définies par GS_Channel_Status pour atteindre GS_Channel_Number. GS_Channel_Number est en mapping avec Index = 0, IEEE 802.15.4 voie = 11, 2,405 MHz ... Index = 14, IEEE 802.15.4 voie = 25, 2,475 MHz. La commande 817 (read channel blacklist, lire liste noire de voies) est utilisée pour identifier le GS_Channel_Status pour chaque voie.

Q.8 Rapport de santé d'appareil

Le rapport de santé d'appareil retourne des informations relatives à la santé d'appareil pour une liste d'appareils (GS_Device_List), chacun étant identifié par GS_Network_Address.

Tous les appareils IEC 62591 mettent en œuvrent et éditent périodiquement la commande 779 (report device neighbor health, rapporter la santé de voisin de l'appareil) pour rendre les informations disponibles au gestionnaire de réseau et aux applications.

Une passerelle de l'IEC 62591 est exigée pour mettre en œuvre la commande 840 (read network device's statistics, lire les statistiques de l'appareil de réseau), qui rapporte la plupart des informations de la commande 779 (aucun statut de puissance). Cette commande utilise un ID unique pour récupérer une diversité d'informations relatives à un appareil spécifique, comprenant:

- nombre de DPDU générés par cet appareil (GS_DPDUs_Transmitted);
- nombre de DPDU arrêtés par cet appareil (GS_DPDUs_Failed_Transmission);
- nombre d'échecs de MIC de la DL (GS_DPDUs_Received, GS_DPDUs_Failed_Reception);
- ombre d'échecs de MIC de la NL (GS_DPDUs_Received, GS_DPDUs_Failed_Reception);
- nombre d'erreurs CRC (GS_DPDUs_Received, GS_DPDUs_Failed_Reception).

La commande 840 est utilisée plusieurs fois pour rassembler des informations pour chaque appareil dans la liste.

Q.9 Rapport de santé de voisin

La santé de voisin est périodiquement éditée vers le gestionnaire de réseau par la commande 780 (report neighbor health list, rapporter la liste de santé de voisin). L'intensité de signal de voisin est périodiquement éditée vers le gestionnaire de réseau par la commande 787 (report neighbor signal levels, rapporter les niveaux de signal de voisin), qui duplique les informations dans la commande 780.

G_Neighbor_Health_Report retourne une liste d'informations relatives à la qualité de la connexion au niveau de liaison pour l'ensemble de voisins d'un appareil spécifique. Le service est principalement mis en œuvre par la commande 833.

Une liste d'appareils connus par la passerelle (et chaque adresse d'appareil GS_Network_Address) peut être récupérée en utilisant le service de rapport de liste d'appareil de GIAP (G_Device_List_Report).

Une passerelle selon l'IEC 62591 est exigée pour mettre en œuvre la commande 833 (read network device's neighbor health) qui retourne une liste d'informations relatives à la qualité de connexion au niveau de la liaison pour l'ensemble de voisins d'un appareil spécifique. Chaque élément dans la liste retourne le surnom de voisin (qui est mapping à GS_Network_Address), le niveau de signal de réception en dB (GS_Signal_Strength), le nombre de paquets émis vers le voisin (GS_DPDUs_Transmitted), le nombre d'émissions échouées vers le voisin lorsqu'aucun ACK/NAK DPDU n'a été reçu (GS_DPDUs_Failed_Transmission), et les paquets reçus en provenance du voisin (GS_DPDUs_Received).

GS_Link_Status = 1 indique que le voisin est disponible pour la communication. GS_Link_Status = 0 indique que le voisin est indisponible pour la communication.

Une passerelle selon l'IEC 62591 est exigée pour mettre en œuvre la commande 840 (read network device's statistics), qui rapporte GS_DPDUs_Failed_Reception comme décrit dans l'article rapport de santé d'appareil.

GS_Signal_Quality n'est pas disponible et il est donc mis à valeur de qualité maximale.

Q.10 Rapport de santé de réseau

Le rapport de santé d'appareil et le rapport de santé de voisin sont utilisés pour déterminer GS_Device_Health_List et GS_Network_Health.

Une passerelle de l'IEC 62591 est exigée pour mettre en œuvre la commande 840 (read network device's statistics). Cette commande utilise un ID unique pour récupérer une diversité d'informations relatives à un appareil spécifique, comprenant:

- nombre de rattachements (GS_Join_Count);
- date du plus récent rattachement et heure de rattachement joints (GS_Start_Date);
- latence moyenne de la passerelle à ce nœud (GS_GPDU_Latency).

ASN est un compte de tous les intervalles de temps qui se sont produits depuis la formation du réseau. Il augmente toujours par incréments et n'est jamais réinitialisé. ASN a une longueur de cinq octets. ASN 0 correspond au moment de la naissance du réseau. GS_Start_Date et GS_Current_Date sont dérivés de l'ASN.

Q.11 Durée

Le temps de réseau selon l'IEC 62591 est mesuré par rapport au numéro d'intervalle de temps absolu 0 (ASN 0), qui est l'instant du dernier redémarrage du réseau. Ce temps progresse en incréments de 10 ms par intervalle.

La distribution de temps est configurée par le gestionnaire de réseau en utilisant la commande 971 (write neighbor property flag, écrire le fanion de propriété de voisin) pour spécifier un voisin avec les fanions de voisin (source de temps 0x01, HCF_SPEC-183:2013, Tableau 59) indiquant un voisin spécifique comme étant une source de temps. La passerelle selon l'IEC 62591 est toujours configurée comme étant la source de temps de réseau.

Le temps d'intervalle est mis à jour à travers les voisins par synchronisation par l'intermédiaire des erreurs de temps vues dans des échanges de paquets (par exemple, un champ ACK/NAK DPDU TsError).

La passerelle virtuelle doit se synchroniser avec une source extérieure de temps au moins une fois par heure. Le temps TUC est mis en correspondance avec le temps d'intervalle issu d'une référence externe à travers la passerelle. Le mapping de l'ASN 0 au TUC est diffusé à partir de la passerelle. La commande 793 (write UTC time mapping, écrire le mapping au temps TUC) est une commande de passerelle qui permet au gestionnaire de réseau d'établir le mapping du début de l'ASN 0 avec le temps TUC sur un appareil.

GS_Time est basé sur le temps TAI. Le temps TUC est basé sur le temps TAI avec des secondes intercalaires ajoutées à intervalles irréguliers. Ce service applique des mises à jour de temps à travers le GIAP. Les mises à jour de temps TAI et TUC se produisent en raison de la dérive. Le TUC ajoute les mises à jour supplémentaires en raison des secondes intercalaires. Une conversion est nécessaire du format de temps HART interne vers GS_Time et vice versa: Date HART 3 octets, heure du jour, 3 octets.

La commande 794 (read UTC time mapping, lire le mapping au temps TUC) est une commande de passerelle qui permet à un appareil ou au gestionnaire de réseau d'établir et

lire le mapping du début de l'ASN 0 avec le temps TUC. GS_Command est utilisé pour établir et lire GS_Time au sein de la passerelle pour des besoins de synchronisation. La commande 89 (set real-time clock, établir l'horloge temps réel) est utilisée pour établir le temps. La commande 90 (read real-time clock, lire l'horloge temps réel) est utilisée pour lire le temps courant.

Q.12 Client/server

Sauf spécification contraire ailleurs dans l'Annexe Q, la passerelle tunnellise toutes les commandes HART par l'intermédiaire du service C/S du GIAP. Ces commandes sont émises d'un maître vers un esclave (appareil de terrain). Le maître joue le rôle de client et l'esclave joue le rôle de serveur.

Les commandes suivent un format de demande/réponse. Des octets de données de demande sont envoyés du client vers le serveur dans GS_Request_Data. Des octets de données de réponse sont retournés du serveur vers le client dans GS_Response_Data. Les codes de réponse spécifique à une commande sont mis en mapping dans GS_Status.

Le fanion GS_Buffer est mis ou dégagé pour spécifier si, oui ou non, une commande doit être placée en tampon. Les commandes suivantes sont tamponnées:

- 0: read unique id
- 11: read unique id associated with tag
- 13: read tag, descriptor, date
- 20: read long tag
- 21: read unique id associated with long tag
- 48: read additional status
- 50: read dynamic variable assignments
- 18: write tag, descriptor, date
- 22: write long tag
- 25: write primary variable range values
- 44: write primary variable units

Plusieurs réponses de serveur peuvent être reçues avec le même GS_Transaction_ID dans le cas d'une réponse différée.

La priorité de C/S est établie par l'intermédiaire du GS_Transfer_Mode.

La priorité selon l'IEC 62591 s'inscrit dans l'un de quatre niveaux, à savoir command (la plus haute priorité), process data, normal, et alarm (la priorité la plus basse). La priorité "command" est réservée pour des paquets contenant la commande réseau, la configuration et le diagnostic. Les paquets de priorité "process data" contiennent des données de processus et sont refusés lorsque les tampons de paquets d'un appareil sont remplis aux trois-quarts. Les paquets de priorité "alarm" contiennent des alarmes et des événements. Seulement un seul paquet de priorité "alarm" est placé en tampon. Les paquets de priorité "normal" sont tous les autres paquets et sont refusés lorsque la moitié des tampons de paquets d'un appareil est remplie.

GS_Transaction_Info n'est pas exigés.

Q.13 Publish/subscribe (éditer/s'abonner)

Q.13.1 Généralités

Le service P/S du GIAP est mis en œuvre à travers la publication des commandes par les appareils conformes à l'IEC 62591 utilisant le mode continu. Les adaptateurs sont capables d'éditer pour le compte de sous-appareils non natifs. L'IEC 62591 agrège de manière native des commandes éditées où le temps s'aligne et la commande 78 (read aggregated commands, lire des commandes agrégées) n'est pas exigée.

Normalement, une passerelle s'abonne à une publication d'appareil. Au sein de G_Subscribe, GS_Publish_Data retourne les données éditées.

Il est exigé qu'une location soit acquise pour l'abonnement (obtenir GS_Lease_ID). L'établissement de location alloue des ressources entre la passerelle et l'appareil en utilisant la commande 799.

L'indication de G_Publish_Watchdog est reçue si la publication n'est pas reçue par le GS_Stale_Limit.

Q.13.2 Établissement de la location

Une location d'abonnement est établie à travers le service de location. GS_Resource spécifie les informations d'abonnement (liste de numéros de commande et de variables de processus) au service de location.

La commande 108 (write publish data mode command number, écrire le numéro de commande en mode publication de données) est utilisée comme moyen de choisir la commande devant être éditée.

Si la commande 108 spécifie la commande universelle 9 (read device variables, lire les variables d'appareil) ou la commande de pratique courante commune 33 (read device variables), des variables de processus seront assignées à des intervalles de temps pour la publication. La commande 107 (write publish data device variables, écrire les variables d'appareil de données d'édition) est utilisée pour assigner les intervalles.

La commande 103 (write publish data period, écrire la période de données d'édition) choisit la période de mise à jour minimale (GS_Period, GS_Phase) et maximale (GS_Stale_Limit) pour une publication (en incréments de 1/32 ms jusqu'à 3 600 s; la valeur demandée et la valeur réelle peuvent différer).

La commande 104 (write publish data trigger, écrire le déclencheur de données d'édition) établit une condition de déclenchement (GS_Update_Policy) pour la publication (continue/à fenêtre/en montée et un niveau) conduisant à des changements dynamiques du temps de publication. La publication se produit au moins aussi souvent que lorsque la période maximale est atteinte.

La commande 109 (publish data mode control, éditer le contrôle de mode de données) active et désactive l'édition. L'appareil de source de publication contacte le gestionnaire de réseau pour demander de la largeur de bande.

Q.13.3 Placement en tampon

Les commandes suivantes sont tamponnées:

- 1: read primary variable
- 2: read current & percent
- 3: read all variables

- 9: device variables and status
- 33: read device variables
- 123: read trend
- Device-specific (spécifique à un appareil)

Q.14 Transfert en masse

Le service de transfert en masse du GIAP correspond au transfert par blocs fourni par l'AL. L'opération permet le téléchargement montant/téléchargement descendant (GS_Mode) en mode semi-duplex ou duplex intégral, et s'appuie sur la TL pour fournir une série de transferts par blocs de niveau application. Le transport effectue la segmentation et le réassemblage selon la MTU limitée dans des couches inférieures et fournit la livraison sans erreur des blocs complets (tous les morceaux sont dans l'ordre).

L'opération utilise plusieurs phases, y compris ouvrir (G_Bulk_Open), transférer (G_Bulk_Transfer), réinitialiser, et fermer (G_Bulk_Close). De nouvelles commandes ont été créées pour exécuter ces phases. Un maître ouvre une session (commande 111) avec un esclave pour initier l'opération (GS_Transfer_ID relie les phases de cette opération). Le maître propose les longueurs de bloc (GS_Block_Size), et l'esclave peut réduire la taille. Un port (un octet) identifie la ressource cible (GS_Resource) pour l'opération (firmware, paramètres, et fichier journal). Toute la taille n'est pas énoncée (GS_Item_Size = 0) et ne peut pas être connue même par l'application (telle qu'un train continu d'échantillons organisés en blocs). Il y a un compteur d'octets sélectionné par chaque extrémité pour suivre la progression. La commande 112 est organisée de façon que la demande contienne des données de téléchargement descendant (GS_Bulk_Data) et la réponse a des données de téléchargement montant (GS_Bulk_Data). La demande crée une indication dans l'esclave; la réponse contient une indication dans le maître. La session est fermée sur des erreurs. Aucune règle n'existe sur la façon de traiter le jeu de données partielles. Le mécanisme de réponse différée est mentionné dans le statut, mais n'est pas plus décrit.

Q.15 Alerte

Le service alerte du GIAP est mis en œuvre par l'intermédiaire de plusieurs mécanismes. Les changements localement placés en tampon comprennent les mises à jour en mode par salves (changements de processus), la notification d'événement (les alarmes et les événements généraux), les changements de statut d'appareil, les changements de configuration d'appareil, les changements de topologie de réseau, et les changements de programme de réseau.

La notification de changement spécifie simplement un changement, et une action supplémentaire doit récupérer les informations altérées des tampons de passerelle. L'entité de passerelle acquitte l'arrivée d'événement aux appareils. Des publications et des alertes sont stockées dans l'entité de passerelle. L'entité de passerelle acquitte l'arrivée des alertes aux appareils.

Par exemple, la passerelle utilise souvent en interne la commande HART 115..118 pour établir une notification de changement et la commande HART 119 pour indiquer que des changements se sont produits.

Les événements sont configurés avec des numéros d'événement assignés sur une base par appareil.

La commande 116 (write event notification bit mask) configure le masque d'événement qui est utilisé pour déclencher une notification d'événement pour un événement spécifique. Le masque d'événement correspond à la commande 48 (read additional device status, lire le statut d'appareil complémentaire), qui se réfère aux tables communes 14, 17, 29, 30, 27, 31, 32, 28 et à un statut spécifique à un appareil.

La commande 117 contrôle la temporisation des notifications d'événement. La notification d'événement utilise le mode par salves pour la livraison lorsqu'un événement est déclenché. Une période anti-rebond est spécifiée pour empêcher les événements qui sont trop courts de déclencher un message à salves. Un temps de répétition de tentative (période de salves souhaitées) et une durée maximale de mise à jour (période à salves maximale) établissent la temporisation de transfert à salves si un événement déclenche un message.

La commande 118 (event notification control, contrôle de notification d'événement) est utilisée pour activer ou désactiver une notification d'événement pour un événement spécifique.

La commande 119 (acknowledge event notification, acquitter la notification d'événement) est utilisée pour acquitter la notification d'événement et dégage l'événement pour l'empêcher d'être envoyé dans des les mises à jour par salves. D'autres événements peuvent être dans la file d'attente.

La commande 115 (read event notification summary, lire le résumé de notification d'événement) est utilisée pour déterminer la configuration d'un événement en fonction d'un numéro d'événement spécifique.

Les commandes suivantes sont tamponnées:

- 119 read event notification status (marqueur temporel + statut d'appareil + commande 48).
- La commande 788 (alarm path down, alarme chemin défaillant), la commande 789 (alarm source route failed, alarme chemin de source défaillant), la commande 790 (alarm graph route failed, alarme chemin par graphe défaillant), et la commande 791 (alarm TL failed) rapportent des défaillances de communication au gestionnaire de réseau.

La commande 836 (write update notification bit mask for a device, écrire le masque de bits de la notification de mise à jour) de passerelle conforme à l'IEC 62591 enregistre un client pour des mises à jour de notifications. L'appareil est adressé par l'ID unique et reçoit un jeu de fanions de notification de changement. Des codes existent pour BurstMode, EventNotification, DeviceStatus, DeviceConfiguration, NetworkTopology (passerelle ou NM), et NetworkSchedule (passerelle ou NM). Cela est utilisé dans G_Alert_Subscription pour s'abonner (en fournissant une GS_Subscription_List avec GS_Alert_Source, GS_Subscribe, et GS_Enable pour un appareil spécifique GS_Network_Address et une catégorie spécifique GS_Category).

La commande 838 de passerelle de l'IEC 62591 (read update notification bit mask for a device, lire le masque de bits de notification de mise à jour pour un appareil) renvoie une liste des notifications de mise à jour pour un appareil. Cela est utilisé dans G_Alert_Subscription pour identifier les abonnements.

La commande 839 (change notification, notification de changement) de passerelle selon l'IEC 62591 est envoyée par la passerelle à un client et renvoie une liste comportant au maximum 10 notifications de changements (commandes placées en cache) pour un appareil. Chaque changement se traduit par une seule G_Alert_Notification.

Q.16 Configuration de passerelle

Il n'y a aucune information d'adaptation spécifique pour cet élément.

Q.17 Configuration d'appareil

Il n'y a aucune information d'adaptation spécifique pour cet élément.

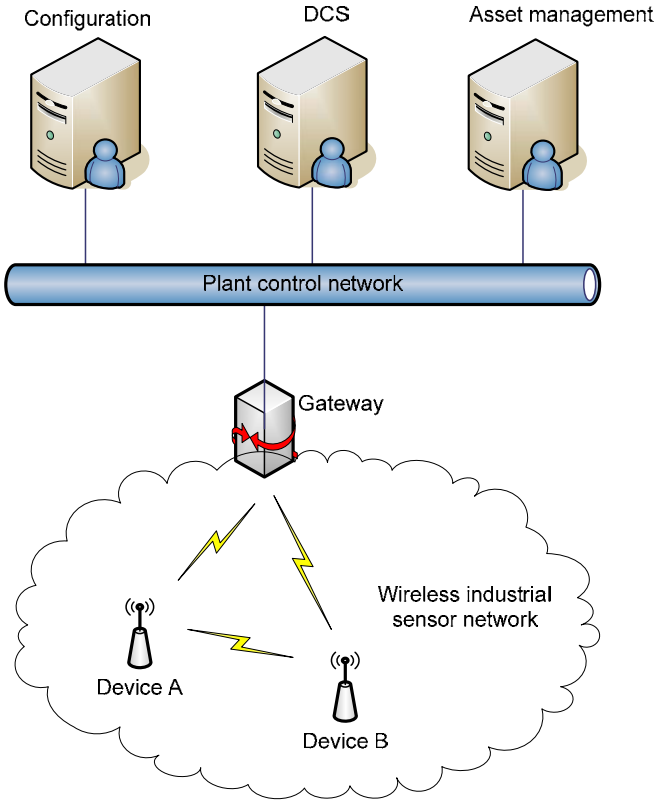
Annexe R
(informative)

Interface système hôte aux appareils conformes à la norme via une passerelle

R.1 Contexte

R.1.1 Modèle de référence d'intégration de système hôte

Un modèle simplifié de référence pour l'intégration de système hôte/appareil conforme à une norme est décrit à la Figure R.1.



Légende

Anglais	Français

Asset management	Gestion d'actifs
Plant control network	Réseau de commande d'installation
Gateway	Passerelle
Device A	Appareil A
Wireless industrial sensor network	Réseau de capteurs industriels sans fil
Device B	Appareil B

Figure R.1 – Modèle de référence d'intégration de système hôte

R.1.2 Outils de gestion d'actifs

La gestion d'actifs implique de superviser la santé des biens de systèmes en surveillant des conditions relatives à la santé afin d'identifier un problème potentiel avant que le processus ou l'exploitation d'installation ne soit affecté(e). Les systèmes hôtes fournissent un outil de gestion d'actifs ou un jeu d'outils pour accomplir la fonction de gestion d'actifs, dans le but d'abaisser les coûts de service, de réduire le temps de panne, et d'assurer que les niveaux appropriés de qualité des produits sont atteints.

R.1.3 Outils de configuration

Une fois la conception du système établie et les composants du système identifiés, le fonctionnement des composants dans le système global doit être configuré. Les systèmes hôtes fournissent un outil de configuration ou un jeu d'outils qui prend en charge la configuration des composants du système et en définit le fonctionnement.

R.1.4 Système de commande distribué

Un système de commande distribué (DCS) est un système de commande qui prend en charge un processus dans lequel les éléments de commande sont géographiquement distribués. Ces éléments distribués sont connectés par des réseaux de communication, qui sont utilisés pour communiquer avec les éléments distribués.

R.1.5 Passerelle

Une passerelle connecte les systèmes hôtes au réseau. Voir l'Annexe U pour plus d'informations relatives à la passerelle.

R.2 Intégration de données d'application d'appareil avec des systèmes hôtes

R.2.1 Généralités

Il existe deux moyens génériques pour les systèmes hôtes d'intégrer des données d'application issues d'appareils connectés:

- intégration par l'intermédiaire d'un mapping de protocoles; et
- intégration par l'intermédiaire de la tunnellisation de protocoles.

R.2.2 Intégration de protocoles natifs par l'intermédiaire du mapping

Les systèmes hôtes existants peuvent intégrer des données d'application d'appareil en effectuant un mapping des relations entre les appareils et les données avec le traitement des informations accompli par le système hôte existant. Cette fonction de mapping est habituellement accomplie par une passerelle entre le système hôte existant et le réseau de capteurs industriels sans fil (WISN).

R.2.3 Intégration de protocoles d'appareil hérités par l'intermédiaire de la tunnellisation

Les systèmes hôtes peuvent intégrer des données d'application issues appareils hérités existants qui utilisent la capacité de tunnellisation d'application du WISN de la même manière par laquelle ils intègrent actuellement des données d'application issues d'appareils hérités.

R.3 Outil de configuration de système hôte

R.3.1 Généralités

Les systèmes hôtes prennent habituellement en charge l'une et/ou l'autre de deux méthodes génériques d'intégration pour configurer des appareils de terrain:

- langage de description électronique de produit (EDDL);
- outil d'appareil de terrain/gestionnaire de type d'appareil (FDT/DTM).

R.3.2 Configuration d'hôte en utilisant le langage de description d'appareil électronique

L'IEC 61804-3, EDDL, décrit un langage générique pour décrire des propriétés d'appareil d'automation. EDDL peut décrire des fonctions d'appareil, des interactions prises en charge par un appareil, des objets pris en charge par un appareil et d'autres propriétés.

EDDL est utilisé par un fournisseur d'appareil pour créer un fichier définition d'appareil électronique (EDD) qui correspond à un appareil particulier. Un fichier d'EDD est un fichier texte en ASCII structuré indépendant vis-à-vis de tout système d'exploitation et de tout système d'automation qui décrit les capacités d'un appareil pour permettre l'intégration de l'appareil avec un système DCS hôte. Cette indépendance permet à des fournisseurs de décrire leurs appareils d'une manière qui permet l'interopérabilité indépendante et l'interopérabilité contrainte vis-à-vis de tout fournisseur de l'appareil à travers des systèmes hôtes. Les fichiers EDD décrivent des données d'appareil, des caractéristiques d'interface utilisateur souhaitées par un fournisseur d'appareil, et le traitement de commandes d'appareil, tel que l'ordonnancement et la temporisation des commandes.

Les DCS d'hôte fournissent des outils pour interpréter les fichiers d'EDD afin de configurer et manipuler l'appareil, comme dans le cas de la surveillance ou celui du traitement de paramètres, pour prendre en charge des applications de commande.

Les fichiers EDD sont définis par des fournisseurs d'appareil et ils sont soumis à essai par l'organisation prenant en charge le bus de terrain approprié.

La Figure R.2 représente la configuration en utilisant un fichier DD.

Figure R.2 – Configuration utilisant une définition d'appareil électronique

R.3.3 Configuration de l'hôte utilisant l'outil d'appareil de terrain/gestionnaire de type d'appareil

La fonctionnalité de l'appareil décrite par l'EDD est limitée par l'IEC 61804-3. La fonctionnalité supplémentaire d'appareil (le cas échéant) qui ne peut pas être décrite par l'intermédiaire de l'EDD peut être prise en charge par l'intermédiaire de prises enfichables ou à fixation directe propriétaires. Pour fournir cette plus grande prise en charge, la technologie FDT/DTM peut être utilisée. La technologie FDT/DTM requiert, par exemple, la prise en charge d'application de PDU FDT dans le DCS. Pour plus d'informations relatives à la FDT/DTM, consulter le FDT Group.

La Figure R.3 représente une configuration utilisant l'approche FDT/DTM.

Based on GW high side interface or proprietary, developed by system vendor	Basée sur l'interface de côté haut de la passerelle (GW) ou propriétaire, développée par le vendeur de système

Figure R.3 – Configuration utilisant l'approche FDT/DTM

R.4 Intégration appareil de terrain/systèmes de commande distribués

R.4.1 Généralités

Les systèmes de commande distribués sont habituellement composés d'appareils tels que contrôleurs, stations d'interface homme-machine (IHM), serveurs d'antécédents de données, applications avancées, etc. Les stations IHM, les serveurs d'antécédents, et les applications avancées utilisent souvent des interfaces avec une sémantique riche de données, telle que l'OPC. La communication avec des contrôleurs utilise habituellement des protocoles plus simples, tels que Modbus, ou l'Ethernet haut débit de la fondation Fieldbus (Foundation Fieldbus high speed Ethernet (FF-HSE).

R.4.2 Fondation Fieldbus – Ethernet haut débit

L'intégration de données d'application avec le FF-HSE peut, par exemple, être accomplie en mappant les données d'application natives à des blocs de transducteurs FF. Les objets d'application ont un mapping aux blocs FF, alors que les attributs d'objets sont mis directement en correspondance aux paramètres de bloc FF.

R.4.3 Modbus

Les données d'application peuvent s'intégrer avec Modbus en assignant une adresse Modbus à la passerelle. La passerelle peut alors présenter un ensemble de tables de registre aux maîtres Modbus. Chaque attribut d'objet peut être mis en correspondance avec un registre spécifique. Le système hôte peut fournir la prise en charge automatisée pour le mapping, ou le mapping peut être accompli manuellement par l'utilisateur.

R.4.4 Connectivité ouverte pour l'automation industrielle

La connectivité ouverte pour l'automation industrielle (OPC) permet à des applications client d'accéder à des données d'une façon cohérente par l'intermédiaire d'un serveur OPC en référençant les données en utilisant une construction Tag.Parameter.

Un client OPC peut être pris en charge par un serveur OPC dans le système hôte ou par une interface OPC de côté haut fournie par une passerelle à un système conforme à une norme.

Par exemple, la présente norme fournit la valeur, la qualité, et les informations de marqueur temporel dans des publications de données, à l'appui de l'accès serveur OPC à des données en ligne. Des alarmes et des événements natifs fournissent également l'appui pour la notification au client OPC.

Le client OPC peut spécifier le Tag.Parameter en utilisant le nom de l'appareil pour Tag, et un ensemble unique d'un nom et d'un attribut pour représenter le paramètre (par exemple, TI101.AITB1.PV). Dans le serveur OPC, Tag est mise en correspondance avec l'appareil, l'instance d'objet est en correspondance avec une instance particulière d'objet d'un UAP particulier, et le nom d'attribut est en correspondance avec l'identificateur d'attribut particulier de l'instance d'objet référencée.

R.5 Passerelle

R.5.1 Généralités

La configuration de système hôte des applications résidant dans la passerelle elle-même, y compris le mapping des données (s'il y a lieu), est définie par le réseau de commande d'installation, qui est l'interface de côté haut de la passerelle qui couple le WISN dans un système de commande de plus haut niveau. Cela inclut, par exemple, la configuration d'une application de gestion de système ou d'une application de tunnellisation. Par conséquent, l'Annexe R décrit dans les grandes lignes le type d'informations qui ont besoin d'être configurées pour la prise en charge de la passerelle.

R.5.2 Appareils pris en charge

Un outil de configuration de système hôte peut avoir besoin d'établir le complément d'appareils conformes à une norme avec lesquels la passerelle communiquera.

R.5.3 Abonnement à des données

Un outil de configuration de système hôte peut avoir besoin d'établir la configuration des objets dispersion dans la passerelle pour les données que la passerelle recevra par l'intermédiaire de la publication.

R.5.4 Publication de données

Un outil de configuration de système hôte peut avoir besoin d'établir la configuration des objets Concentrator dans la passerelle pour les données que la passerelle publiera elle-même.

R.5.5 Accès client/serveur

Des communications C/S non relatives à une gestion peuvent, par exemple, être établies par la passerelle sur une base selon la nécessité par l'intermédiaire d'objets d'interface.

R.5.6 Réception d'alertes

Un outil de configuration de système hôte peut avoir besoin d'établir les catégories d'alertes associées à un(des) objet(s) récepteur(s) d'alertes (ARO) résidant dans une passerelle.

R.6 Prise en charge d'application de gestion d’actifs

R.6.1 Généralités

Un outil de gestion d’actifs peut accéder à des informations relatives à un appareil qui sont soit stockées dans la passerelle, soit accessibles par l'intermédiaire de celle-ci, en utilisant des services de réseau de commande d'installation.

Une passerelle peut accéder aux informations directement à partir d'un appareil de terrain pour satisfaire aux demandes de gestion d’actifs. La passerelle peut, par exemple, utiliser des services de C/S pour lire des données, écrire des données ou exécuter une méthode particulière sur une instance d'objet particulière au sein de l'appareil sans fil.

Une passerelle peut agir comme un sas pour des information de biens directement d'un bien vers une application de gestion d’actifs par l'intermédiaire d'un tunnel de réseau de commande d'installation si le réseau de commande d'installation prend en charge une telle capacité de tunnellisation.

R.6.2 Outil d'appareil de terrain/gestionnaire de type d'appareil

Un DTM peut être fourni par un fournisseur d'appareil pour fournir des informations de processus et d'appareil à un outil de gestion d’actifs. Un système hôte prenant en charge un PDU FDT peut utiliser le DTM de l'appareil et un DTM de communication pour la passerelle pour acquérir les informations nécessaires pour gérer l'appareil par l'intermédiaire de la passerelle.

R.6.3 HART

Un appareil conforme à la norme peut être forcé à apparaître comme un appareil HART[16] natif sur une application de gestion d'actifs HART (ASM) de différentes façons:

- Manuellement ou en utilisant l'automation avec conversion soit explicitement codée, soit guidée par des données, les règles fournissent un fichier source DD de HART pour l'appareil. Le fichier DD HART peut être passé à travers un marqueur à jetons (tokenizer) HART pour produire des fichiers binaires représentant le contenu du DD. La plupart des clients de HART utilisent le format binaire des fichiers DD.
- Des commandes normalisées peuvent être définies dans HART pour intégrer l'ASM avec la présente norme, telles que les commandes HART pour READ_IEC62734_ATTRIBUTE, WRITE_IEC62734_ATTRIBUTE et EXECUTE_IEC62734_METHOD.
- Des tables de mapping dans la passerelle peuvent être utilisées pour définir le mapping de valeurs qui diffère entre la présente norme et HART, comme dans le cas des indices en unités d'étude.

R.6.4 OPC

La connectivité ouverte pour l'automation industrielle (OPC) permet à des applications client d'accéder à des données d'une façon cohérente par l'intermédiaire d'un serveur d'OPC. Un client OPC peut être pris en charge par un serveur OPC dans le système hôte ou par une interface OPC de côté haut fournie par une passerelle à un système conforme à une norme.

Par exemple, des informations de santé d'appareil peuvent être fournies par le serveur OPC à un client OPC.

---

16 HART est l'appellation commerciale de HCF. Cette information est donnée à l'intention des utilisateurs de la présente norme et ne signifie nullement que l'IEC approuve ou recommande l´emploi exclusif du (des) produit(s) ainsi désigné(s). La conformité à ce profil n'exige pas l'utilisation de la marque déposée. L'utilisation des marques déposées exige l'obtention préalable d'autorisations auprès du propriétaire des marques.

Annexe T
(informative)

En-têtes de liaison de données et de réseau pour des demandes de rattachement

T.1 Vue d'ensemble

L'Annexe T décrit l'en-tête de la DL et l'en-tête de la NL pour une demande de rattachement typique.

T.2 En-tête MAC (MHR)

L'en-tête MAC pour messages de rattachement est montré dans le Tableau T.1. La convention IEEE montre le bit 0 sur la droite, qui est l'ordre nominal de transmission. D'après la convention IEEE 802.15.4, les champs Sequence Number et Addressing du MHR, lorsqu'ils sont considérés comme des entiers non signés, sont d'abord transmis en mode LSB (octet de poids le plus faible).

NOTE En fait, IEEE 802.15.4 2,4 GHz DSSS transmet des quartets de quatre bits simultanément sous la forme d'un signal à étalement de spectre de 32 puces; il n'existe donc pas de "premier" ou "dernier" bit transmis dans le quartet. Néanmoins, le quartet de poids de bits inférieur dans un octet, lorsqu'il est interprété en tant que valeur Unsigned8, est transmis avant le quartet de poids de bits supérieur du même octet tandis que l'octet de poids inférieur est transmis avant l'octet de poids supérieur.

Le Tableau T.1 suit la convention de la présente norme en montrant le bit 7 sur la gauche.

Tableau T.1 – MHR échantillon pour demande de rattachement

<table>
<tr><th rowspan="2">Sous-trame</th><th rowspan="2">Nombre d'octets</th><th colspan="8">bits</th></tr>
<tr><th>7</th><th>6</th><th>5</th><th>4</th><th>3</th><th>2</th><th>1</th><th>0</th></tr>
<tr><td rowspan="2">Contrôle de trame</td><td rowspan="2">2</td><td>Réservé</td><td>PAN ID Compress = 1 (yes)</td><td>ACK Request = 0 (no)</td><td>Frame Pending = 0 (no)</td><td>Security Enabled = 0 (no)</td><td colspan="3">Frame Type = 1 (Data)</td></tr>
<tr><td colspan="2">Source Addressing Mode= 3 (64-bit)</td><td colspan="2">Frame Version = 1</td><td colspan="2">Dest Addressing Mode=2 (16-bit)</td><td colspan="2">Réservé</td></tr>
<tr><td>Numéro de séquence</td><td>1</td><td colspan="8">(déterminé par le DLE au moment de la transmission)</td></tr>
<tr><td rowspan="3">Adressage</td><td>2</td><td colspan="8">PAN ID (LSB), depuis l'annonce</td></tr>
<tr><td>2</td><td colspan="8">Adresse de destination (16 bits, LSB), depuis l'annonce</td></tr>
<tr><td>8</td><td colspan="8">Adresse source (64 bits, LSB), adresse EUI64 de l'appareil</td></tr>
</table>

T.3 En-tête de DL (DHR)

L'en-tête DL pour messages de rattachement est montré dans le Tableau T.2. Cet exemple suppose que l'annonce ne spécifie pas de lent saut de voie.

Tableau T.2 – DHR échantillon pour demande de rattachement

Sous-titre	octets	bits							
		7	6	5	4	3	2	1	0
DHDR	1	ACK/NAK DPDU needed = 1 (yes)	Signal quality in ACK/NAK DPDU = 0 (no)	Request EUI64Address = 0 (no)	Include DAUX = 0 (no)	Include slow channel hopping-offset = 0 (no)	Clock recipient = 1(yes)	DL version = 00	
DMXHR	1	Reserved=0			Key identifier mode = 1		Security level = 1 (MIC-32)		
	1	Crypto key identifier = 0: K_global							
DAUX	0	(absent par réglage DHDR)							
DROUT	1	Compress = 1	Priority = 0 (irrelevant)				DlForwardLimit = 1		
	1	GraphID (Unsigned8) =0 (Single hop source routing)

	1	DestAddr = 0 (Use DL16Address in MHR)							

T.4 En-tête de NL

L'en-tête réseau pour messages de rattachement est montré dans le Tableau T.3.

Tableau T.3 – En-tête réseau pour messages de rattachement

octets	bits							
	7	6	5	4	3	2	1	0
1	LOWPAN_IPHC dispatch = 011			LOWPAN_IPHC encoding (bits 8..12) = 11 101				
2	LOWPAN_IPHC encoding (bits 0..7) = 0111 0111							

Annexe U
(informative)

Rôle de la passerelle

U.1 Généralités

U.1.1 Vue d'ensemble

Le but primaire d'une passerelle telle que décrite par la présente norme est de permettre à des applications de niveau hôte d'interagir avec des appareils de terrain sans fil. Une grande base d'applications installée existe, y compris des appareils d'automation, des contrôleurs, et des systèmes de surveillance, qui utilisent ensemble de nombreux protocoles hérités, ce qui exige une conversion de protocoles pour interagir avec des appareils de terrain sans fil. Une telle conversion de protocole peut être présente dans la passerelle et également dans des adaptateurs aux appareils de terrain câblés hérités. Dans la présente norme, le terme adaptateur est utilisé pour identifier des appareils qui convertissent un protocole de bus de terrain câblés en un protocole de bus de terrain sans fil pour le compte d'un ou plusieurs appareils de terrain.[17] Une telle conversion de protocole sert généralement à tunnelliser un protocole étranger à travers un réseau sans fil tel que décrit dans la présente norme ou à convertir un protocole hérité vers un format natif de la présente norme et vice versa. Le terme appareil de terrain natif se réfère à un appareil de terrain qui fonctionne exclusivement par l'intermédiaire de l'utilisation des objets natifs, des interfaces natives et du contenu de message natif tels que définis dans la présente norme.[18] Il est également possible d'écrire ou de modifier des applications de niveau hôte pour utiliser directement le protocole d'application natif, réduisant ou éliminant le besoin de conversion de protocole au sein d'une passerelle.

NOTE Les exemples fournis à l'Annexe U sont symétriques, potentiellement applicables sans modification aux passerelles et aux adaptateurs. Techniquement, une passerelle est une interface d'une voie de communication à une autre voie de communication, où la conversion de protocole est utilisée à une ou plusieurs couches de la suite de protocoles. Il existe un précédent établi dans l'industrie d'automation consistant à (incorrectement) utiliser le terme adaptateur pour identifier des appareils qui convertissent un protocole de bus de terrain câblés en un protocole de bus de terrain sans fil pour le compte d'un ou plusieurs appareils de terrain.

La description du rôle de passerelle se rapporte aux capacités suivantes:

- Interfacer des applications étrangères de niveau hôte:
  - directement aux appareils de terrain "natifs" (c'est-à-dire conformes à la présente norme); et
  - indirectement aux appareils de terrain câblés hérités via des adaptateurs hérités.
- Interfacer des applications de niveau hôte à plusieurs systèmes sans fil, y compris une combinaison d'un ou plusieurs système sans fil tels que décrits dans la présente norme et un ou plusieurs systèmes sans fil étrangers, par l'intermédiaire d'un seul appareil (conceptuel) avec une interface commune de côté haut.

---

[17] L'utilisation du terme adaptateur n'est pas uniforme. Techniquement, un adaptateur est une interface d'une CPU avec une voie de communication. Techniquement, une passerelle est une interface d'une voie de communication à une autre voie de communication, où la conversion de protocole est utilisée à une ou plusieurs couches de la suite de protocoles. Il existe un précédent établi dans l'industrie d'automation consistant à (incorrectement) utiliser le terme adaptateur pour identifier des appareils qui convertissent un protocole de bus de terrain câblés en un protocole de bus de terrain sans fil pour le compte d'un ou plusieurs appareils de terrain. Il existe également un précédent dans l'industrie d'automation consistant à (correctement) utiliser le terme passerelle pour identifier des appareils qui convertissent un protocole de bus de terrain sans fil en un protocole de bus de terrain câblé pour le rattachement à un système de commande. Le présent document adhère à l'usage de l'industrie d'automation dans une tentative de réduire au maximum la confusion.

[18] L'objet tunnel natif utilise les services natifs de tunnel et de publication pour transporter un contenu de message étranger. Un appareil de terrain qui requiert le contenu de message étranger pour accomplir sa fonction ne peut pas être considéré comme étant un appareil natif.

La présente norme fournit la fonctionnalité de prise en charge pour la construction de passerelles. Elle ne fournit pas les détails complets sur la façon de construire une passerelle particulière quelconque. L'Annexe U est strictement informative, car aucune passerelle n'est spécifiée. À ce titre, elle fournit une base suggérée pour la future construction d'une spécification de passerelles, mais elle n'en est pas une elle-même. Aucune validation du contenu de l'Annexe U n'a eu lieu.

L'Annexe U décrit la fonctionnalité de prise en charge pour les besoins de conversion de protocoles étrangers, mais elle ne décrit pas en détails la façon d'accomplir une conversion spécifique de protocoles ou la façon d'interfacer à un quelconque réseau d'installation.

Les protocoles hérités n'ont pas été conçus pour opérer sur des réseaux sans fil. Ils n'accèdent pas à l'information d'une manière qui conserve l'énergie, et ils sont souvent intolérants à l'accès différé aux appareils au repos qui conservent l'énergie. La fonctionnalité de prise en charge de passerelle de la présente norme est, en grande partie, prévue pour permettre la construction de passerelles qui adaptent des protocoles hérités aux conditions des appareils sans fil à faible consommation d'énergie.

Le rôle de passerelle inclut un UAP spécialisé. La fonctionnalité est fournie par des objets d'AL et le fonctionnement interne de passerelles. Les objets utilisent les interfaces de la suite de protocoles de communication pour prendre en charge des fonctions d'interface de côté haut des passerelles.

U.1.2 Diagrammes hypothétiques des suites de protocoles de passerelles pour appareils et adaptateurs natifs

Le diagramme à la Figure 17 montre une passerelle hypothétique interfaçant une application de niveau hôte (le système de commande exemplaire) à un appareil de terrain sans fil. Dans ce cas, l'appareil de terrain est un appareil natif. La conversion de protocole est accomplie dans la passerelle pour convertir entre le protocole de réseau d'installation et le protocole natif de la présente norme. Les routeurs peuvent exister entre la passerelle et l'appareil de champ (voir Figure 17), mais du point de vue de la passerelle, leur opération est transparente.

Le diagramme à la Figure 19 montre une passerelle hypothétique interfaçant une application de niveau hôte (le système de commande exemplaire) à un appareil E/S par un système sans fil qui se conforme à la présente norme. Dans ce cas spécifique, l'appareil E/S interfacé est un appareil hérité, pas un appareil sans fil natif, et un adaptateur est donc exigé. La conversion de protocole est accomplie à la fois dans la passerelle et dans l'adaptateur. La passerelle et l'adaptateur convertissent chacun entre les protocoles hérités et les protocoles de transmission spécifiés par la présente norme.

NOTE 1 Il est souvent possible de mettre en œuvre un adaptateur à un seul appareil E/S câblé hérité en accomplissant une conversion de protocole vers et depuis des formats natifs, sans transporter un quelconque contenu de message étranger. À une passerelle, une telle combinaison d'un adaptateur et d'un appareil hérité connecté est indiscernable d'un appareil E/S natif. Aucune disposition de passerelle spéciale n'est adoptée pour de tels appareils. En plus, il n'y a aucune disposition de passerelle spéciale de faciliter le multiplexage d'un tel adaptateur à plusieurs appareils E/S câblés hérités.

Comme montré à la Figure 19, une passerelle hypothétique et un adaptateur hypothétique partagent une structure commune. Ils ont tous les deux une interface et une suite de protocoles pour un réseau étranger. Ils ont tous les deux une interface et une suite de protocoles telles que décrites dans la présente norme. Ils ont tous les deux des convertisseurs de protocoles. La structure commune s'étend même davantage – ils peuvent partager des objets communs et une structure commune d'interface de côté haut. Pour cette raison, aucun rôle séparé n'a été décrit pour un adaptateur.

NOTE 2 Les différences entre une passerelle et un adaptateur se rapportent surtout à la mise en œuvre. Par exemple, certains protocoles hérités éditent seulement à partir du terrain, ce qui requiert la prise en charge de la fonctionnalité de producteur, mais pas la fonctionnalité de consommateur, dans l'adaptateur. D'autres protocoles hérités prennent également en charge l'édition vers le terrain et, donc, exigent à la fois la fonctionnalité de producteur et celle de consommateur. Dans un autre exemple, des outils d'étude hérités transportés sur le terrain

et branchés au réseau hérité derrière l'adaptateur ont parfois besoin d'utiliser les mêmes fonctions que s'ils étaient derrière la passerelle.

Pour qu'une passerelle et un adaptateur soient interopérables, ils exigent la conversion de protocole commun. Si l'adaptateur convertit vers et depuis un format natif, la passerelle peut faire la même chose. Si l'adaptateur tunnellise un protocole hérité, la passerelle peut tunnelliser le même protocole.

U.1.3 Scénarios de passerelles

Des scénarios communs de passerelle sont montrés à la Figure U.1. Cette figure ne tente pas de fournir une description exhaustive de toutes les variantes; elle est plutôt incluse pour montrer les limites de la présente norme.

Figure U.1 – Scénarios de passerelles

Telle que décrite à l'Article 5, une passerelle met en œuvre un rôle au sein du système. Une diversité de mises en œuvre physique est possible.

Certaines mises en œuvre d'appareil peuvent avoir une interface sans fil de Classe A et une pile de protocoles intégrés dans le même paquetage que la passerelle, fournissant l'accès direct au réseau sans fil. De façon indépendante, des mises en œuvre peuvent avoir des rôles de gestion de système et de sécurité qui coexistent avec le rôle de passerelle.

Les rôles de gestionnaire de système et de gestionnaire de sécurité peuvent ne pas être corésidents avec le rôle de passerelle. La passerelle n'interagit pas directement avec le gestionnaire de sécurité, mais indirectement par l'intermédiaire du gestionnaire de système. La fonctionnalité de passerelle exige un chemin de communication avec un gestionnaire de système pour fonctionner comme partie intégrante d'un système opérationnel.

Un appareil mettant en œuvre un rôle de passerelle peut utiliser des routeurs dorsaux pour communiquer avec des appareils de terrain sans fil conformes à la présente norme.

La communication de passerelle avec des appareils de terrain via des routeurs dorsaux est de fonctionnement transparent. Des extensions de NL existent dans d'autres parties de la présente norme pour prendre en charge cette transparence. Il est toutefois nécessaire de configurer ce routage au sein de la passerelle et des routeurs dorsaux. Les routeurs dorsaux peuvent être utilisés pour étendre la portée géographique des appareils connectés par une passerelle. Des routeurs dorsaux peuvent également être utilisés pour augmenter la largeur de bande ou pour ajouter des chemins redondants entre une passerelle et un maillage.

Plusieurs passerelles indépendantes peuvent exister sur un système. Cela est facilité par un adressage et des relations de communication indépendants entre appareils. Une utilisation pour les passerelles indépendantes consiste à prendre en charge plusieurs protocoles. Aucune disposition spéciale n'est prise dans la présente norme pour le fonctionnement interdépendant entre passerelles, comme pour la redondance ou le partage de charge.

U.1.4 Modèle de passerelle de base

Les passerelles peuvent suivre le modèle général montré à la Figure U.2.

Figure U.2 – Modèle de passerelle de base

Dans cet exemple, les passerelles et les adaptateurs hébergent des convertisseurs de protocoles étrangers qui reçoivent et émettent des messages d'interface étrangers (habituellement issus d'un système de commande, d'un système de gestion d'actifs, ou d'un système d'ingénierie) et utilisent des interfaces de passerelle pour interagir avec des appareils sans fil. Les interfaces de passerelle sont fournies par l'intermédiaire d'une interface de côté haut qui est atteinte en un GIAP. Les convertisseurs de protocoles locaux à un appareil utilisent ces interfaces par le GIAP.

La conversion de protocoles achemine les informations d'application pour la commande, la surveillance, la configuration, et la gestion. Les messages de protocole étrangers contiennent ces informations. La tunnellisation, la communication d'application de protocole étranger (FPAC), et des méthodes d'accès aux objets natifs sont fournies dans les objets décrits dans la présente norme pour prendre en charge la conversion de protocoles, telles que décrites en Annexe N. Chaque méthode nécessite des compromis spécifiques d'effort de conversion, d'efficacité énergétique et de performances. Les convertisseurs de protocoles pratiques sont susceptibles d'utiliser une combinaison de ces méthodes.

Les passerelles et les adaptateurs peuvent chacun avoir des processus d'application qui s'interfacent aux convertisseurs de protocoles par l'intermédiaire du GIAP. Chaque processus fournit les interfaces de côté haut en utilisant des objets d'application (OBJ). La communication entre objets utilise les méthodes de messagerie fournies par l'intermédiaire de la sous-couche d'application (ASL).

Les interfaces de GIAP sont utilisées pour la gestion de réseau, la tunnellisation de protocoles, le chargement et le téléchargement, les alertes, la gestion du temps, et l'accès aux objets natifs d'application et de gestion. Le GIAP est décrit en détail à l'Article U.2.

Pour les appareils d'automation câblés, un adaptateur accomplit une fonction symétrique et convertit des messages d'interface étrangers vers une interface côté haut d'adaptateur (aussi GIAP) par l'intermédiaire d'un convertisseur de protocole homologue de passerelle.

L'accès de passerelle à un appareil de terrain natif (à partir d'une passerelle) est activé par le même GIAP; cependant, les interactions d'objet utilisent la messagerie native exclusivement. Un processus d'application natif interagit avec le processus de passerelle ou d'adaptateur d'une manière qui dépend du type de l'objet.

Les passerelles, les adaptateurs et les appareils de terrain natifs peuvent être gérés par la même méthode symétrique. Le processus DMAP est le processus homologue dans ce cas. Cette gestion est spécifique à la présente norme et pas nécessairement aux protocoles étrangers. Ceux-ci peuvent fournir des méthodes complémentaires de gestion d'appareil et de bus de terrain câblé qui ne relèvent pas du domaine d'application de la présente norme.

Le modèle de base de passerelle inclut l'interfaçage au gestionnaire de système, qui permet au gestionnaire de système d'être accessible par l'intermédiaire de la passerelle.

Les routeurs dorsaux et les appareils de routage ne sont pas montrés à la Figure U.2, parce que la fonctionnalité de passerelle se produit au sein la couche d'application, pas au sein des couches de communication inférieures.

U.2 GIAP hypothétique

U.2.1 Résumé des interfaces et des primitives

La partie passerelle de la présente norme décrit un GIAP hypothétique qui peut servir d'interface de côté haut au-dessus d'une suite de protocoles de communication sans fil pour acheminer des informations sans fil et gérer le comportement sans fil. Ce GIAP hypothétique est générique et pourrait être utilisé comme une interface commune au-dessus de l'AL de la présente norme et au-dessus d'une autre fonctionnalité dans de semblables suites de protocoles de communication. L'Annexe P décrit une mise en œuvre potentielle des interfaces de GIAP pour la suite de protocoles sans fil de la présente norme, en utilisant les objets et interfaces d'AL définis. L'Annexe Q décrit une autre mise en œuvre d'interface de GIAP hypothétique pour une variante de suite de protocoles sans fil.

NOTE 1 Une intention première des interfaces de GIAP exemplaires est de permettre l'accès multimode où plusieurs interfaces sans fil sont disponibles à la passerelle. Dans les configurations où le chemin allant du gestionnaire de système au réseau d'installation est seulement par l'intermédiaire du rôle de passerelle, le GIAP prend en charge des informations de comptes-rendus cohérentes relatives à chaque interface sans fil sous-jacente pour promouvoir une coexistence améliorée. Des informations de gestion de système peuvent être incluses dans un rapport relatif aux performances de communication pour identifier des problèmes potentiels d'interférence, dans un rapport relatif à la topologie pour identifier les appareils contigus, et dans un rapport relatif aux informations de voies et de programmes pour identifier des conflits potentiels d'utilisation.

NOTE 2 Une autre intention du GIAP exemplaire est de fournir un modèle pour la configuration et l'accès de plusieurs réseaux sans fil sous-jacents. Cela réduit potentiellement l'effort pour les développeurs de passerelles s'ils ont plusieurs protocoles de bus de terrain à prendre en charge. Les interfaces de GIAP peuvent ou peuvent ne pas être applicables à des développeurs de passerelles spécialisées, tels que ceux qui servent un seul protocole étranger; les passerelles spécialisées peuvent préférer utiliser des interfaces internes personnalisées.

Cette interface de GIAP hypothétique est utilisable par une diversité de convertisseurs de protocoles pour s'interfacer à des suites de protocoles de communication sans fil pour acheminer des informations sans fil et gérer le comportement sans fil. Un convertisseur de protocole existe dans une passerelle. En fonction de la mise en œuvre, un convertisseur de protocoles et un GIAP peuvent également exister dans un adaptateur. Les convertisseurs de protocoles auront une complexité variable en fonction du protocole qui existe au-dessus de la passerelle et en dessous des adaptateurs. Certains protocoles utiliseront un sous-ensemble

de ces interfaces de GIAP hypothétiques. Par exemple, un protocole peut seulement exiger l'interaction C/S et ne pas exiger des interfaces P/S. Fonctionellement, un adaptateur est considéré comme étant un sous-ensemble d'une passerelle et serait seulement censé prendre en charge un sous-ensemble de ces interfaces de GIAP hypothétiques relatives à l'acheminent d'informations sans fil.

NOTE 3 Ce débat relatif aux passerelles ne décrit pas la conversion de protocoles pour des protocoles de fieldbus spécifiques.

Les interfaces de GIAP sont résumées dans le Tableau 1.

Tableau 1 – Résumé des exemples d'interfaces de côté haut de passerelles hypothétiques

Exemple d'interface	Sous-type d'interface	Primitive	Description
Session	-	G_Session request G_Session confirm	Un convertisseur de protocoles étrangers au sein de la passerelle peut établir des sessions pour le compte de clients distants
En leasing	-	G_Lease request G_Lease confirm	Les locations permettent à la passerelle de gérer en interne ses ressources de communication internes sur une base par session
Device_List_Report	-	G_Device_List_Report request G_Device_List_Report confirm	Détermine les appareils associés au rôle de passerelle
Topology_Report	-	G_Topology_Report request G_Topology_Report confirm	Fournit un rapport de topologie relatif aux appareils dans un maillage sans fil. Cette interface peut être utile si, par exemple, le rôle de la passerelle fonctionne dans un système dans lequel l'interface de gestion du système vers le réseau de l'usine se fait via le rôle de la passerelle
Schedule_Report	-	G_Schedule_Report request G_Schedule_Report confirm	Fournit des allocations détaillées d'intervalles de temps et de voies sur une base par appareil. Cette interface peut être utile si, par exemple, le rôle de la passerelle fonctionne dans un système dans lequel l'interface de gestion du système vers le réseau de l'usine se fait via le rôle de la passerelle
Device_Health_Report	-	G_Device_Health_Report request G_Device_Health_Report confirm	Le rapport de santé d'appareil pour des appareils associés à la passerelle. Cette interface peut être utile si, par exemple, le rôle de la passerelle fonctionne dans un système dans lequel l'interface de gestion du système vers le réseau de l'usine se fait via le rôle de la passerelle

Exemple d'interface	Sous-type d'interface	Primitive	Description
Neighbor_Health_Report	-	G_Neighbor_Health_Report request	Le rapport de santé de communication pour l'ensemble d'appareils voisins associés à un appareil spécifique qui est associé à la passerelle. Cette interface peut être utile si, par exemple, le rôle de la passerelle fonctionne dans un système dans lequel l'interface de gestion du système vers le réseau de l'usine se fait via le rôle de la passerelle
		G_Neighbor_Health_Report confirm	
Network_Health_Report	-	G_Network_Health_Report request	Résumé de rapport de santé de communication pour le réseau sans fil. Cette interface peut être utile si, par exemple, le rôle de la passerelle fonctionne dans un système dans lequel l'interface de gestion du système vers le réseau de l'usine se fait via le rôle de la passerelle
		G_Network_Health_Report confirm	
Durée	-	G_Time request	Récupération et réglage du temps pour le réseau sans fil associé à la passerelle
		G_Time confirm	
Client/server	-	G_Client_Server request	Fournit la communications client/serveur
		G_Client_Server indication	
		G_Client_Server response	
		G_Client_Server confirm	
Publish/Subscribe (éditer/s'abonner)	Publish	G_Publish request	Fournit la communication éditeur/abonné
		G_Publish indication	
		G_Publish confirm	
	S'abonner	G_Subscribe request	
		G_Subscribe confirm	
	Publish_Timer	G_Publish_Timer indication	
	Subscribe_Timer	G_Subscribe_Timer indication	
	Watchdog_Timer	G_Watchdog_Timer indication	
Bulk_Transfer [a]	Ouvert	G_Bulk_Open request	Autorise le téléchargement montant et le téléchargement descendant d'éléments volumineux tels que des images de firmware et des tampons d'échantillons
		G_Bulk_Open confirm	
	Transfert	G_Bulk_Transfer request	
		G_Bulk_Transfer confirm	
	Close	G_Bulk_Close request	
		G_Bulk_Close confirm	

Exemple d'interface	Sous-type d'interface	Primitive	Description
Alerte	S'abonner	G_Alert_Subscription request	Autorise l'abonnement et la réception d'alertes spécifiques
		G_Alert_Subscription confirm	
	Notify (notifier)	G_Alert_Notification indication	
Gateway_Configuration	Read	G_Read_Gateway_Configuration request	Fournit l'accès en lecture et écriture à des attributs de configuration de la passerelle
		G_Read_Gateway_Configuration confirm	
	Write	G_Write_Gateway_Configuration request	
		G_Write_Gateway_Configuration confirm	
Device_Configuration	Read	G_Read_Device_Configuration request	Autorise la passerelle à déterminer quels appareils lui sont associés
		G_Read_Device_Configuration confirm	
	Write	G_Write_Device_Configuration request	
		G_Write_Device_Configuration confirm	
a Les primitives d'interface sont communes aux opérations de téléchargement montant et descendant.			

U.2.2 Séquence de primitives

La Figure U.3, la Figure U.4, la Figure U.5, la Figure U.6, la Figure U.7, la Figure U.8, la Figure U.9, la Figure U.10, la Figure U.11, la Figure U.12, la Figure U.13, la Figure U.14 et la Figure U.15 montrent les séquences de primitives pour les interfaces de côté haut de passerelles. Les figures sont décrites en termes de client interne à une passerelle, d'entité de passerelle, de client d'appareil, et d'entité d'appareil. Un client interne à une passerelle est un utilisateur des interfaces de GIAP au sein d'une passerelle. Une entité de passerelle est un fournisseur d'interfaces de GIAP au sein de la passerelle. La fourniture d'interfaces nécessite des interactions complémentaires à travers le réseau sans fil à un ou plusieurs appareils. Un client d'appareil est un utilisateur d'interfaces de GIAP au sein d'un appareil. Une entité d'appareil est un fournisseur d'interfaces de GIAP au sein de l'appareil.

U.2.3 Description détaillée des paramètres

U.2.3.1 Généralités

Les paramètres qui sont communs à plusieurs interfaces sont décrits en U.2.3. Les paramètres qui sont uniques à une interface sont décrits au sein de l'interface en question.

NOTE Sachant que la présente norme ne définit aucune passerelle, et parce que le GIAP débattu est hypothétique, tous ces paramètres sont également strictement hypothétiques, tout comme le sont tous les énoncés à leur sujet.

U.2.3.2 Paramètre GS_Session_ID

Le paramètre GS_Session_ID identifie de façon univoque une session spécifique.

Un identificateur de session valide qui n'a pas expiré est fourni afin d'invoquer toutes les interfaces, à l'exception des interfaces de session.

U.2.3.3 Paramètre GS_Transaction_ID

Le paramètre GS_Transaction_ID identifie de façon univoque les parties demande et réponse d'une transaction au sein du contexte d'une session spécifique.

L'identificateur de transaction est utilisé pour apparier une demande d'interface de GIAP avec la réponse d'interface de GIAP correspondante.

U.2.3.4 Paramètre GS_Lease_ID

GS_Lease_ID identifie les ressources d'entité de passerelle et les ressources de communication qui sont allouées à une session particulière.

L'identificateur de location est fourni par l'utilisateur d'interface de GIAP lorsqu'une interface est invoquée pour identifier les ressources de communication particulières utilisées pour prendre en charge l'interface.

U.2.3.5 Paramètre GS_Status

GS_Status est retourné par une primitive "confirm". Il peut représenter soit le statut résultant du traitement d'une demande locale, soit le statut correspondant à une réponse reçue en provenance d'une entité distante.

Le statut indique le succès ou l'échec de l'appel d'interface et, le cas échéant, la raison de l'échec.

U.2.3.6 Paramètre GS_Network_Address

GS_Network_Address est une adresse IPv6 utilisée pour identifier un appareil logique qui est unique à travers tous les réseaux.

Ce paramètre identifie de façon univoque une NLE spécifique.

U.2.3.7 Paramètre GS_Unique_Device_ID

GS_Unique_Device_ID est une adresse EUI64.

Ce paramètre identifie de façon univoque un appareil physique spécifique pour des besoins de gestion d'actifs.

U.2.3.8 Paramètre GS_Network_ID

GS_Network_ID est un identificateur unique pour un de plusieurs réseaux qui peuvent être accessibles par l'intermédiaire d'une seule passerelle.

Ce paramètre identifie de façon univoque un réseau spécifique.

U.2.3.9 Paramètre GS_Time

GS_Time est champ de temps TAI de 48 bits.

Le paramètre de temps est utilisé pour décrire les champs relatifs au temps tels qu'un marqueur temporel, un temps de démarrage et un temps d'arrêt.

U.2.3.10 Paramètre GS_Transfer_Mode

GS_Transfer_Mode identifie des variantes de transfert au niveau d'une GPDU.

GS_Transfer_Mode est fourni avec chaque GPDU fournie pour le transfert afin d'indiquer la qualité de service désirée et la priorité associée au transfert des PDU générées pour prendre en charge la primitive d'interface hypothétique.

U.2.4 Description détaillée des interfaces

U.2.4.1 Interface de gestion de session

U.2.4.1.1 Généralités

Une entité de passerelle est un processus au sein d'une passerelle qui fournit des interfaces de passerelle par le GIAP. Un client interne à une passerelle est un utilisateur d'interfaces fournies par une entité de passerelle. Les clients types internes à une passerelle incluent des systèmes hôtes, des systèmes de gestion d'actifs, et des outils d'ingénierie.

Les entités de passerelle fournissent des interfaces aux clients internes à une passerelle au sein du contexte d'une session. L'interface de gestion de session est utilisée pour établir et gérer ces sessions. Toutes les autres interfaces fournies par une entité de passerelle sont utilisées dans le contexte d'une session établie.

Un convertisseur de protocoles étrangers au sein de la passerelle peut établir des sessions pour le compte de clients distants et accomplir une conversion de protocoles sur les flux de communication qui correspondent à des interfaces fournies par une entité de passerelle.

Le but premier d'une session est d'autoriser une allocation de ressources et la récupération en masse des ressources de passerelle et de communication sur une base par client d'entité de passerelle.

Une session peut être établie par un processus local ou à distance (comme par une session distante TCP/IP).

Une ou plusieurs sessions peuvent exister simultanément entre une entité de passerelle et un ou plusieurs clients internes à une passerelle. Chaque session est identifiée de façon univoque.

NOTE Le nombre de sessions simultanées prises en charge est dépendant d'une mise en œuvre. Il est possible que certaines réalisations fournissent à une passerelle de fonction fixe une seule session, alors que d'autres mises en œuvre fournissent un certain nombre de sessions qui sont allouées à la demande à une diversité d'applications, y compris des systèmes hôtes, des historiens, des outils de gestion d'actifs et des outils d'ingénierie.

Le client interne à une passerelle utilise la primitive G_Session pour créer, renouveler ou supprimer une session.

U.2.4.1.2 Primitive G_Session

U.2.4.1.2.1 Primitives et leurs paramètres

Le Tableau U.2 décrit l'utilisation des paramètres pour la primitive G_Session.

Tableau U.2 – Utilisation des paramètres de la primitive G_Session

Nom du paramètre	G_Session	
	Demande	Confirmation
GS_Session_ID	M	M
GS_Session_Period	M	M
GS_Network_ID	M	-
GS_Status	-	M

U.2.4.1.2.2 Utilisation de demande de G_Session

Le client interne à une passerelle utilise la primitive de demande de G_Session pour créer, renouveler ou supprimer une session.

Une session est créée en fournissant un identificateur de session null (GS_Session_ID = 0) et une durée de session demandée. La présentation de GS_Session_Period > 0 demande une session de durée limitée, spécifiée en secondes. La présentation de GS_Session_Period = -1 demande une durée de session indéfinie.

Une session de durée limitée est renouvelée en fournissant un identificateur de session existant (autre que null) et une durée de session supérieure à 0 s. Une session de durée indéfinie n'a pas besoin d'être renouvelée.

Changer une session de durée limitée en une session de durée indéfinie en tentant de la renouveler avec une durée spécifiée de -1 n'est pas autorisé.

NOTE La limite supérieure de la durée de session est dépendante de la mise en œuvre. Par exemple, des mises en œuvre sont capables de dédier des ressources à des applications spécifiques, telles qu'un système hôte, ne libérant jamais les ressources en question.

Une session est supprimée en fournissant un identificateur de session existant (autre que null) et une durée de session de 0 s.

Une passerelle peut se connecter à plusieurs réseaux. Chaque session est associée à un réseau spécifique. Un identificateur de réseau (GS_Network_ID) est spécifié pour établir un réseau particulier pour la session. La portée d'identificateurs supplémentaires utilisés au sein d'une session est limitée au réseau particulier.

U.2.4.1.2.3 Utilisation de confirmation de G_Session

L'entité de passerelle utilise la primitive de confirmation de G_Session pour parachever la demande de G_Session au client interne à une passerelle.

Pour une demande réussie de création de session, l'entité de passerelle retourne un identificateur de session unique et non null. Cet identificateur est utilisé dans les opérations ultérieures de renouvellement et de suppression de session. GS_Session_Period est retourné avec la réelle durée de session allouée par l'entité de passerelle.

La valeur de GS_Session_Period retournée peut ne pas être la même que la valeur demandée.

Pour une demande de renouvellement de session, l'identificateur de session de demande est repris en écho et une nouvelle durée de session est retournée.

Pour une demande de suppression de session, l'identificateur de session est repris en écho, et la durée de session est mise à 0 s.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.3.

Tableau U.3 – GS_Status pour confirmation de G_Session

Valeur	Colonne
0	Réussite; nouvelle session créée, renouvelée ou supprimée
1	Réussite; nouvelle session créée ou renouvelée avec période réduite
2	Echec; la session n'existe pas pour renouvellement ou suppression
3	Echec; la session ne peut pas être créée (aucune session supplémentaire disponible) Cela peut se produire si, par exemple, des sessions ont expiré mais n'ont pas été explicitement supprimées
4	Echec; autre

U.2.4.2 Interface de gestion de locations

U.2.4.2.1 Généralités

Les entités de passerelle allouent des ressources de communication aux clients internes à une passerelle par l'intermédiaire de locations. L'interface de gestion de locations est utilisée pour établir et gérer des locations.

Le but premier d'une location est de permettre l'allocation et la récupération à grain fin de ressources de communication sur une base par session.

Des ressources peuvent être allouées séparément selon les besoins de communication. Par exemple, les ressources C/S, P/S, de transfert en masse et d'abonnement d'alertes peuvent être allouées séparément.

Une ou plusieurs locations peuvent exister simultanément entre une entité de passerelle et un ou plusieurs clients internes à une passerelle. Chaque location est identifiée de façon univoque au sein d'une session.

U.2.4.2.2 Utilisation de l'interface

Le client interne à une passerelle utilise la primitive G_Lease pour créer, renouveler ou supprimer une location.

U.2.4.2.3 Primitive G_Lease

U.2.4.2.3.1 Primitives et leurs paramètres

Le Tableau U.4 décrit l'utilisation des paramètres pour la primitive G_Lease.

Tableau U.4 – Utilisation des paramètres de la primitive G_Lease

Nom du paramètre	G_Lease	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Lease_ID	M	M
GS_Lease_Period	M	M

GS_Status	-	M

U.2.4.2.3.2 Utilisation de demande de G_Lease

Le client interne à une passerelle utilise la primitive de demande de G_Lease pour créer, renouveler ou supprimer une location.

Un identificateur de session (GS_Session_ID) est inclus dans les primitives de demande de G_Lease.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

Une location est créée en fournissant un identificateur de location null (GS_Lease _ID = 0) et une durée de location demandée. La présentation de GS_Lease_Period > 0 demande une location de durée limitée, spécifiée en secondes. La présentation de GS_Lease_Period = 0 demande une durée de location indéfinie.

Une location de durée limitée est renouvelée en fournissant un identificateur de location existant (autre que null) et une durée de location supérieure à 0 s. Une location de durée indéfinie n'a pas besoin d'être renouvelée. Une location de durée limitée ne peut pas être changée en une location de durée indéfinie par renouvellement avec une durée de 0 s.

La valeur prise en charge maximale est dépendante d'une mise en œuvre. Des mises en œuvre sont autorisées à choisir de dédier des ressources à des applications spécifiques, telles qu'un système hôte, ne libérant jamais les ressources en question.

Une location est supprimée en fournissant un identificateur de location existant et une durée de location demandée de 0 s.

Les différents types de locations sont disponibles, tels que spécifiés par GS_Lease_Type et montrés dans le Tableau U.5. Chaque type de location alloue des ressources d'entité de passerelle spécifiques à une location et des ressources de communication pour le compte du client interne à une passerelle.

Tableau U.5 – GS_Lease_Type pour demande de G_Lease

Valeur	Colonne
0	Client
1	Serveur
2	Editeur
3	Abonné
4	Client de transfert en masse
5	Serveur de transfert en masse
6	Abonnement d'alerte

GS_Protocol_Type identifie le protocole qui est associé à la location, tel que spécifié dans l'Annexe M. La spécification du type de protocole permet le traitement spécial pour des protocoles particuliers au sein de l'entité de passerelle.

Toutes les locations se rapportent à l'établissement des interfaces de communication entre l'entité de passerelle et un ou plusieurs appareils spécifiés par un ou plusieurs éléments dans GS_Network_Address_List. Les locations d'abonnement d'alertes n'allouent pas de ressources de communication au cours de l'établissement de location, mais le font dynamiquement à mesure que les abonnements alertes sont modifiés. GS_Network_Address_List n'est pas utilisé avec le type de location d'abonnement d'alertes.

Client, serveur, abonné, client de transfert en masse et serveur de transfert en masse décrivent seulement un seul élément au sein de GS_Network_Address_List. Le type de location d'éditeur peut décrire plusieurs éléments.

La spécification de plusieurs adresses IPv6 au sein de GS_Network_Address_List représente un groupe de multidiffusion. Les éléments au sein de G_Network_Address_List incluent GS_Network_Address.

GS_Lease_Parameters est une structure de paramètres avec la spécification des paramètres nécessaires pour l'établissement de certains types de location. L'utilisation de GS_Lease_Parameters est conditionnée au type de location spécifique comme suit.

NOTE L'Annexe P fournit des informations complémentaires relatives à l'utilisation détaillée de GS_Lease_Parameters.

Les locations client, serveur, éditeur, et abonné décrivent un GS_Resource unique. Cette valeur identifie des points d'extrémité de connexion client et serveur concordants et elle identifie également des points d'extrémité éditeur et abonné concordants. GS_Resource est également spécifié par le client de transfert en masse pour identifier l'élément de téléchargement montant/téléchargement descendant.

Les locations éditeur exigent une spécification de GS_Update_Policy, de GS_Period, de GS_Phase et de GS_Stale_Limit pour commander la temporisation et le comportement tamponné. GS_Transfer_Mode est également spécifié afin d'établir la qualité de transfert par défaut de l'interface et la priorité.

Les locations abonnées exigent une spécification de GS_Update_Policy, de GS_Period, de GS_Phase et de GS_Stale_Limit pour commander la temporisation et le comportement tamponné.

Un éditeur et un abonné peuvent accepter de décrire GS_Connection_Info dans la location abonnée pour la mise à disposition sur chaque réception de publication.

Les locations client et serveur décrivent GS_Transfer_Mode afin d'établir la qualité de transfert par défaut de l'interface et la priorité.

Une utilisation complémentaire du champ GS_Wireless_Parameters dépend de la construction de la passerelle. Cela permet l'accès à toutes les caractéristiques de communication qui sont exposées et peuvent être demandées.

U.2.4.2.3.3 Utilisation de confirmation de G_Lease

L'entité de passerelle utilise la primitive G_Lease pour parachever la demande de G_Lease au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Pour une demande réussie de création de session, l'entité de passerelle retourne un identificateur de location unique de session. Cet identificateur de liaison est utilisé dans les opérations ultérieures de renouvellement et de suppression de location. GS_Lease_Period est retourné avec la réelle durée de location allouée par l'entité de passerelle.

Pour une demande de renouvellement de location, l'identificateur de location de demande est repris en écho et la durée de location réelle est donnée.

Pour une demande de suppression de location, l'identificateur de location est repris en écho, et la durée de location est mise à 0 s.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.6.

Tableau U.6 – GS_Status pour confirmation de G_Lease

Valeur	Colonne
0	Réussite; nouvelle location créée, renouvelée ou supprimée
1	Réussite; nouvelle location créée ou renouvelée avec période réduite
2	Echec; la location n'existe pas pour renouvellement ou suppression
3	Echec; aucune location supplémentaire disponible
4	Echec; aucun appareil n'existe à l'adresse IPv6
5	Echec; type de location non valide
6	Echec; information de type de location non valide
7	Echec; autre

U.2.4.3 Interface de rapports de liste d'appareils

U.2.4.3.1 Généralités

L'interface de rapports de liste d'appareils fournit un rapport relatif aux appareils qui sont associés à une passerelle. Cela est utile pour établir un mapping d'appareils sans fil à des systèmes hôtes et à des navigateurs de réseau.

Le client interne à une passerelle utilise la primitive G_Device_List_Report pour récupérer un rapport relatif aux appareils associés à une entité de passerelle.

U.2.4.3.2 Primitive G_Device_List_Report

U.2.4.3.2.1 Primitives et leurs paramètres

Le Tableau U.7 décrit l'utilisation des paramètres pour la primitive G_Device_List_Report.

Tableau U.7 – Utilisation des paramètres de la primitive G_Device_List_Report

Nom du paramètre	G_Device_List_Report	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Device_List	-	M
GS_Network_Address	-	M
GS_Device_Type	-	M
GS_Unique_Device_ID	-	M
GS_Manufacturer	-	M
GS_Model	-	M
GS_Revision	-	M
GS_Status	-	M

Le client interne à une passerelle utilise la primitive de demande de G_Device_List_Report pour récupérer un rapport relatif aux appareils associés à une entité de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

U.2.4.3.2.2 Utilisation de confirmation de G_Device_List_Report

L'entité de passerelle utilise la primitive de confirmation de G_Device_List_Report pour parachever la demande de G_Device_List_Report au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Une liste d'appareils associés à l'entité de passerelle (GS_Device_List) est retournée. Pour chaque appareil, la liste inclut l'adresse IPv6 (GS_Network_Address), le type de l'appareil (GS_Device_Type), et l'identificateur d'appareil unique (GS_Unique_Device_ID).

La liste inclut également des informations complémentaires relatives à un fabricant (GS_Manufacturer, GS_Model, et GS_Revision).

Lorsque la passerelle inclut le rôle d'appareil de configuration, l'adresse IPv6 peut être une adresse de défaut. L'identificateur unique et les informations fabricant sont utilisés au sein des applications de niveau hôte pour commander la mise en service de l'appareil par l'intermédiaire de l'interface de configuration d'appareil.

Par exemple, un navigateur peut afficher une liste d'appareils disponibles pour être configurés accompagnée d'informations d'identification. Des appareils d'un ensemble sélectionné sont pris dans l'affichage et sont mis en service avec l'adresse IPv6 et d'autres informations pour rejoindre le système. L'affichage de navigation est alors rafraîchi avec des appareils qui sont disponibles pour la liaison à une stratégie de commande.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

Tableau U.8 – GS_Status pour confirmation de G_Device_List_Report

Valeur	Colonne
0	Succès
1	Echec

U.2.4.4 Interface de rapport de topologie

U.2.4.4.1 Généralités

Dans les configurations de système où l'accès à l'information de gestion de système s'effectue par l'intermédiaire de la passerelle, l'interface de rapport de topologie fournit un rapport de topologie qui relie des appareils au sein d'un maillage sans fil.

Le client interne à une passerelle utilise la primitive G_Topology_Report pour récupérer un rapport relatif aux appareils associés à une entité de passerelle.

U.2.4.4.2 Primitive G_Topology_Report

U.2.4.4.2.1 Primitives et leurs paramètres

Le Tableau U.9 décrit l'utilisation des paramètres pour la primitive G_Topology_Report.

Tableau U.9 – Utilisation des paramètres de la primitive G_Topology_Report

Nom du paramètre	G_Topology_Report	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Device_List	-	M
GS_Network_Address	-	M
GS_Neighbor_List	-	M
GS_Network_Address	-	M
GS_Graph_List	-	M
GS_Graph_ID	-	M
GS_Network_Address	-	M
GS_Status	-	M

U.2.4.4.2.2 Utilisation de demande de G_Topology_Report

Le client interne à une passerelle utilise la primitive de demande de G_Topology_Report pour récupérer un rapport relatif à la topologie des appareils associés à une entité de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

U.2.4.4.2.3 Utilisation de confirmation de G_Topology_Report

L'entité de passerelle utilise la primitive de confirmation de G_Topology_Report pour parachever la demande de G_Topology_Report au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement d'une primitive de confirmation avec la primitive de demande d'origine.

Une liste d'appareils associés à l'entité de passerelle (GS_Device_List) est retournée. La liste inclut l'adresse IPv6 (GS_Network_Address) pour chaque appareil.

En outre, il est inclus dans la liste une deuxième liste (GS_Neighbor_List) des appareils voisins associés à chaque appareil. La liste inclut l'adresse IPv6 (GS_Network_Address) de tous les voisins (tels que décrits dans le rapport de santé de voisins).

En outre, il est inclus dans la liste une troisième liste (GS_Graph_List) des connexions de graphe associées à chaque appareil. Pour chaque connexion de graphe, la liste inclut le graphe identifié (GS_Graph_ID) et une liste d'adresses IPv6 associée (GS_Network_Address) des voisins sur le graphe.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

U.2.4.5 Interface de rapport de programme

U.2.4.5.1 Généralités

Dans les configurations de système où l'accès à l'information de gestion de système s'effectue par l'intermédiaire de la passerelle, l'interface de rapport de programme fournit un rapport de programme détaillant les allocations d'intervalles de temps et de voies sur une base par appareil.

Le client interne à une passerelle utilise la primitive de demande de G_Schedule_Report pour récupérer un rapport relatif au programme des appareils associés à une entité de passerelle.

U.2.4.5.2 Primitive G_Schedule_Report

U.2.4.5.2.1 Primitives et leurs paramètres

Le Tableau U.10 décrit l'utilisation des paramètres pour la primitive G_Schedule_Report.

Tableau U.10 – Utilisation des paramètres de la primitive G_Schedule_Report

Nom du paramètre	G_Schedule_Report	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Network_Address	M	-
GS_Channel_List	-	M
GS_Channel_Number	-	M
GS_Channel_Status	-	M
GS_Device_Schedule	-	M
GS_Network_Address	-	M
GS_Superframe_List	-	C
GS_Superframe_ID	-	C
GS_Num_Time_Slots	-	C
GS_Start_Time	-	C
GS_Link_List	-	C
GS_Network_Address	-	C
GS_Slot_Size	-	C
GS_Channel	-	C
GS_Direction	-	C
GS_Link_Type	-	C
GS_Status	-	M

U.2.4.5.2.2 Utilisation de demande de G_Schedule_Report

Le client interne à une passerelle utilise la primitive de demande de G_Schedule_List_Report pour récupérer un rapport de programme pour un appareil spécifique associé à une entité de passerelle. L'appareil particulier est identifié par son adresse IPv6 (GS_Network_Address).

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

U.2.4.5.2.3 Utilisation de confirmation de G_Schedule_Report

L'entité de passerelle utilise la primitive de confirmation de G_Schedule_Report pour parachever la demande de G_Schedule_Report au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Une liste de voies est retournée. Chaque élément de la liste inclut le numéro de voie (GS_Channel_Number) et le statut de la voie (GS_Channel_Status). Le statut de la voie est mis à 0 pour indiquer une voie désactivée ou à 1 pour indiquer une voie activée.

Un programme d'appareil (GS_Device_Schedule) est également retourné. Le programme inclut les informations d'identification d'appareil (GS_Network_Address) et une liste de supertrames (GS_Superframe_List) qui sont utilisées par l'appareil pour la communication.

Si un appareil n'utilise pas des supertrames, GS_Superframe_List n'est pas retourné.

La liste des supertrames inclut les informations générales relatives aux supertrames, y compris un identificateur de supertrame (GS_Superframe_ID), le nombre d'intervalles de temps dans la supertrame (GS_Num_Time_Slots), et le temps de début de la supertrame (GS_Start_Time). Seules les supertrames actives sont rapportées.

GS_Start_Time est un décalage par rapport au début du temps TAI. Ce nombre a une signification seulement par rapport au temps de réseau courant, à moins que la communication ne soit synchronisée à une source extérieure. GS_Start_Time est mis à -1 pour indiquer que la supertrame n'a aucune synchronisation connue.

La liste de supertrames inclut également une liste ordonnée (GS_Link_List) avec un élément par intervalle de temps dans la supertrame. Les éléments de liste de liaisons sont utilisés pour décrire des relations de communication relatives à la supertrame. Chaque élément de liste de liaison décrit la durée d'intervalle de temps en microsecondes (GS_Slot_Size) et la voie (GS_Channel) pour la communication au sein de la supertrame. Le paramètre de liaison (GS_Direction) décrit le sens des communications. Une valeur de 0 décrit la réception, et une valeur de 1 décrit l'émission. L'adresse IPv6 (GS_Network_Address) décrit l'adresse IPv6 logique d'un partenaire de communication pour l'intervalle de temps.

Le type de liaison (GS_Link_Type) décrit le but de la communication:

- Une valeur de 0 décrit la communication de données apériodiques.
- Une valeur de 1 décrit la communication de gestion apériodique.
- Une valeur de 2 décrit la communication de données périodiques.
- Une valeur de 3 décrit la communication de gestion périodique.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

U.2.4.6 Interface de rapports de santé d'appareils

U.2.4.6.1 Généralités

L'interface de rapports de santé d'appareil fournit un rapport de santé de communication pour la vue de sa propre santé pour chaque appareil.

Le client interne à une passerelle utilise la primitive G_Device_Health_Report pour récupérer un rapport de santé d'appareil pour un ensemble spécifié d'appareils qui sont associés à une entité de passerelle.

U.2.4.6.2 Primitive G_Device_Health_Report

U.2.4.6.2.1 Primitives et leurs paramètres

Le Tableau U.11 décrit l'utilisation des paramètres pour la primitive G_Device_Health_Report.

Tableau U.11 – Utilisation des paramètres de la primitive G_Device_Health_Report

Nom du paramètre	G_Device_Health_Report	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Device_List	M	M
GS_Network_Address	M	M(=)
GS_DPDUs_Transmitted	-	M
GS_DPDUs_Received	-	M
GS_DPDUs_Failed_Transmission	-	M
GS_DPDUs_Failed_Reception	-	M
GS_Status	-	M

U.2.4.6.2.2 Utilisation de demande de G_Device_Health_Report

Le client interne à une passerelle utilise la primitive de demande de G_Device_Health_Report pour récupérer un rapport de santé d'appareil pour un ensemble spécifié d'appareils qui sont associés à une entité de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

Un rapport de santé est demandé pour une liste spécifique d'appareils (GS_Device_List). L'adresse IPv6 de chaque appareil (GS_Network_Address) est exigée.

U.2.4.6.2.3 Utilisation de confirmation de G_Device_Health_Report

L'entité de passerelle utilise la primitive de confirmation de G_Device_Health_Report pour parachever la demande de G_Device_Health_Report au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Une liste d'appareils (GS_Device_List) est retournée. Elle inclut des informations d'identification d'appareil (GS_Network_Address) et des informations de santé de communication. Les informations de santé de communication incluent le nombre total des DPDU émises (GS_DPDUs_Transmitted) de l'appareil vers tous les voisins, le nombre total des DPDU reçues (GS_DPDUs_Received) de l'appareil par tous les voisins, le nombre total des DPDU vers tous les voisins qui ont échoué à l'émission (GS_DPDUs_Failed_Transmission), ainsi que le nombre total des DPDU provenant de tous les voisins qui ont échoué à la réception (GS_DPDUs_Failed_Reception). Les réceptions échouées incluent les DPDU identifiables qui sont rejetées en raison d'une corruption relative à l'émission.

NOTE Les réceptions échouées seront vraisemblablement moins nombreuses que les émissions échouées, car de nombreuses DPDU échouées n'auront pas assez d'informations non corrompues pour déterminer l'adressage. La réception échouée n'inclut pas des erreurs relatives aux protocoles.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

U.2.4.7 Interface de rapports de santé des voisins

U.2.4.7.1 Généralités

Dans des configurations de système où l'accès à l'information de gestion de système s'effectue par l'intermédiaire de la passerelle, l'interface de rapports de santé des voisins fournit un rapport de santé de communication pour la vue de chaque appareil de ses voisins.

Un appareil voisin est un partenaire de communication sans fil de niveau liaison qui est configuré pour l'échange direct de DPDU (émission RF sans sauts). Les interfaces de rapport de santé de voisins fournissent des informations relatives à ces voisins physiques. Les appareils voisins sont capables de recueillir les statistiques d'échange de DPDU qui indiquent des états RF locales.

Le client interne à une passerelle utilise la primitive G_Neighbor_Health_Report pour récupérer un rapport de santé de communication pour l'ensemble d'appareils voisins qui sont associés à un appareil spécifique qui est associé à une entité de passerelle.

U.2.4.7.2 Primitive G_Neighbor_Health_Report

U.2.4.7.2.1 Primitives et leurs paramètres

Le Tableau U.12 décrit l'utilisation des paramètres pour la primitive G_Neighbor_Health_Report.

Tableau U.12 – Utilisation des paramètres de la primitive G_Neighbor_Health_Report

Nom du paramètre	G_Neighbor_Health_Report	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Network_Address	M	-
GS_Neighbor_Health_List	-	M
GS_Network_Address	-	M
GS_Link_Status	-	M
GS_DPDUs_Transmitted	-	M
GS_DPDUs_Received	-	M
GS_DPDUs_Failed_Transmission	-	M
GS_DPDUs_Failed_Reception	-	M
GS_Signal_Strength	-	M
GS_Signal_Quality	-	M
GS_Status	-	M

U.2.4.7.2.2 Utilisation de demande de G_Neighbor_Health_Report

Le client interne à une passerelle utilise la primitive de demande de G_Neighbor_Health_Report pour récupérer un rapport de santé de communication pour l'ensemble d'appareils voisins qui sont associés à un appareil spécifique qui est associé à une entité de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

Un rapport de santé de voisins est demandé pour un appareil en une adresse IPv6 spécifique (GS_Network_Address).

U.2.4.7.2.3 Utilisation de confirmation de G_Neighbor_Health_Report

L'entité de passerelle utilise la primitive de confirmation de G_Neighbor_Health_Report pour parachever la demande de G_Neighbor_Health_Report au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Une liste de santé de voisins (GS_Neighbor_Health_List) est retournée. La liste inclut des informations d'identification d'appareil voisin (GS_Network_Address) et des informations de santé de communication. Les informations de santé de communication incluent un statut général (GS_Link_Status). GS_Link_Status = 1 indique que le voisin est disponible pour la communication. GS_Link_Status = 0 indique que le voisin est indisponible pour la communication.

Les informations de santé incluent également le nombre des DPDU émises vers le voisin (GS_DPDUs_Transmitted), le nombre des DPDU reçues en provenance du voisin (GS_DPDUs_Received), le nombre de tentatives d'émission échouées (GS_DPDUs_Failed_Transmission), et le nombre de réceptions échouées (GS_DPDUs_Failed_Reception) provenant du voisin. Les réceptions échouées incluent les DPDU identifiables qui sont rejetées en raison d'une corruption relative à l'émission.

NOTE Les réceptions échouées seront vraisemblablement moins nombreuses que les émissions échouées, car de nombreuses DPDU échouées n'auront pas assez d'informations non corrompues pour déterminer l'adressage. La réception échouée n'inclut pas des erreurs relatives aux protocoles.

Les informations de santé incluent également GS_Signal_Strength et GS_Signal_Quality. Ces paramètres retournent des valeurs entre 0 (le plus mauvais signal) et 100 (le meilleur signal). GS_Signal_Strength indique le niveau moyen de puissance non corrélé des signaux reçus en provenance d'un voisin spécifique par rapport à la gamme du récepteur. GS_Signal_Quality indique le niveau moyen de puissance corrélé des signaux reçus en provenance d'un voisin spécifique par rapport à la gamme du récepteur.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

U.2.4.8 Interface de rapports de santé de réseau

U.2.4.8.1 Généralités

Dans des configurations de système où l'accès à l'information de gestion de système s'effectue par l'intermédiaire de la passerelle, l'interface de rapports de santé des voisins fournit un rapport de santé de communication pour la vue de chaque appareil de ses voisins.

Le client interne à une passerelle utilise la primitive G_Network_Health_Report pour récupérer un rapport de santé de communication sommaire pour un réseau tout entier.

U.2.4.8.2 Primitive G_Network_Health_Report

U.2.4.8.2.1 Primitives et leurs paramètres

Le Tableau U.13 décrit l'utilisation des paramètres pour la primitive G_Network_Health_Report.

Tableau U.13 – Utilisation des paramètres de la primitive G_Network_Health_Report

Nom du paramètre	G_Network_Health_Report	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Network_Health	-	M
GS_Network_ID	-	M
GS_Network_Type	-	M
GS_Device_Count	-	M
GS_Start_Date	-	M
GS_Current_Date	-	M
GS_DPDUs_Sent	-	M
GS_DPDUs_Lost	-	M
GS_GPDU_Latency	-	M
GS_GPDU_Path_Reliability	-	M
GS_GPDU_Data_Reliability	-	M
GS_Join_Count	-	M
GS_Device_Health_List	-	M
GS_Network_Address	-	M
GS_Start_Date	-	M
GS_Current_Date	-	M
GS_DPDUs_Sent	-	M
GS_DPDUs_Lost	-	M
GS_GPDU_Latency	-	M
GS_GPDU_Path_Reliability	-	M
GS_GPDU_Data_Reliability	-	M
GS_Join_Count	-	M
GS_Status	-	M

U.2.4.8.2.2 Utilisation de demande de G_Network_Health_Report

Le client interne à une passerelle utilise la primitive de demande de G_Network_Health_Report pour récupérer un rapport de santé de communication sommaire pour un réseau tout entier.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

U.2.4.8.2.3 Utilisation de confirmation de G_Network_Health_Report

L'entité de passerelle utilise la primitive de confirmation de G_Network_Health_Report pour parachever la demande de G_Network_Health_Report au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Un résumé de santé de réseau (GS_Network_Health) est retourné. Le sommaire inclut des informations d'identification de réseau (GS_Network_ID et GS_Network_Type) et des informations de résumé de santé de communication de réseau. Les informations de santé de communication incluent le nombre d'appareils dans le réseau (GS_Device_Count), la date de début et la date courante pour le réseau (GS_Start_Date et GS_Current_Date), les statistiques d'émission (GS_DPDUs_Sent, GS_DPDUs_Lost, et GS_GPDU_Latency), les statistiques de fiabilité (GS_GPDU_Path_Reliability et GS_GPDU_Data_Reliability), et les statistiques de rattachement (GS_Join_Count).

Un résumé de santé spécifique à un appareil (GS_Device_Health_List) est également retourné. La liste inclut des informations d'identification d'appareil (GS_Network_Address) et les statistiques de communication qui sont un sous-ensemble identique de celles contenues

dans le résumé de santé de réseau (GS_Start_Date, GS_Current_Date, GS_DPDUs_Sent, GS_DPDUs_Lost, GS_GPDU_Latency, GS_GPDU_Path_Reliability, GS_GPDU_Data_Reliability, et GS_Join_Count).

GS_Start_Date est un champ de temps TAI de 48 bits indiquant le moment où un appareil a commencé à fonctionner pour la première fois. Cela est utile pour le calcul des programmes de remplacement de batteries.

GS_Current_Date est un champ de temps TAI de 48 bits indiquant le temps courant tel que vu par l'appareil. Il s'agit du temps utilisé par l'appareil pour les besoins d'horodatage.

GS_GPDU_Latency est un nombre dans la plage 0..100 indiquant le pourcentage des GPDU programmées qui arrivent plus tard que prévu. Ces GPDU peuvent être retardées en raison de la livraison sur des chemins secondaires ou en raison de l'encombrement dans des appareils intermédiaires.

GS_GPDU_Path_Reliability est un nombre dans la plage 0..100 indiquant le pourcentage de succès de premier chemin pour l'émission de GPDU acquittée. Les GPDU qui sont émises sur un chemin secondaire peuvent arriver avec succès, mais elles peuvent réduire la fiabilité du chemin.

GS_GPDU_Data_Reliability est un nombre dans la plage 0..100 indiquant le pourcentage des GPDU totales qui sont des GPDU réussies. Le total des GPDU est le nombre de GPDU d'émission acquittées qui sont tentées plus le nombre des GPDU reçues. Les GPDU réussies sont des GPDU émises acquittées qui sont correctement transférées à la première tentative plus les GPDU de réception qui réussissent aux contrôles d'intégrité.

GS_Join_Count est un nombre entier positif qui indique le nombre de fois qu'un appareil a rejoint le système. Le compte des rattachements peut augmenter si l'alimentation électrique est interrompue, un appareil est réinitialisé, le réseau est reformé, ou un appareil est déplacé vers un nouveau réseau. Des rattachements excessifs peuvent indiquer des problèmes d'intégrité ou de communication d'appareil.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

U.2.4.9 Interface de temps

U.2.4.9.1 Généralités

L'interface de temps permet la récupération et le réglage du temps pour un réseau sans fil associé à une passerelle. Cela est utile pour la synchronisation du temps d'un réseau d'appareils sans fil avec un système hôte et d'autres applications de niveau hôte.

Le client interne à une passerelle utilise la primitive G_Time pour récupérer un rapport relatif aux appareils associés à une entité de passerelle.

U.2.4.9.2 Primitive G_Time

U.2.4.9.2.1 Primitives et leurs paramètres

Le Tableau U.14 décrit l'utilisation des paramètres pour la primitive G_Time.

Tableau U.14 – Utilisation des paramètres de la primitive G_Time

Nom du paramètre	G_Time	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Command	M	-
GS_Time	C	M
GS_Status	-	M

U.2.4.9.2.2 Utilisation de demande de G_Time

Le client interne à une passerelle utilise la primitive de demande de G_Time pour lire ou établir le temps réseau.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

GS_Command = 0 lit le temps réseau. GS_Time n'est pas inclus.

GS_Command = 1 tente de définir le temps réseau. Un nouveau temps (GS_Time) est fourni.

U.2.4.9.2.3 Utilisation de confirmation de G_Time

L'entité de passerelle utilise la primitive de confirmation de G_Time pour parachever la demande de G_Time au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Si GS_Command = 0 dans la demande, le temps réseau courant (GS_Time) est retourné.

Si GS_Command = 1 dans la demande, l'interface tente d'établir le temps réseau. Le temps réseau courant (GS_Time) est retourné. Si la mise à jour a réussi, le temps courant reflétera la modification.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.15.

Tableau U.15 – GS_Status pour confirmation de G_Time

Valeur	Colonne
0	Succès
1	Echec; non autorisé à définir le temps dans cette configuration
2	Echec; autre

U.2.4.10 Interface client/serveur

U.2.4.10.1 Généralités

L'interface client/serveur permet la prise en charge du transfert de données client/serveur. Les ressources de communication nécessaires pour permettre le transfert sont allouées par l'utilisation de l'interface de location. Le client et le serveur accomplissent, chacun, des rôles distincts, mais connexes. La liaison du client et du serveur est accomplie par l'établissement de locations avec des informations de location concordantes. Les ressources de communication incluent les moyens de tampons locaux afin de réduire au maximum les transactions énergivores. Les clients et les serveurs peuvent exister soit dans la passerelle, soit dans des appareils.

La primitive G_Client_Server est utilisée pour envoyer une charge utile de données de demande client interne à un serveur et pour déclencher la réception d'une charge utile correspondante de données de réponse serveur. En fonction de la mise en œuvre, la charge utile de réponse peut venir en provenance du tampon client interne au sein de la passerelle ou en provenance de l'appareil de terrain.

U.2.4.10.2 Primitive G_Client_Server

U.2.4.10.2.1 Primitives et leurs paramètres

Le Tableau U.16 décrit l'utilisation des paramètres pour la primitive G_Client_Server.

Tableau U.16 – Utilisation des paramètres de la primitive G_Client_Server

Nom du paramètre	G_Client_Server			
	Demande	Affichage	Réponse	Confirmation
GS_Session_ID	M	-	-	M(=)
GS_Transaction_ID	M	-	-	M(=)
GS_Lease_ID	M	-	-	-
GS_Buffer	M	-	-	-
GS_Transfer_Mode	M	-	M	-
GS_Request_Data	M	C(=)	-	-
GS_Response_Data	-	-	C	M
GS_Transaction_Info	C	-	-	C(=)
GS_Status	-	-	M	M

U.2.4.10.2.2 Utilisation de demande de G_Client_Server

La primitive de demande de G_Client_Server est utilisée pour tenter d'acquérir les données demandées localement à partir de la passerelle (si GS_Buffer = 1), pour envoyer une demande correspondante de données d'application client native selon WISN en utilisant le contenu du paramètre de charge utile de données (GS_Request_Data) vers un appareil communiquant selon WISN et pour déclencher la réception d'une réponse serveur selon WISN correspondante. Que les données demandées soient accessibles localement ou à distance, les données sont retournées par l'intermédiaire du paramètre de primitive réponse/confirmation pour la charge utile de réponse (GS_Response_Data).

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

L'appareil serveur est connu par l'intermédiaire de l'identificateur de location (GS_Lease_ID) qui a été obtenu à partir de l'interface de location.

Les données de réponse seront demandées à l'appareil serveur si le tampon est désactivé pour la transaction (GS_Buffer = 0). Les données de réponse seront livrées à partir du tampon si le tampon est activé pour la transaction (GS_Buffer = 1) et le tampon contient une réponse concordante qui n'a pas expiré.

GS_Transfer_Mode est fourni avec la demande afin d'indiquer la qualité de l'interface et la priorité pour le transfert des données.

Si GS_Transaction_Info est fourni comme partie intégrante d'une demande, il est retourné par la primitive de confirmation correspondante.

U.2.4.10.2.3 Utilisation d'indication de G_Client_Server

La primitive d'indication de G_Client_Server sert à signaler l'arrivée d'une charge utile de données de demande client au niveau du serveur en vue du traitement.

L'indication est conditionnée à la question de savoir si, oui ou non, la charge utile de données de réponse serveur a pu être livrée à partir du tampon client.

U.2.4.10.2.4 Utilisation de réponse de G_Client_Server

La primitive de réponse de G_Client_Server sert à retourner une charge utile de données de réponse serveur vers le client.

GS_Transfer_Mode est fourni avec la réponse afin d'indiquer la qualité de l'interface et la priorité pour le transfert des données.

La réponse est conditionnée à la question de savoir si, oui ou non, la charge utile de données de réponse serveur a pu être livrée à partir du tampon client.

U.2.4.10.2.5 Utilisation de confirmation de G_Client_Server

La primitive de confirmation de G_Client_Server sert à parachever la demande de G_Client_Server destinée au client.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Une charge utile de données de réponse serveur est retournée. La charge utile est livrée soit à partir du tampon client, soit à partir du serveur.

Si GS_Transaction_Info était fourni dans la demande, il doit être retourné dans la confirmation.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.17.

Tableau U.17 – GS_Status pour confirmation de G_Client_Server

Valeur	Colonne
0	Succès
1	Echec; le serveur n'est pas accessible pour la demande sans mémoire tampon
2	Echec; le serveur n'est pas accessible est la mémoire tampon n'est pas valide pour la demande avec mémoire tampon
3	Echec; la location a expiré
4	Echec; autre

U.2.4.11 Interface publish/subscribe

U.2.4.11.1 Généralités

L'interface publish/subscribe fournit des mécanismes pour le transfert de données publish/subscribe. Les ressources de communication nécessaires pour permettre l'échange de messages sont allouées par l'utilisation de l'interface de location. L'éditeur et l'abonné accomplissent, chacun, des rôles distincts, mais connexes. La liaison de l'éditeur et de l'abonné est accomplie par l'établissement distinct de communication concordante. Les ressources de communication incluent les moyens de tampons locaux dans l'éditeur et l'abonné afin de réduire au maximum les transactions énergivores. Les éditeurs et les abonnés peuvent exister dans les passerelles, dans les adaptateurs, ou dans les appareils natifs.

U.2.4.11.2 Établissement de la location

L'interface G_Lease est utilisée avant l'utilisation de l'interface G_Publish afin d'établir un GS_Lease_ID. Le GS_Lease_Type est mis soit à "publisher", soit à "subscriber", pour configurer le côté respectif et pour établir et réserver les ressources d'entité de passerelle et de voies de communication sous-jacentes.

GS_Network_Address_List est utilisé par l'éditeur et l'abonné pour établir l'identité des autres points d'extrémité. Un éditeur peut décrire plusieurs adresses dans la liste afin de configurer plusieurs abonnés.

Dans les limites de la location, GS_Protocol_Type est utilisé pour décrire le protocole d'application qui sera tunnellisé à travers l'interface. Cela permet que le traitement spécifique à un protocole se produise.

GS_Lease_Parameters est utilisé pour établir l'interaction de protocole attendue entre un éditeur et un abonné.

U.2.4.11.3 Publication

La primitive G_Publish est utilisée par un éditeur pour initier le transfert d'une charge utile de données éditeur vers un ou plusieurs abonnés.

La charge utile de données éditeur est stockée dans un tampon local et transmise du tampon vers les abonnés. Les paramètres de configuration de location déterminent le moment où la transmission sera produira. La transmission se produit afin de respecter les dates limites programmées. Sur une période de temps, la même charge utile peut être transmise plusieurs fois pour indiquer que l'éditeur existe toujours et empêcher la temporisation. Une invocation avec des données inchangées ne peut pas donner lieu à une transmission.

U.2.4.11.4 Abonnement

La primitive G_Subscribe est utilisée par un abonné pour récupérer du tampon local les plus récentes données de publication.

L'abonné reçoit également la plus récente publication associée à une location d'abonné par l'intermédiaire de la primitive d'indication de G_Publish.

La primitive G_Publish_Watchdog est utilisée au sein d'un abonné pour signaler l'expiration d'un temporisateur de chien de garde. Le temporisateur expire en l'absence des mises à jour attendues issues d'un éditeur. Le temporisateur est réinitialisé à l'arrivée de la charge utile de données de publication au niveau de l'abonné. Le temporisateur de chien de garde est configuré comme étant une partie des paramètres de configuration de location.

La primitive G_Publish_Timer est utilisée au sein d'un éditeur pour signaler l'expiration d'un temporisateur de publication. Le temporisateur de publication est un temporisateur périodique qui expire avant la date limite pour transmettre la charge utile de données éditeur. L'indication peut être utilisée pour éditer des données fraîches. Le temporisateur de publication est configuré avec les paramètres de configuration de location.

La primitive G_Subcribe_Timer est utilisée au sein d'un abonné pour signaler l'expiration d'un temporisateur d'abonnement. Le temporisateur d'abonnement est un temporisateur périodique qui expire à la date limite de livraison pour recevoir la charge utile de données éditeur. L'indication est utilisée pour traiter des données de publication existantes. L'arrivée des données fraîches réinitialisera le temporisateur et donnera lieu à une indication G_Publish. Le temporisateur d'abonnement est configuré avec les paramètres de configuration de location.

U.2.4.11.5 Types de primitives et paramètres

U.2.4.11.5.1 Primitive G_Publish et ses paramètres

Le Tableau U.18 décrit l'utilisation des paramètres pour la primitive G_Publish.

Tableau U.18 – Utilisation des paramètres de la primitive G_Publish

Nom du paramètre	G_Publish		
	Demande	Affichage	Confirmation
GS_Session_ID	M	M	M
GS_Transaction_ID	M	-	M(=)
GS_Lease_ID	M	M	-
GS_Transfer_Mode	M	-	-
GS_Publish_Data	M	C(=)	-
GS_Status	-	-	M

U.2.4.11.5.2 Utilisation de demande de G_Publish

La primitive de demande de G_Publish est utilisée pour initier un transfert d'une charge utile de données éditeur (GS_Publish_Data) vers un ou plusieurs abonnés. La charge utile de données éditeur est stockée dans un tampon local et transmise du tampon vers les abonnés.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

L'adressage d'abonné est connu par l'intermédiaire de l'identificateur de location (GS_Lease_ID) qui a été obtenu à partir de l'interface de location.

Dans les paramètres de location, GS_Resource est une valeur identique spécifiée pour un éditeur et un ou plusieurs abonnés afin de faciliter l'établissement de liaison entre les points d'extrémité.

GS_Transfer_Mode est fourni avec la demande afin d'indiquer la qualité de l'interface et la priorité pour le transfert des données.

U.2.4.11.5.3 Utilisation d'indication de G_Publish

La primitive d'indication de G_Publish est utilisée pour signaler l'arrivée d'une charge utile de données éditeur au niveau d'un abonné en vue du traitement.

La charge utile de données éditeur (GS_Publish_Data) est livrée avec l'indication.

L'identificateur de session d'abonné (GS_Session_ID) et l'identificateur de location d'abonné (GS_Lease_ID) sont retournés pour permettre l'association de la primitive d'indication à une relation P/S spécifique.

L'indication est conditionnée à la livraison chronométrée dépendante de la configuration à partir de l'éditeur et indique des données de publication fraîches.

U.2.4.11.5.4 Utilisation de confirmation de G_Publish

La primitive de confirmation de G_Publish sert à parachever la demande de G_Publish.

L'identificateur de session éditeur (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.19.

Tableau U.19 – GS_Status pour confirmation de G_Publish

Valeur	Colonne
0	Succès
1	Echec; la location a expiré
2	Echec; autre

U.2.4.11.5.5 Primitive G_Subscribe et ses paramètres

Le Tableau U.20 décrit l'utilisation des paramètres pour la primitive G_Subscribe.

Tableau U.20 – Utilisation des paramètres de la primitive G_Subscribe

Nom du paramètre	G_Subscribe	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Lease_ID	M	-
GS_Publish_Data	-	M
GS_Status	-	M

U.2.4.11.5.6 Utilisation de demande de G_Subscribe

La primitive de demande de G_Subscribe est utilisée pour récupérer du tampon local les plus récentes données de publication (GS_Publish_Data).

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

L'adressage d'éditeur est connu par l'intermédiaire de l'identificateur de location (GS_Lease_ID) qui a été obtenu à partir de l'interface de location.

U.2.4.11.5.7 Utilisation de confirmation de G_Subscribe

La primitive de confirmation de G_Subscribe sert à parachever la demande de G_Subscribe.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.21.

Tableau U.21 – GS_Status pour confirmation de G_Subscribe

Valeur	Colonne
0	Réussite; données fraîches
1	Réussite; données périmées
2	Echec; la location a expiré
3	Echec; autre

U.2.4.11.5.8 Primitive G_Publish_Timer et ses paramètres

Le Tableau U.22 décrit l'utilisation des paramètres pour la primitive G_Publish_Timer.

Tableau U.22 – Utilisation des paramètres de la primitive G_Publish_Timer

Nom du paramètre	G_PublishTimer
	Affichage
GS_Session_ID	M
GS_Lease_ID	M

U.2.4.11.5.9 Utilisation d'indication G_Publish_Timer

La primitive d'indication de G_Publish_Timer est utilisée au sein d'un éditeur pour signaler l'expiration d'un temporisateur de publication.

L'identificateur de session publisher (GS_Session_ID) et l'identificateur de location publisher (GS_Lease_ID) sont retournés pour permettre l'association de la primitive d'indication à une relation P/S spécifique.

U.2.4.11.5.10 Primitive G_Subscribe_Timer et ses paramètres

Le Tableau U.23 décrit l'utilisation des paramètres pour la primitive G_Publish_Timer.

Tableau U.23 – Utilisation des paramètres de la primitive G_Subscribe_Timer

Nom du paramètre	G_SubscribeTimer
	Affichage
GS_Session_ID	M
GS_Publish_Data	M
GS_Lease_ID	M

U.2.4.11.5.11 Utilisation d'indication de G_Publish_Timer

La primitive d'indication de G_Subcribe_Timer est utilisée au sein d'un abonné pour signaler l'expiration d'un temporisateur d'abonnement. Le temporisateur est réinitialisé par l'indication de G_Publish.

La charge utile de données éditeur (GS_Publish_Data) est livrée à partir du tampon d'abonné avec l'indication.

L'identificateur de session d'abonné (GS_Session_ID) et l'identificateur de location d'abonné (GS_Lease_ID) sont retournés pour permettre l'association de la primitive d'indication à une relation P/S spécifique.

U.2.4.11.5.12 Primitive G_Publish_Watchdog et ses paramètres

Le Tableau U.24 décrit l'utilisation des paramètres pour la primitive G_Publish_Watchdog.

Tableau U.24 – Utilisation des paramètres de la primitive G_Publish_Watchdog

Nom du paramètre	G_Publish_Watchdog
	Affichage
GS_Session_ID	M
GS_Publish_Data	M
GS_Lease_ID	M

U.2.4.11.5.13 Utilisation d'indication de G_Publish_Watchdog

La primitive d'indication de G_Publish_Watchdog est utilisée au sein d'un abonné pour signaler l'expiration d'un temporisateur de chien de garde en raison de l'absence des mises à jour attendues en provenance d'un éditeur. Le temporisateur est réinitialisé par l'indication de G_Publish.

La charge utile de données éditeur désormais périmées (GS_Publish_Data) est livrée à partir du tampon d'abonné avec l'indication.

L'identificateur de session (GS_Session_ID) et l'identificateur de location (GS_Lease_ID) sont retournés pour permettre l'association de la primitive d'indication à une relation P/S spécifique.

U.2.4.12 Interface de transfert en masse

U.2.4.12.1 Généralités

L'interface de transfert en masse permet la prise en charge du transfert de données en masse. Le transfert de données en masse est utilisé pour transférer des éléments volumineux entre des clients à une passerelle et les appareils sans fil.

Les transferts en masse fonctionnent dans le contexte d'une session entre le fournisseur d'interface de GIAP et l'utilisateur d'interface de GIAP. Toutes les primitives prises en charge par la passerelle par l'intermédiaire d'un GIAP incluent le GS_Session_ID correspondant.

Le client de la session gère les GS_Transaction_IDs propres à une session pour chaque primitive invoquée par le client. Cela est nécessaire afin de maintenir la coordination entre les primitives de transfert en masse.

Le GS_Lease_ID, qui représente les ressources de communication nécessaires allouées au sein de la passerelle, est fourni avec chaque primitive.

Des transferts en masse parallèles distincts sont différenciés par un GS_Transfer_ID. Un GS_Transfer_ID est également inclus dans chaque primitive d'interface de GIAP. L'état de transfert est maintenu pour chaque transfert en masse qui est en cours. Par exemple, le numéro de bloc transféré est maintenu par les points d'extrémité.

G_Bulk_Open sert à ouvrir un transfert en masse. G_Bulk_Close sert à fermer un transfert en masse. G_Bulk_Transfer sert à accomplir le transfert réel de segments de données au sein du transfert en masse.

U.2.4.12.2 Types de primitives et paramètres

U.2.4.12.2.1 Primitive G_Bulk_Open et ses paramètres

Le Tableau U.25 décrit l'utilisation des paramètres pour la primitive G_Bulk_Open.

Tableau U.25 – Utilisation des paramètres de la primitive G_Bulk_Open

Nom du paramètre	G_Bulk_Open	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Lease_ID	M	-
GS_Transfer_ID	M	-
GS_Resource	M	-
GS_Mode	M	-
GS_Block_Size	M	M
GS_Item_Size	C	C
GS_Status	-	M

U.2.4.12.2.2 Utilisation de demande de G_Bulk_Open

La primitive de demande de G_Bulk_Open sert à initier un transfert en masse. L'appareil-cible pour un transfert en masse est sous-entendu par GS_Lease_ID.

L'élément-cible pour un transfert en masse est identifié par GS_Resource.

Un transfert est directionnel (téléchargement montant ou téléchargement descendant) et GS_Mode décrit le sens du transfert. GS_Mode = 0 décrit le téléchargement descendant et GS_Mode = 1 décrit le téléchargement montant.

L'utilisateur d'interface de GIAP positionne GS_Block_Size pour demander une taille de bloc pour la phase de transfert ultérieure.

L'utilisateur d'interface de GIAP positionne le GS_Item_Size pour demander le téléchargement descendant d'un élément d'une taille particulière. L'élément peut dépasser les limites de téléchargement descendant disponibles, ce qui entraîne une réponse d'erreur. GS_Item_Size = 0 demande le téléchargement descendant d'un élément de taille indéterminée.

U.2.4.12.2.3 Utilisation de confirmation de G_Bulk_Open

La primitive de confirmation de G_Bulk_Open est utilisée en réponse à une demande de G_Bulk_Open.

Le GS_Item_Size est positionné par le fournisseur d'interface de GIAP pour indiquer la taille de l'élément. Pour un téléchargement descendant, il s'agit de la taille maximale d'élément qui sera acceptée. Pour un téléchargement montant, il s'agit de la taille réelle d'élément. GS_Item_Size = 0 indique qu'il n'y a aucune limite imposée à la taille d'élément.

Le fournisseur d'interface de GIAP détermine et retourne le GS_Block_Size qui doit être utilisé pour la phase de transfert suivante. La taille de bloc peut être réduite (en fonction des ressources disponibles) par rapport à la taille d'origine demandée dans la demande de GS_Bulk_Open.

GS_Status indique le succès ou l'échec du G_Bulk_Open, conformément au Tableau U.26.

Tableau U.26 – GS_Status pour confirmation de G_Bulk_Open

Valeur	Colonne
0	Succès
1	Echec; l'élément dépasse les limites
2	Echec; ressource inconnue
3	Echec; mode non valide
4	Echec; autre

U.2.4.12.3 Primitive G_Bulk_Transfer et ses paramètres

Le Tableau U.27 décrit l'utilisation des paramètres pour la primitive G_Bulk_Transfer.

Tableau U.27 – Utilisation des paramètres de la primitive G_Bulk_Transfer

Nom du paramètre	G_Bulk_Transfer	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Lease_ID	M	-
GS_Transfer_ID	M	-
GS_Bulk_Data	C	C
GS_Status	-	M

U.2.4.12.3.1 Utilisation de demande de G_Bulk_Transfer

La primitive de demande de G_Bulk_Transfer sert à déplacer des données en masse. GS_Bulk_Data est un segment de transfert qui est conditionnellement envoyé à la cible dans le cas d'un téléchargement.

G_Bulk_Transfer est utilisé autant de fois qu'exigé pour parachever le transfert d'un élément volumineux. G_Bulk_Close est utilisé par l'utilisateur d'interface de GIAP pour indiquer l'achèvement du transfert.

U.2.4.12.3.2 Utilisation de "confirm" G_Bulk_Transfer

La primitive de confirmation de G_Bulk_Transfer est utilisée en réponse à une demande de G_Bulk_Transfer. GS_Bulk_Data est un segment de transfert qui est conditionnellement reçu en provenance de la cible dans le cas d'un chargement.

GS_Status indique le succès ou l'échec du G_Bulk_Transfert, comme indiqué dans le Tableau U.28.

Tableau U.28 – GS_Status pour confirmation de G_Bulk_Transfer

Valeur	Colonne
0	Succès
1	Echec; la communication a échoué
2	Echec; le transfert a été abandonné
3	Echec; autre

U.2.4.12.4 Primitive G_Bulk_Close et ses paramètres

Le Tableau U.29 décrit l'utilisation des paramètres pour la primitive G_Bulk_Close.

Tableau U.29 – Utilisation des paramètres de la primitive G_Bulk_Close

Nom du paramètre	G_Bulk_Close	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Lease_ID	M	-
GS_Transfer_ID	M	-
GS_Status	-	M

U.2.4.12.4.1 Utilisation de demande de G_Bulk_Close

La primitive de demande de G_Bulk_Close est utilisée pour parachever un transfert en masse, et pour nettoyer toute ressource ou tout traitement d'état nécessaire dans le fournisseur d'interface de GIAP.

U.2.4.12.4.2 Utilisation de confirmation de G_Bulk_Close

La primitive de confirmation de G_Bulk_Close est utilisée en réponse à une demande de G_Bulk_Close.

U.2.4.13 Interface d'alerte

U.2.4.13.1 Généralités

L'interface d'alerte permet la prise en charge de l'établissement des événements de notification d'alertes des clients internes à une passerelle. Des opérations complémentaires peuvent être exigées pour recueillir des informations complémentaires relatives à l'alerte ou pour répondre à l'alerte.

Les interfaces d'alerte fonctionnent dans le contexte d'une session entre le fournisseur d'interface de GIAP et l'utilisateur d'interface de GIAP. Toutes les primitives prises en charge par la passerelle par l'intermédiaire d'un GIAP incluent le GS_Session_ID correspondant.

Le client de la session gère les GS_Transaction_IDs en cours qui sont propres à une session pour chaque primitive qu'il invoque. Cela est nécessaire afin de maintenir la coordination entre les primitives d'alertes.

Le GS_Lease_ID, qui représente l'entité de passerelle nécessaire et les ressources de communication nécessaires, est fourni avec chaque primitive.

G_Alert_Subscription est utilisé pour s'abonner à des alertes soit par catégorie, soit par alertes spécifiques.

U.2.4.13.2 Types de primitives et paramètres

U.2.4.13.2.1 Primitive G_Alert_Subscription et ses paramètres

Le Tableau U.30 décrit l'utilisation des paramètres pour la primitive G_Alert_Subscription.

Tableau U.30 – Utilisation des paramètres de la primitive G_Alert_Subscription

Nom du paramètre	G_Alert_Subscription	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Lease_ID	M	-
GS_Subscription_List	M	C
GS_Category	C	C
GS_Network_Address	C	C
GS_Alert_Source_ID	C	C
GS_Subscribe	M	C
GS_Enable	M	C
GS_Status	-	M

U.2.4.13.2.2 Utilisation de demande de G_Alert_Subscription

La primitive de demande G_Alert_Subscription sert à gérer une liste d'abonnements d'alertes.

GS_Subscription_List contient une ou plusieurs demandes de modification d'abonnements d'alertes. Chaque élément de liste peut être utilisé pour modifier l'abonnement pour une catégorie particulière d'alertes ou pour modifier l'abonnement pour une alerte spécifique issue d'une source spécifique.

Les éléments de liste peuvent décrire le paramètre GS_Category pour indiquer la modification d'abonnement pour une catégorie particulière d'alertes. Les catégories d'alertes comprennent:

0 = appareil;

1 = réseau;

2 = sécurité; et

3 = processus.

GS_Network_Address et GS_Alert_Source_ID ne sont pas fournis si GS_Category est fourni.

En variante, les éléments de liste peuvent décrire GS_Network_Address et GS_Alert_Source_ID au lieu de GS_Category pour décrire un appareil spécifique et un identificateur d'une alerte spécifique issue de l'appareil en question.

NOTE Il est prévu que certains clients internes à une passerelle, tels que des systèmes complets de gestion d'alarme, utiliseront des catégories complètes, tandis que d'autres clients internes à une passerelle sont capables de restreindre leur utilisation au seul ensemble sélectionné d'alertes.

GS_Subscribe et GS_Enable commandent les actions pour chaque élément de liste. GS_Subscribe sert à décrire quelles alertes doivent être reçues au sein de l'entité de passerelle et être transmises vers l'utilisateur d'interface de GIAP sous la forme d'indications de G_Alert_Notification. GS_Enable sert à commander la production sous-jacente d'alertes au niveau de la source. GS_Subscribe = 1 abonne à une alerte spécifique ou à une catégorie d'alertes, alors que GS_Subscribe = 0 désabonne de l'alerte. GS_Enable = 1 active une alerte spécifique ou une catégorie d'alertes, alors que GS_Enable = 0 désactive l'alerte.

Afin de synchroniser l'état d'alarme entre la source d'alarme et l'entité de passerelle, la récupération d'alarme est initiée sur des abonnements.

U.2.4.13.2.3 Utilisation de confirmation de G_Alert_Subscription

La primitive de confirmation de G_Alert_Subscription est utilisée en réponse à une demande de G_Alert_Subscription.

GS_Status indique le succès ou l'échec de la demande de G_Alert_Subscription, comme indiqué dans le Tableau U.31. Un paramètre GS_Subscription_List avec un seul élément est retourné conditionnellement si l'opération échoue. Le code statut se rapporte à l'élément particulier. Le traitement de la liste s'arrête au premier élément défaillant.

Tableau U.31 – GS_Status pour confirmation de G_Alert_Subscription

Valeur	Colonne
0	Succès
1	Echec; catégorie non valide
2	Echec; alerte individuelle non valide
3	Echec; autre

U.2.4.13.2.4 Primitive G_Alert_Notification et ses paramètres

Le Tableau U.32 décrit l'utilisation des paramètres pour la primitive G_Alert_Notification.

Tableau U.32 – Utilisation des paramètres de la primitive G_Alert_Notification

Nom du paramètre	G_Alert_Notification
	Affichage
GS_Session_ID	M
GS_Lease_ID	M
GS_Alert	M
GS_Network_Address	M
GS_Alert_Source_ID	M
GS_Time	M
GS_Class	M
GS_Direction	M
GS_Category	M
GS_Type	M
GS_Priority	M
GS_Alert_Data	C

U.2.4.13.2.5 Utilisation de confirmation de G_Alert_Notification

L'indication de G_Alert_Notification est générée par le fournisseur d'interface de GIAP et envoyée à l'utilisateur de GIAP en réponse à une alerte reçue par la passerelle. Une notification est fournie seulement pour les alertes auxquelles le client de GIAP s'est abonné et pour lesquelles la notification a été activée.

Une structure GS_Alert est fournie dans l'indication pour fournir les détails spécifiques d'alertes comme suit:

- GS_Network_Address indique l'appareil source de l'alerte.
- GS_Alert_Source_ID indique l'alerte spécifique au sein de l'appareil source.

- GS_Time est un marqueur temporel qui indique le moment auquel l'alerte a été produite à l'origine.
- GS_Class = 0 identifie l'alerte comme étant un événement; GS_Class = 1 identifie l'alerte comme étant une alarme.
- GS_Direction classe en plus les alarmes comme suit:
  0: la condition d'alarme est terminée;
  1: la condition d'alarme a commencé.
- GS_Category décrit la catégorie alertes comme suit:
  0: relatif au processus;
  1: relatif à l'appareil;
  2: relatif au réseau;
  3: relatif à la sécurité.
- GS_Type décrit les sous-catégories pour les alertes. La valeur réelle est spécifique à une application.
- GS_Priority décrit une priorité pour l'alerte. Plus la valeur est élevée, plus la priorité est haute. La valeur réelle est spécifique à une application.
- GS_Alert_Data autorise l'inclusion d'informations relatives à une alerte. Ce champ est conditionné à la disponibilité ou à la non-disponibilité d'informations d'alerte complémentaires. La valeur réelle est spécifique à une application.

L'entité de passerelle acquitte la réception de l'alerte.

U.2.4.14 Interface de configuration de passerelle

U.2.4.14.1 Généralités

L'interface de configuration de passerelle permet la prise en charge de la lecture et de l'écriture des attributs de configuration de la passerelle.

Le client interne à une passerelle utilise la primitive G_Read_Gateway_Configuration pour récupérer des attributs de configuration de passerelle.

U.2.4.14.2 Types de primitives et paramètres

U.2.4.14.2.1 Primitive G_Read_Gateway_Configuration et ses paramètres

Le Tableau U.33 décrit l'utilisation des paramètres pour la primitive G_Read_Gateway_Configuration.

Tableau U.33 – Utilisation des paramètres de la primitive G_Read_Gateway_Configuration

Nom du paramètre	G_ReadGatewayConfiguration	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Attribute_Identifier	M	-
GS_Attribute_Value	-	C
GS_Status	-	M

U.2.4.14.2.2 Utilisation de demande de G_Read_Gateway_Configuration

Le client interne à une passerelle utilise la primitive de demande de G_Read_Gateway_Configuration pour récupérer des paramètres de configuration de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

L'attribut demandé est spécifié par l'identificateur d'attribut (GS_Attribute_Identifier), conformément au Tableau 34. La valeur demandée est spécifiée par la valeur d'attribut (GS_Attribute_Value).

Tableau 34 – Valeurs de GS_Attribute_Identifier pour la demande de G_Read_Gateway_Configuration

Valeur	Colonne
0	GS_GUID
1	GS_Max_Retries
2	GS_Max_Devices
3	GS_Actual_Devices

U.2.4.14.2.3 Utilisation de confirmation de G_Read_Gateway_Configuration

L'entité de passerelle utilise la primitive de confirmation de G_Read_Gateway_Configuration pour parachever la demande de G_Read_Gateway_Configuration au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Si l'opération réussit, la valeur (GS_Attribute_Value) est retournée pour l'attribut demandé (GS_Attribute_Identifier).

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

U.2.4.14.2.4 Primitive G_Write_Gateway_Configuration et ses paramètres

Le Tableau U.35 décrit l'utilisation des paramètres pour la primitive G_Write_Gateway_Configuration.

Tableau U.35 – Utilisation des paramètres de la primitive G_Write_Gateway_Configuration

Nom du paramètre	G_Write_Gateway_Configuration	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Attribute_Identifier	M	-
GS_Attribute_Value	M	-
GS_Status	-	M

U.2.4.14.2.5 Utilisation de demande de G_Write_Gateway_Configuration

Le client interne à une passerelle utilise la primitive de demande de G_Write_Gateway_Configuration pour modifier des attributs de configuration de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

L'attribut demandé est spécifié par l'identificateur d'attribut (GS_Attribute_Identifier), conformément au Tableau U.36. La valeur demandée est spécifiée par la valeur d'attribut (GS_Attribute_Value).

Tableau U.36 – Valeurs de GS_Attribute_Identifier pour la demande de G_Write_Gateway_Configuration

Valeur	Colonne
0	GS_GUID
1	GS_Max_Retries

U.2.4.14.2.6 Utilisation de confirmation de G_Write_Gateway_Configuration

L'entité de passerelle utilise la primitive de confirmation de G_Write_Gateway_Configuration pour parachever la demande de G_Write_Gateway_Configuration au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.37.

Tableau U.37 – GS_Status pour confirmation de G_Write_Gateway_Configuration

Valeur	Colonne
0	Succès
1	Echec; valeur d'attribut non valide
2	Echec; autre

U.2.4.15 Interface de configuration d'appareil

U.2.4.15.1 Généralités

L'interface de configuration d'appareil fournit une méthode pour gérer la configuration des appareils qui sont associés à une passerelle. Cela est utile pour la mise en service d'appareils sans fil pour des systèmes hôtes et des applications connexes.

La configuration d'appareil a des interfaces pour réécrire et pour relire la configuration pour un ou plusieurs appareils.

Un identificateur unique est utilisé pour apparier la configuration à un appareil spécifique. Une adresse IPv6 est spécifiée pour être utilisée dans la configuration de l'appareil, permettant l'accès logique ultérieur de l'appareil.

L'interface de rapport de liste d'appareils est utilisée pour déterminer les appareils associés à la passerelle. Cette interface fonctionne conjointement avec l'interface de rapports de listes d'appareils en fournissant la capacité de limiter les appareils qui sont associés à une passerelle.

Un fichier de configuration peut être fourni pour chaque appareil. Le format d'un tel fichier de configuration est dépendant d'une mise en œuvre de passerelle. Les informations contenues dans ce fichier visent à permettre à des passerelles de configurer automatiquement des appareils pour rejoindre le réseau. Une configuration supplémentaire est accomplie de façon biunivoque par les interfaces client serveur et de transfert en masse.

Si la passerelle est utilisée pour configurer des appareils, le rapport de listes d'appareil doit être vide jusqu'à ce que les appareils soient configurés et rejoignent le système.

Le client interne à une passerelle utilise la primitive G_Write_Device_Configuration pour établir la configuration pour des appareils associés à une entité de passerelle.

U.2.4.15.2 Types de primitives et paramètres

U.2.4.15.2.1 Primitive G_Write_Device_Configuration et ses paramètres

Le Tableau U.38 décrit l'utilisation des paramètres pour la primitive G_Write_Device_Configuration.

Tableau U.38 – Utilisation des paramètres de la primitive G_Write_Device_Configuration

Nom du paramètre	G_Write_Device_Configuration	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Device_List	M	-
GS_Configure	M	-
GS_Unique_Device_ID	M	-
GS_Network_Address	M	-
GS_Provisioning_Info	U	-
GS_Status	-	M

U.2.4.15.2.2 Utilisation de demande de G_Write_Device_Configuration

Le client interne à une passerelle utilise la primitive de demande de G_Write_Device_Configuration pour configurer les appareils associés à une entité de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

Une liste d'appareils associés à l'entité de passerelle (GS_Device_List) est fournie. Pour chaque appareil dans la liste, l'identificateur unique d'appareil (GS_Unique_Device_ID) indique l'appareil associé à la configuration. Si GS_Configure = 1, la configuration est ajoutée pour l'appareil spécifique, tandis que si GS_Configure = 0, la configuration est retirée pour l'appareil spécifique. Une adresse IPv6 (GS_Network_Address) concordante indique l'adresse logique à associer à l'appareil.

Les informations de configuration d'appareil (GS_Provisioning_Info) sont fournies à la passerelle pour que la passerelle commande la configuration de l'appareil.

U.2.4.15.2.3 Utilisation de confirmation de G_Write_Device_Configuration

L'entité de passerelle utilise la primitive de confirmation de G_Write_Device_Configuration pour parachever la demande de G_Write_Device_Configuration au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.39.

Tableau U.39 – GS_Status pour confirmation de G_Write_Device_Configuration

Valeur	Colonne
0	Succès
1	Echec; adresse IPv6 non valide ou en double
2	Echec; mémoire saturée
3	Echec; appareils maximaux de la passerelle dépassés
4	Echec; informations de configuration non valide
5	Echec; autre

U.2.4.15.2.4 Primitive G_Read_Device_Configuration et ses paramètres

Le Tableau U.40 décrit l'utilisation des paramètres pour la primitive G_Read_Device_Configuration.

Tableau U.40 – Utilisation des paramètres de la primitive G_Read_Device_Configuration

Nom du paramètre	G_Read_Device_Configuration	
	Demande	Confirmation
GS_Session_ID	M	M(=)
GS_Transaction_ID	M	M(=)
GS_Device_List	U	M
GS_Unique_Device_ID	U	M
GS_Network_Address	-	M
GS_Provisioning_Info	-	U
GS_Status	-	M

U.2.4.15.2.5 Utilisation de demande de G_Read_Device_Configuration

Le client interne à une passerelle utilise la primitive de demande de G_Read_Device_Configuration pour récupérer la configuration des appareils associés à une entité de passerelle.

Un identificateur de session (GS_Session_ID) est obtenu à partir de l'interface G_Session et il est inclus dans la demande.

Un identificateur de transaction unique de session (GS_Transaction_ID) est spécifié pour chaque invocation de l'interface.

Si la liste d'appareils associés à l'entité de passerelle (GS_Device_List) est fournie, la demande s'applique à ces appareils spécifiques et l'identificateur unique d'appareil (GS_Unique_Device_ID) indique l'appareil associé à la configuration devant être lue. Si aucune liste n'est fournie, la demande s'applique à tous les appareils.

U.2.4.15.2.6 Utilisation de confirmation de G_Read_Device_Configuration

L'entité de passerelle utilise la primitive de confirmation de G_Read_Device_Configuration pour parachever la demande de G_Read_Device_Configuration au client interne à une passerelle.

L'identificateur de session (GS_Session_ID) et l'identificateur de transaction (GS_Transaction_ID) sont retournés pour permettre l'appariement de la primitive de confirmation avec la primitive de demande d'origine.

Une liste d'appareils associés à l'entité de passerelle (GS_Device_List) est retournée. Pour chaque appareil dans la liste, l'identificateur unique d'appareil (GS_Unique_Device_ID) indique l'appareil associé à la configuration. Une adresse IPv6 (GS_Network_Address) concordante indique l'adresse logique associée à l'appareil. Le fichier de configuration d'appareil (GS_Provisioning_Info), lorsqu'il est présent, fournit des informations de configuration pour l'appareil.

GS_Status est retourné pour spécifier le succès ou l'échec de l'opération, conformément au Tableau U.8.

U.3 Utilisations exemplaires de services et objets normalisés WISN

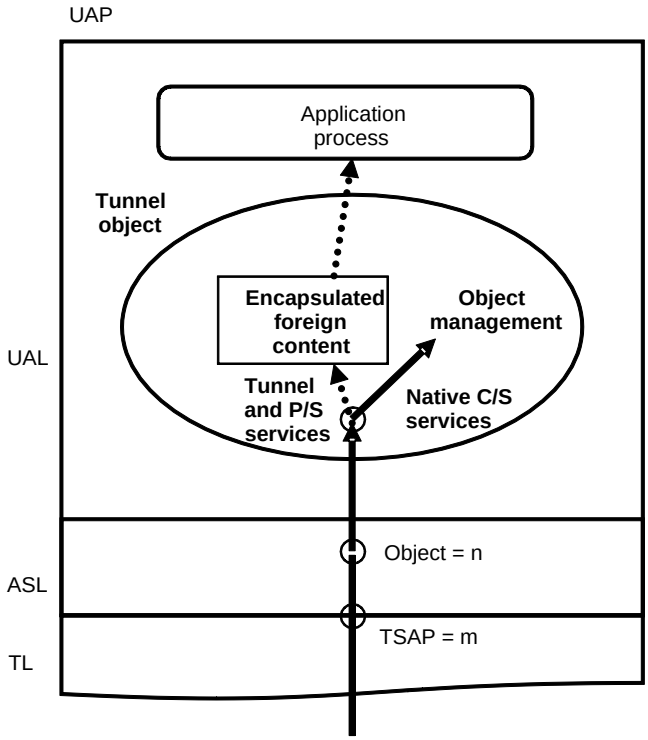
U.3.1 Tunnellisation

U.3.1.1 Généralités

L'objet tunnel (TUN) est un objet natif qui agit comme un point d'extrémité de communication pour la messagerie suivante:

- contenu de protocole étranger encapsulé (représenté sous la forme d'une ligne pointillée à la Figure U.16); et
- contenu d'interface natif (montré sous la forme d'une ligne en trait continu à la Figure U.16) pour configurer et gérer l'objet tunnel.

Les processus de passerelles et les processus d'adaptateurs utilisent des objets tunnel pour prendre en charge la conversion de protocoles étrangers. Un aspect important de l'objet TUN est qu'il fournit le comportement de message tamponné pour le contenu étranger.



Légende

Anglais	Français
Application process	Processus d'application
Tunnel object	Objet tunnel
Encapsulated foreign content	Contenu étranger encapsulé
Object management	Gestion d'objet
Tunnel and P/S services	Services tunnel et P/S
Native C/S services	Services C/S natifs
Object = n	Objet = n
TSP = m	TSP = m

Figure U.16 – Modèle d'objet tunnel

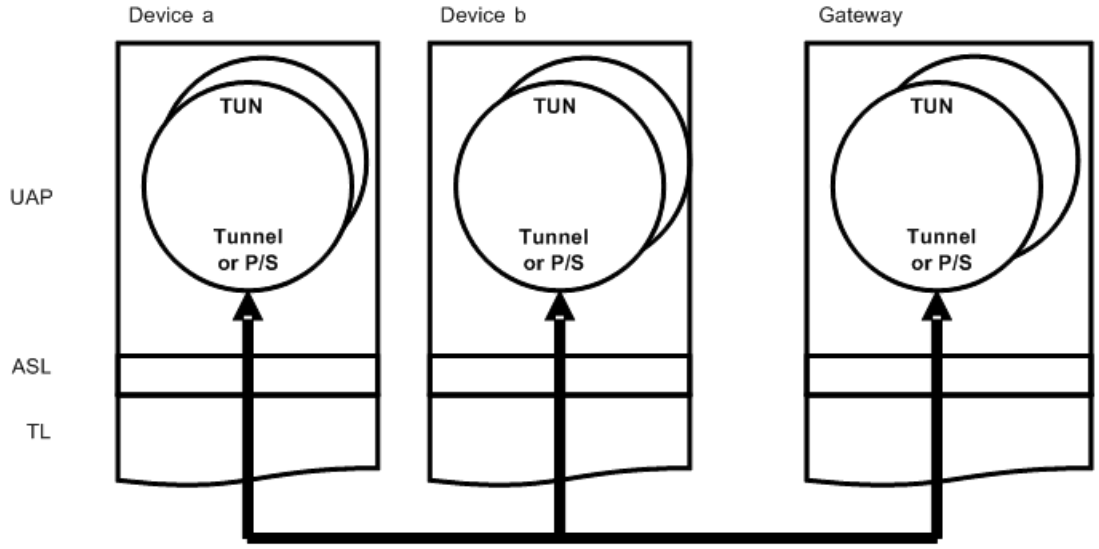
Un ou plusieurs TUN peuvent exister au sein d'un UAP.

Chaque objet TUN peut traiter un protocole étranger complet ou une partie de celui-ci. Les appareils qui traitent plusieurs protocoles étrangers auront besoin de mettre en œuvre plusieurs TUN. L'objet TUN est indépendant vis-à-vis du protocole étranger.

L'objet TUN s'appuie sur la sous-couche d'application (ASL) afin d'acheminer des messages entre les TUN homologues et entre un objet TUN et d'autres objets autres que TUN.

U.3.1.2 Distribution des objets tunnel

Chaque appareil peut avoir un ou plusieurs TUN. Les appareils de tunnellisation comportent au moins un objet TUN comme point d'extrémité pour des tunnels. La Figure U.17 montre un groupe d'appareils connexes avec des points d'extrémité de tunnel interconnectés entre TUN.



Légende

Anglais	Français
Device-a	Appareil a
Device-b	Appareil b
Gateway	Passerelle
Tunnel or P/S	Tunnel ou P/S

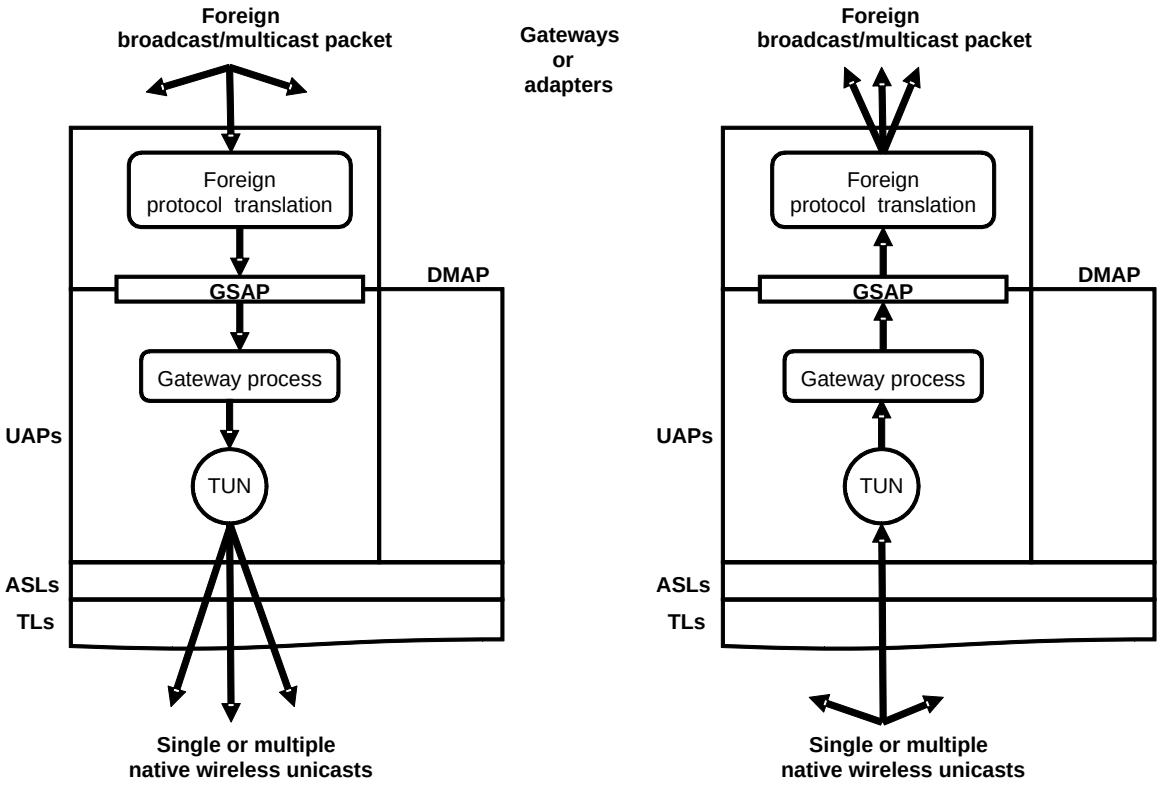
Figure U.17 – Points d'extrémité de tunnels distribués

Les appareils de terrain et les adaptateurs peuvent contenir des TUN qui coopèrent avec d'autres TUN dans une passerelle. Un groupe de TUN connexes communique par l'intermédiaire d'un protocole étranger commun. L'utilisation typique des TUN est de communiquer entre les appareils d'extrémité et un système hôte par l'intermédiaire de la passerelle. Le tunnellisation direct appareil à appareil est également prise en charge au sein du modèle d'objet.

La communication d'objet TUN est établie en utilisant des interfaces TL invoquées et augmentées par l'intermédiaire de l'ASL. Les relations de communication comportent l'édition, l'abonnement, le tunnel à deux parties et le tunnel à quatre parties. Plusieurs relations peuvent être établies simultanément.

U.3.1.3 Messagerie en multidiffusion, en diffusion et "un à plusieurs"

Comme montré à la Figure U.18, les protocoles étrangers peuvent exiger la conversion de relations de messagerie en diffusion/multidiffusion lors de l'utilisation d'interfaces telles que P/S et la distribution d'alertes. Cette messagerie requiert la prise en charge de la conversion au sein de la présente norme.



Légende

Anglais	Français
Foreign broadcast/multicast packet	Paquet étranger en diffusion/multidiffusion
Foreign protocol translation	Conversion de protocole étranger
Gateway process	Processus de passerelle
Single or multiple native wireless unicasts	Une seule ou plusieurs monodiffusions sans fil natives
Gateways or adapters	Passerelles ou adaptateurs

Figure U.18 – Messagerie en multidiffusion, en diffusion et "un à plusieurs"

La présente norme fournit la prise en charge de la messagerie "un à plusieurs" dans l'objet tunnel afin de prendre en charge les demandes en monodiffusion et en diffusion de conversion du protocole étranger. Les couches sous-jacentes de la suite de protocoles ne fournissent pas d'interfaces de diffusion ou de multidiffusion à l'AL. La messagerie "un à plusieurs" est réalisée par l'intermédiaire d'une série d'opérations en monodiffusion. Les applications de conversion de protocoles ne peuvent pas s'appuyer sur une livraison simultanée de messages en monodiffusion.

U.3.1.4 Comportement de messages tamponnés tunnel

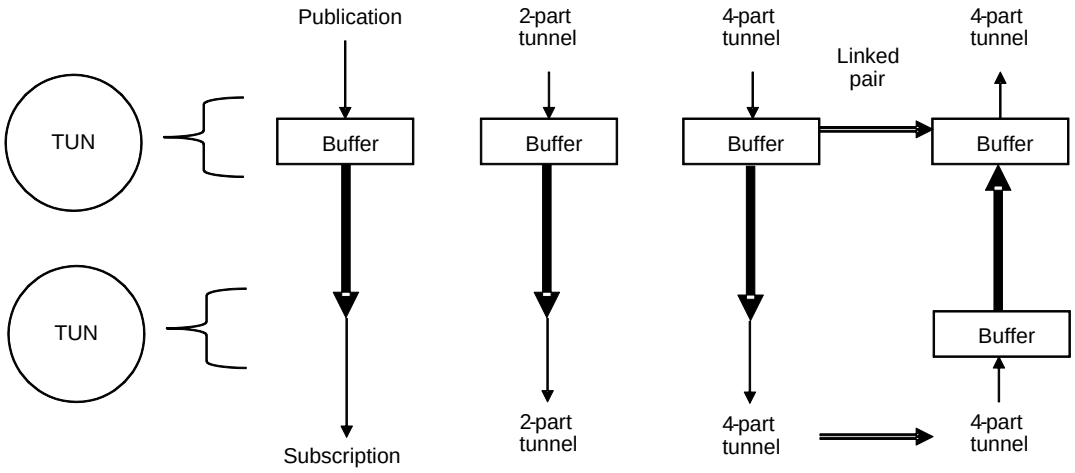
La communication d'objet TUN peut être mise en œuvre pour fournir des capacités pour le comportement tamponné et non tamponné pour des échanges de messages P/S et basés sur des tunnels. Les TUN sont capables de traiter de manière coopérative le comportement tamponné pour réduire les transactions sans fil.

NOTE 1 Certains protocoles hérités utilisent les échanges de messagerie tamponnés pour prendre en charge une conversion de protocoles à haut rendement énergétique et haute performance.

NOTE 2 Certaines applications sont incapables de tolérer le comportement tamponné, habituellement en raison d'exigences relatives à la sécurité et à la synchronisation.

NOTE 3 Les tampons ont une profondeur d'un seul élément. Rien dans la présente norme n'empêche la mise en œuvre d'améliorations de la mise en cache et du placement en file d'attente.

Comme montré à la Figure U.19, chaque point d'extrémité d'un flux de communication a une différente responsabilité relative au placement en tampon, selon la relation.



Légende

Anglais	Français
Publication	Publication
2-part tunnel	Tunnel à deux parties
4-part tunnel	Tunnel à quatre parties
Linked pair	Paire reliée
Buffer	Tampon
Subscription	Abonnement

Figure U.19 – Placement en tampon des objets tunnel

La Figure U.19 montre deux objets TUN. Les flèches en trait fin indiquent des interactions issues d'applications de tunnel qui utilisent les objets. Les flèches en trait épais indiquent les flux de messages à travers le réseau entre les objets. Trois types de transaction sont montrées, une transaction P/S, une transaction de tunnel à deux parties et une transaction de tunnel à quatre parties. Des tampons sont montrés pour illustrer le comportement de messagerie tamponné entre les points d'extrémité de tunnel.

Un éditeur et un abonné sont reliés d'un objet TUN à un objet TUN pour les mises à jour périodiques. Les éditeurs utilisent des publications de tampons de changement d'état pour d'éviter d'envoyer des informations répétées; les abonnés tolèrent des intervalles limités avec des publications absentes.

La messagerie avec l'interface de tunnel à deux parties se comporte d'une façon similaire, excepté que la messagerie est apériodique.

La messagerie avec l'interface de tunnel à quatre parties distingue un côté demande et un côté réponse par l'intermédiaire du bit de demande/ réponse dans l'en-tête de l'interface de tunnel. Le côté demande met en tampon la première demande et transmet également la demande. Une réponse est générée telle qu'indiqué par la double flèche sur le côté réponse à la Figure U.19. La réponse est stockée dans un deuxième tampon lié du côté demande, comme indiqué par la double flèche à la Figure U.19. Le traitement à changement d'état s'applique aux demandes en doublons ultérieures, dans lesquelles la réponse est retournée en provenance du tampon local. Lorsque le changement d'état indique une demande altérée, la demande est transmise et le tampon local de réponse est mis à jour. Un tampon final est montré à la Figure U.19 sur le côté réponse. Ce tampon prend en charge le comportement de changement d'état dans lequel une seule demande produit plusieurs réponses au fil du temps pour mettre à jour le côté demande.

U.3.1.5 Attributs d'objet tunnel

Les attributs d'un objet TUN sont décrits à l'Article 12, mais font l'objet d'une description plus approfondie dans le présent document.

L'attribut Protocol est utilisé pour configurer le protocole associé à l'objet tunnel et aux objets tunnel distants associés. Lorsque le protocole est mis à none (aucun), le tunnel peut être configuré. Une fois qu'un autre protocole est positionné, la configuration d'objet tunnel est appliquée et le statut est mis à jour pour refléter le résultat.

La structure de points d'extrémité de tunnel décrit les informations d'adresses pointant vers un seul objet tunnel distant. La matrice de points d'extrémité de tunnel permet la spécification d'un ou plusieurs points d'extrémité de tunnel représentant des objets tunnel distants. Cela permet à une seule relation de communication de couvrir plusieurs objets tunnel si besoin est. Max_Peer_tunnels indique le nombre maximal d'entrées dans la matrice. Num_Peer_tunnels indique le nombre réel d'entrées configurées dans la matrice.

L'un de plusieurs types de types de flux de communication est choisi entre les objets tunnel par la configuration de l'attribut de Flow_Type. Les types de flux comprennent le tunnel en deux parties, le tunnel à quatre parties, "publish" et "subscribe".

Pour les Flow_Types "publish" et "subscribe", l'Update_Policy permet la configuration de la publication périodique ou de la publication de changement d'état. La publication périodique se produit à chaque occasion. La publication CoSt se produit seulement lorsque des données de publication fraîches sont disponibles. La fréquence de publication est fonction de l'attribut Period. La temporisation réelle est basée sur une combinaison des attribut Period et Phase. Le Stale_Limit est utilisé dans l'abonné pour configurer le comportement pour la détection de la perte excessive ou du retard excessif de publications. Stale_Limit est un multiplicateur qui configure le nombre de périodes qu'un abonné attendra avant de considérer des publications perdues pour indiquer un problème.

Foreign_Destination_Address et Foreign_Source_Address sont les adresses associées au point d'extrémité de tunnel par le protocole étranger. Le format est fonction du protocole étranger. Ces adresses sont retournées aux applications de conversion de protocole à mesure que les messages d'objet tunnel sont reçus. Elles permettent l'utilisation de l'adressage IPv6 tel que défini dans la présente norme au lieu de transporter l'adressage étranger. Le mapping par l'intermédiaire de l'objet tunnel permet la reconstruction des PDU étrangères contenant des informations relatives aux adresses.

NOTE La PDU étrangère variera en fonction de la conversion de protocole étranger spécifique. La plupart des protocoles de bus de terrain formeront des DPDU pour une livraison directe sur une liaison locale. Par contraste, les protocoles basés sur IP forment habituellement des NPDU, où une encapsulation finale est réalisée par un protocole de résolution d'adresse.

Connection_Info[ ] et Transaction_Info[ ] sont des chaînes d'octets qui sont écrites par le convertisseur de protocole, le cas échéant. Connection_Info[ ] sert à fournir le contenu de message statique spécifique à un protocole à la réception de message afin d'éliminer le transfert de message sans fil répété du contenu. Transaction_Info[ ] sert à fournir le contenu de message spécifique à un protocole à la réception d'une réponse, où le contenu aurait autrement été repris en écho à partir de la demande dans la réponse, éliminant le transfert sans fil du contenu. Une description supplémentaire est fournie dans U.3.1.9 et Annexe O.

Il est de la responsabilité de la mise en œuvre de l'objet TUN de maintenir un contrat connexe pour chaque point d'extrémité de tunnel.

U.3.1.6 Messagerie d'objet tunnel

U.3.1.6.1 Utilisation d'interface de sous-couche d'application

Des objets TUN peuvent être mis en œuvre pour fournir les interfaces de connexion qui comprennent une interface P/S, une interface de tunnel à deux parties de tunnel, et une

interface de tunnel à quatre parties de tunnel. Chaque interface peut être mise en œuvre dans un mode de fonctionnement tant tamponné que non tamponné.

Une interface externe facultative pour invoquer les interfaces de connexion de passerelles est décrite à l'Article U.2.

L'objet TUN utilise l'ASL pour livrer et recevoir le contenu d'interface tel que décrit pour l'interface "publish" en 12.17.3.2 et pour l'interface tunnel en 12.17.6.2. L'ASL fournit la livraison objet vers objet de charges utiles P/S dans des formats externes par l'intermédiaire de la primitive de demande de d'éditeur. L'ASL fournit également une primitive de demande de tunnel et une primitive de réponse de tunnel qui sont liées.

L'en-tête est décrit en 12.22.2.3. Cet en-tête permet la spécification des demandes et des réponses, la spécification du type d'interface ("publish" ou tunnel), et le mode d'adressage d'identificateur d'objet (de 4 bits, de 8 bits ou de 16 bits). Un grand nombre d'objets tunnel conduira à un espace adresse plus grand et à plus de surdébit dans l'en-tête.

Le format de charge utile d'interface "publish" est décrit en 12.22.2.12 par le Tableau 348. Il n'y a aucune taille explicite dans l'en-tête. La taille de la publication est fournie avec la demande d'édition et est connue de l'abonné grâce aux informations fournies avec l'indication.

Les formats de charge utile de demande et de réponse d'interface tunnel sont décrits en 12.22.2.9. La demande autorise une taille de 7 bits (charges utiles de 0..127 octets) ou une taille de 15 bits (charges utiles de 128..32 767 octets). L'inclusion de la taille permet au message de tunnel d'être concaténé par l'ASL.

NOTE La plupart des messages encapsulés provenant de protocoles hérités référencés par la présente norme s'inscrivent dans la plage inférieure à une charge utile de 127 octets, conduisant donc à un champ de 7 bits.

U.3.1.6.2 Règles relatives à la classification et au transfert d'informations

D'un point de vue de la mise en cache et du placement en tampon, une information peut être classée comme étant "constant", "static", "dynamic" ou "non-cacheable". Ces classifications sont décrites en 12.6.3 pour les attributs d'objets natifs. La même ligne directrice s'applique à la sélection de la mise en tampon pour les interfaces "publish" et tunnel pour les charges utiles étrangères.

Il convient que des informations "constant" ne soient pas transférées plus d'une fois entre des TN, excepté lorsque les copies locales sont perdues en raison de cycles de puissance, d'une réinitialisation, d'un effacement de cache ou d'une élimination de références aux informations.

Il convient que les informations "static" ne soient transférées plus d'une fois entre des TN, excepté dans les conditions indiquées pour les informations "constant" et lorsque les informations statiques ont été modifiées.

Il convient de transférer une information "dynamic" seulement entre des TN lorsque sa valeur a changé, sauf s'il est exigé plus souvent d'indiquer que la source ou la destination est encore active.

Les informations "non-cacheable" peuvent être transférées entre les TN sur chaque demande.

U.3.1.6.3 Interface publish/subscribe

L'objet tunnel peut être mis en œuvre pour fournir des moyens d'accomplir la messagerie P/S pour la mise à jour des informations dynamiques.

Les organigrammes de la Figure U.20, de la Figure U.21 et de la Figure U.22 décrivent le comportement des objets TUN éditeurs et abonnés qui utilisent le tampon. Le comportement

décrit l'accord de transfert de messages de base entre un éditeur et un abonné en fonction des configurations des attributs des objets TN.

NOTE L'interprétation et les actions pour des données initiales, périmées et répétées sont basées sur la mise en œuvre, comme l'est l'algorithme CoSt.

La connexion d'éditeur P/S fonctionne conformément à la Figure U.20 lorsque les mises à jour de CoSt sont configurées.

U.3.1.6.4 Interface de tunnel

L'objet tunnel peut être mis en œuvre pour fournir des moyens d'accomplir une messagerie d'interface tunnel tamponnée et non tamponnée. La messagerie non tamponnée d'interface tunnel fournit la prise en charge pour le transfert inconditionnel des informations "non-cacheable" et "constant". La messagerie tamponnée d'interface tunnel fournit la prise en charge pour la mise en tampon et le transfert contingent d'informations "static" et "dynamic".

U.3.1.7 Réponses multiples du serveur

Certaines demandes C/S reçoivent plusieurs réponses. Une raison est que la demande exige un traitement prolongé et une réponse immédiate est envoyée, qui indique que la demande a été reçue et que la réponse réelle sera envoyée après que le traitement aura été parachevé. Cela s'appelle, dans certains protocoles, une réponse différée. Dans d'autres cas, le serveur fournit les mises à jour complémentaires au fil du temps pour satisfaire à la demande initiale. Certains protocoles recueillent, de cette manière, des variables de processus ou des informations historiques.

Les interfaces tamponnées et non amorties de C/S prennent en charge plusieurs réponses d'application à ces fins. Dans le cas de la réponse tamponnée, le tampon de lecture maintient la réponse la plus récente. Le client reçoit une indication sur chaque réponse.

U.3.1.8 Mapping d'adresses d'objet tunnel

L'objet TUN peut être mis en œuvre pour contenir trois champs d'adresse (Foreign_Destination_Address, Foreign_Source_Address, et Array of Tunnel endpoints) qui sont utilisées dans la conversion entre adresses étrangères et adresses natives.

Telles que montrées à la Figure U.23, les adresses de multidiffusion étrangères et les adresses de diffusion requièrent une conversion en adresses et messagerie natives.

Le premier cas est celui dans lequel la multidiffusion ou la diffusion a son origine sur le réseau étranger. Sachant que plusieurs hôtes, protocoles ou applications peuvent partager un réseau sans fil tel que décrit dans le présent document, il n'est pas efficace d'envoyer une diffusion étrangère vers tous les appareils sans fil. Ainsi, la diffusion étrangère dans le réseau

sans fil utilise la multidiffusion simulée vers un groupe limité. L'objet TUN est utilisé pour simuler la livraison en multidiffusion (messagerie "un à plusieurs") en maintenant une liste d'adresses de monodiffusion (matrice de points d'extrémité de tunnel) et en utilisant une séquence de livraisons en monodiffusion.

Le deuxième cas est celui où la multidiffusion ou la diffusion a son origine sur le réseau sans fil et elle est destinée au réseau étranger. Une seule APDU est livrée du réseau sans fil et est traitée par un convertisseur de protocoles pour générer une PDU de multidiffusion ou de diffusion sur le réseau étranger.

Native simulated multicast	Multidiffusion simulée native
Implied native unicast source + native unicast destination	Source de monodiffusion native + destination de monodiffusion native implicites

Figure U.23 – Mappings d'adresses réseau

La Figure U.23 montre également une paire de conversions d'adresses de monodiffusion.

Le premier cas convertit une paire d'adresses source et destination étrangères en une paire d'adresses natives. Le second cas convertit une paire d'adresses source et destination natives en une paire d'adresses étrangères. Foreign_Destination_Address et Foreign_Source_Address sont utilisés tous les deux. Seules sont nécessaires les informations relatives aux adresses issues d'un seul point d'extrémité de tunnel, car l'objet TUN a accès à sa propre adresse native pour une utilisation dans les champs source ou destination. La définition de source et de destination étrangères dépend du sens du transfert.

U.3.1.9 Informations relatives à une connexion et à une transaction

Les objets TN fonctionnent comme des points d'extrémité d'initiateur (demande d'éditeur et de tunnel) et des points d'extrémité correspondants (réponse d'abonné et de tunnel). La conversion de protocoles envoie le contenu étranger sous la forme de TUN-DATA entre les points d'extrémité. Sachant que la plupart des protocoles hérités ne sont pas optimisés pour la communication sans fil à faible consommation d'énergie, divers mécanismes sont disponibles pour augmenter l'efficacité.

Lorsqu'un convertisseur de protocoles tunnellise une PDU étrangère, il n'est pas efficace d'envoyer à répétitions les parties statiques de la PDU étrangère entre les points d'extrémité. De telles informations statiques comprennent des préambules et l'adressage fixe secondaire, tel que les identificateurs d'unités logiques. Tels que montrés à la Figure U.24, les objets

TUN fournissent un mécanisme générique (Connection_Info) pour la mise à disposition d'informations statiques à la réception de PDU étrangères sans transfert sans fil par message des informations statiques.

NOTE La PDU étrangère variera en fonction de la conversion de protocole étranger spécifique. La plupart des protocoles de bus de terrain formeront des DPDU pour une livraison directe sur une liaison locale. Par contraste, les protocoles basés sur IP forment habituellement des NPDU, où une encapsulation finale est réalisée par un protocole de résolution d'adresse.

Figure U.24 – Utilisation de Connection_Info dans la conversion de protocoles

Lorsqu'un convertisseur de protocole accomplit une transaction, il n'est pas efficace de transporter des informations spécifiques à une transaction qui sont seulement utilisées pour identifier la transaction au niveau de l'initiateur. De telles informations comprennent des informations pour relier la demande d'origine à la réponse, lorsque la connaissance du point d'extrémité peut être utilisée. Tels que montrés à la Figure U.25, les objets TUN fournissent un mécanisme générique (Transaction_Info) pour mettre à disposition les informations spécifiques à une transaction sans transporter le surdébit dans le transfert sans fil.

Connection_Info et Transaction_Info peuvent être utilisés simultanément tous les deux.

U.3.1.10 Mécanisme de tunnellisation interopérable

U.3.1.10.1 Vue d'ensemble

L'Annexe U décrit un mécanisme de communication pour que les nœuds de réseau étrangers communiquent à travers un réseau sans fil par l'intermédiaire de passerelles et d'adaptateurs. Ce mécanisme permet le développement, indépendant vis-à-vis de tout fournisseur, des passerelles et des adaptateurs en mettant en œuvre un sous-ensemble restreint des caractéristiques de communication au sein de la présente norme. La communication interopérable est réalisée par l'utilisation d'un mécanisme de tunnellisation contrainte. Les passerelles et les adaptateurs servent à interconnecter deux ou plus de deux segments de réseau étrangers en pontant les DPDU de protocole étranger par l'intermédiaire du réseau sans fil tel que décrit à la Figure U.26. Les processus d'application de passerelle et d'adaptateur utilisent les objets et les interfaces tunnel de l'AL pour l'échange de DPDU de monodiffusion étrangères et des DPDU de diffusion/multidiffusion étrangères. Le mécanisme par lequel les processus d'application de passerelle et d'adaptateur échangent ces DPDU avec des nœuds étrangers n'est pas spécifié par la présente norme.

Figure U.26 – Vue d'ensemble d'un mécanisme de tunnellisation interopérable

U.3.1.10.2 Placement d'objet tunnel

Un ou plusieurs nœuds de réseau étrangers, individuellement adressables par une adresse de DPDU en monodiffusion, peuvent exister derrière une passerelle ou un adaptateur. Un nœud de réseau étranger derrière une passerelle ou un adaptateur peut exiger la communication avec un nœud de réseau étranger associé placé derrière une autre passerelle ou un autre adaptateur.

Pour chaque passerelle et chaque adaptateur associés, un objet tunnel est disposé et configuré pour transporter des DPDU étrangères adressées en diffusion et multidiffusion, une

pour un premier segment de réseau étranger associé et une pour chaque segment de réseau étranger associé supplémentaire.

Pour chaque paire de nœuds de réseau étrangers associés, une paire d'objets tunnel est disposée et configurée pour transporter des DPDU adressées en monodiffusion, une dans la passerelle ou dans l'adaptateur pour un premier nœud associé et une dans la passerelle ou dans l'adaptateur pour un second nœud associé.

U.3.1.10.3 Configuration d'objet tunnel

Le fonctionnement de tunnel est commandé comme décrit à l'Article 12. Les objets tunnel sont configurés par l'intermédiaire des valeurs de réglage des attributs. Les modifications apportées à la configuration doivent être correctement ordonnancées en positionnant l'attribut Protocol et en surveillant l'attribut Status.

Les paires d'objets tunnel en monodiffusion sont configurées comme suit:

- L'attribut Flow_Type est configuré pour un tunnel à deux parties.
- Les attributs Array of Tunnel endpoints sont configurés pour un seul élément d'adresse, où chaque objet tunnel dans la paire adresse l'autre objet tunnel dans la paire en question.
- Les attributs Connection_Info[ ] et Transaction_Info[ ] ne sont pas utilisés.
- Les attributs Update_Policy, Phase, Period et Stale_Limit ne sont pas utilisés.

Pour les objets tunnel de monodiffusion, l'attribut Foreign_Destination_Address de chaque objet tunnel local est mis à l'adresse de DPDU de l'appareil étranger associé derrière la passerelle distante ou l'adaptateur et l'attribut Foreign_Source_Address de chaque objet tunnel local sont mis à l'adresse de DPDU de l'appareil étranger associé derrière la passerelle locale ou l'adaptateur.

Les objets tunnel dans l'ensemble d'objets tunnel de diffusion/multidiffusion sont configurés comme suit:

- L'attribut Flow_Type est configuré pour un tunnel à deux parties.
- Les attributs Array of Tunnel endpoints sont configurés pour un ou plusieurs éléments d'adresse, où chaque objet tunnel dans l'ensemble adresse tous les autres objets tunnel dans l'ensemble en question.
- Les attributs Connection_Info[ ] et Transaction_Info[ ] ne sont pas utilisés.
- Les attributs Update_Policy, Phase, Period et Stale_Limit ne sont pas utilisés.

Pour des objets tunnel de diffusion/multidiffusion, l'attribut Foreign_Destination_Address et l'attribut Foreign_Source_Address sont mis à une valeur égale.

L'utilisation de l'attribut Foreign_Source_Address et de l'attribut de Foreign_Destination_Address permet que des passerelles et des adaptateurs utilisant le mécanisme de tunnellisation interopérable soient strictement configurés par la configuration des objets tunnel.

Les passerelles et les adaptateurs associés peuvent envoyer et recevoir des DPDU étrangères issues soit de versions identiques, soit de versions interopérables du même protocole étranger. Pour permettre l'état de marche après que les autres attributs ont été configurés, l'attribut Protocol est configuré le dernier et est configuré à la même valeur dans tous les objets tunnel associés à tous les segments de réseau étrangers relatifs connexes sur le sous-réseau D. La valeur finale de l'attribut Protocol est mise conformément à l'Annexe K. Les processus d'application de passerelle et d'adaptateur peuvent rapporter le Status d'objet tunnel = 2 (configuration échouée) si une tentative est faite de configurer un tunnel avec un protocole non pris en charge.

Un protocole étranger compatible peut être capable de prendre en charge la temporisation imposée par les mécanismes sans fil, soit de façon inhérente, soit par configuration. L'échange de DPDU étrangère peut ne pas être la méthode de tunnel la plus efficace, mais il s'assure que des informations suffisantes sont disponibles pour traiter le paquet au sein des processus d'application de passerelle et d'adaptateur. Il assure également que plusieurs fournisseurs acheminent les mêmes informations entre les processus d'application de passerelle et d'adaptateur. Il assure également que des information suffisantes sont disponibles dans le processus d'application de passerelle et d'adaptateur pour relier les demandes et les réponses C/S. L'adressage est également transporté et permet à plusieurs appareils de réseau étrangers de s'asseoir derrière chaque passerelle ou chaque adaptateur.

U.3.1.10.4 Fonctionnement de tunnel

Les DPDU de réseau étrangères peuvent être livrées vers les processus d'application de passerelle et d'adaptateur de l'une de deux manières, soit par l'intermédiaire d'un objet tunnel, soit à partir d'une source étrangère à l'extérieur du réseau sans fil. La source extérieure sera habituellement un réseau câblé (et sa pile de protocoles associée) rattaché directement ou indirectement à la passerelle ou à l'adaptateur. En variante, les PDU peuvent être générées par le logiciel ou le firmware interagissant avec (ou intégré dans) le processus d'application de passerelle ou d'adaptateur directement. Dans un cas comme dans l'autre, l'échange de PDU tunnellisée entre les passerelles et les adaptateurs peut rester identique.

Les processus d'application de passerelle et d'adaptateur peuvent examiner l'adresse de destination de DPDU de réseau étrangère avant de transmettre la PDU sur le réseau sans fil. Les DPDU sans destination connue qui sont accessibles par l'intermédiaire des tunnels ne sont pas transmises.

Les processus d'application de passerelles et d'adaptateurs peuvent transmettre des DPDU de monodiffusion de protocoles étrangers vers les destinations d'adresses de DPDU qui sont accessibles par l'intermédiaire d'une paire reliée d'objets tunnel de monodiffusion.

Les processus d'application de passerelle et d'adaptateur transmettent les PDU de diffusion et de multidiffusion de protocoles étrangers par le tunnel de diffusion/multidiffusion qui existe au sein de chaque passerelle et chaque adaptateur associés, distribuant la même PDU vers une ou plusieurs destinations. La PDU n'est pas reprise en écho vers la source.

Les processus d'application de passerelle et d'adaptateurs peuvent utiliser des PDU d'établissement de groupe de multidiffusion issues de l'intérieur du protocole étranger, lorsque de telles PDU existent, afin de limiter la portée de la distribution.

Sachant que la génération de plusieurs copies du même message est presque certaine de se produire, le protocole étranger peut tolérer le biais de temporisation.

U.3.1.10.5 Fonctionnement efficace

Il convient que les protocoles étrangers qui utilisent le mécanisme de tunnellisation interopérable ramènent les échanges des PDU au minimum qui est acceptable au protocole étranger et à ses applications. Cela est accompli en allongeant des périodes et des temporisations de mise à jour pour la mise à jour périodique. Cela est également accompli par élimination de transfert redondant d'informations statiques en maintenant des copies locales.

U.3.2 Transfert en masse

Le transfert d'éléments volumineux est accompli par l'intermédiaire d'objets téléchargement montant/téléchargement descendant (les UDO), tels que montrés à la Figure U.27. Les transferts d'éléments volumineux sont utiles pour des mises à jour de firmware, le transfert de tampons d'échantillons volumineux tels que les formes d'onde capturées, et pour la configuration générale. Un UDO représente un seul élément qui peut être transféré dans l'un ou l'autre sens (téléchargé en montant ou téléchargé en descendant) vers/depuis une autre

application. L'élément devant être transféré existe à l'emplacement de l'UDO. Les objets interface (IFO) agissent comme des clients pour initier des transferts. Le protocole de transfert fournit le placement en tampon, le contrôle de flux ainsi qu'une livraison garantie et ordonnée. Les convertisseurs de protocole ont accès à l'UDO par l'intermédiaire du GIAP.

Des éléments sont associés à une chaîne qui peut être utilisée pour coder des informations relatives à l'identification et à la révision spécifiques à un élément. Des systèmes de gestion d'actifs peuvent être construits pour surveiller des révisions pour des industries régulées et pour effectuer des sauvegardes de secours et restaurer des éléments par des moyens génériques, sans connaissance du contenu de l'élément. Les convertisseurs de protocole peuvent également transférer des éléments volumineux en passant par des protocoles étrangers par l'intermédiaire de la tunnellisation, mais cela empêche la gestion d'actifs indépendant vis-à-vis de tout protocole.

Des applications finales sont censées comprendre le contenu de l'élément transféré et la manière de l'appliquer. Des dispositions existent (en fonction des capacités d'appareil) pour demander l'utilisation de l'élément (en altérant possiblement le comportement en temps d'exécution) et pour le stockage de l'élément dans une mémoire non volatile.

Les UDO et le protocole de transfert en masse de téléchargement montant et de téléchargement descendant sont décrits en 12.15.2.4.

U.3.3 Alertes

Les alertes peuvent être générées par plusieurs des objets définis dans la présente norme. Certains objets résident au sein d'UAP d'appareil, alors que d'autres résident dans le DMAP comme objets de gestion pour chaque couche.

Les alertes au sein d'un appareil sont consolidées au sein de l'objet de gestion de rapports d'alertes (ARMO). Chaque appareil a un seul ARMO qui réside au sein du DMAP. Toutes les alertes au sein d'un appareil sont commodément consolidées dans ce seul emplacement.

L'ARMO dans chaque DMAP est responsable de rapporter des alertes par l'intermédiaire d'une interface AlertReport à un objet récepteur d'alertes (ARO). L'ARO acquitte la réception d'alerte par l'intermédiaire de l'interface AlertAcknowledge. Ce transfert se produit indépendamment du traitement réel des alertes.

Les alertes s'inscrivent dans quatre catégories:

- processus;
- appareil;
- réseau; et
- sécurité.

Chaque catégorie peut être livrée par un ARMO à un ARO différent. Ainsi, un seul ARO simple pourrait recueillir toutes les alertes de processus à travers un réseau entier, ou un ensemble d'ARO peut être utilisé, avec chaque ARO recueillant seulement une seule catégorie d'alertes. Si chaque ARO recueille un seul type d'alerte, la collecte de toutes les alertes exige quatre ARO.

La passerelle contient un ou plusieurs ARO qui permettent la collecte, la production de rapports et la gestion des alertes.

Les convertisseurs de protocole ont accès à des alertes par l'intermédiaire du GIAP et peuvent les gérer, conformément au modèle d'alerte montré à Figure U.28. Les interfaces d'abonnement permettent la sélection des alertes par l'intermédiaire du GIAP.

DMAP process	Processus de DMAP
Adapter process	Processus d'adaptateur
Gateway process	Processus de passerelle

Figure U.28 – Modèle d'alerte

Les alertes s'inscrivent dans deux classes, à savoir alarmes et événements. Les événements sont informationnels et génèrent des messages d'événement par l'intermédiaire du GIAP. Les alarmes ont des états et requièrent des actions spécifiques à une alarme pour éliminer les alarmes. Habituellement, la messagerie client/serveur est utilisée pour entreprendre ces actions.

Les applications de passerelle et d'adaptateur peuvent également générer des alertes natives à partir des instances d'IFO. Cela permet à des convertisseurs de protocoles de générer des alertes au sein du contexte d'un système de gestion d'alertes normalisées.

Dans certaines circonstances, l'état d'alertes peut être perdu au niveau de l'ARO, comme lorsqu'une passerelle est réinitialisée ou remplacée. Dans un tel cas, les ARMO d'origine ne contiendront plus d'informations relatives à des événements, mais maintiendront les informations d'état relatives aux alarmes. Une procédure de récupération d'alarme peut être initiée afin de récupérer l'état d'alarme du système.

La présente norme ne prend pas en charge les alertes en multidiffusion. Il en résulte que les mêmes alertes ne peuvent pas être acheminées à la passerelle et au gestionnaire de système si elles ne sont pas contiguës physiquement. Des alertes réseau et sécurité sont actuellement envoyées dans le gestionnaire de système par défaut. Des alertes processus et appareil peuvent être envoyées vers le rôle de passerelle.

Le modèle d'alerte ne pas prend en charge les alertes de multidiffusion. Les alertes réseau et les alertes sécurité sont potentiellement utiles dans une passerelle pour la transformation en messages d'erreur de protocoles étrangers génériques. Le gestionnaire de système est la destination par défaut pour ces alertes. Dans des configurations de système où le gestionnaire de système est connecté au WISN par l'intermédiaire de la passerelle, l'ARO dans la passerelle, lorsqu'il est configuré pour recueillir des alertes pour des besoins du réseau et de la sécurité, est capable de présenter à nouveau les alertes par l'intermédiaire de l'ARMO local au gestionnaire de système. C'est ce que montre la Figure U.29.

U.3.4 Accès P/S et client/serveur natif

La présente norme fournit des interfaces P/S et C/S par l'intermédiaire de l'ASL qui est utilisée pour interagir avec les objets natifs spécifiques à une application.

Pour les interfaces P/S, les objets concaténation (CON) et dispersion (DIS) sont utilisés comme des points d'extrémité.

Pour les interfaces C/S, deux points d'extrémité d'objet sont exigés afin d'utiliser ces interfaces. L'IFO peut agir comme un point d'extrémité pour ces interfaces au sein de passerelles. Toute autre application ou tout autre objet de gestion au sein du système peut agir comme étant l'autre point d'extrémité.

Comme montré à la Figure U.30, l'utilisation de ces objets permet à des convertisseurs de protocoles d'intégrer des appareils simples qui ne comportent pas de protocoles hérités.

Figure U.30 – Accès P/S et client/serveur natif

Dans une passerelle, les objets CON et DIS peuvent fournir le comportement de message tamponné pour l'opération de changement d'état.

Au sein d'une passerelle, l'IFO peut fournir le comportement de message tamponné tel que décrit pour la messagerie tunnel à quatre parties entre les objets tunnel pour les interfaces de lecture C/S. L'IFO peut utiliser la classification des attributs pour déterminer le comportement du placement en tampon. Les attributs "non-cacheable" ne sont pas tamponnés. Les attributs "constant" sont tamponnés. Le placement en tampon des attributs "static" et "dynamic" est déterminé par les exigences relatives à l'application.

Le convertisseur de protocoles peut utiliser l'adressage natif (Network_Address, Transport_Port, OID, et identificateur d'attribut) pour identifier les messages natifs.

NOTE La tunnellisation suppose que des messages de protocoles étrangers sont transférés entre des points d'extrémité. À ce titre, les adresses étrangères sont associées aux messages et utilisées pour la démolition et la reconstruction des messages afin d'éviter le transfert. Aucune hypothèse de cette nature n'est posée pour la messagerie native, où un flux de message biunivoque est moins susceptible d'exister.

U.3.5 Gestion du temps

Le temps d'hôte peut être propagé par une passerelle vers un système sans fil, donnant au système hôte et aux appareils de terrain le même sens du temps (dans les limites des tolérances). Cela permet d'utiliser le temps d'hôte pour des besoins tels que le marquage temporel uniforme des alertes et la séquence de détermination d'événements qui recouvrent les appareils sans fil et les appareils câblés connectés à l'hôte. Sans synchronisation périodique au temps d'hôte, le système sans fil dérivera et, donc, la capacité de réajustement périodique est souhaitable. Le système d'hôte et le système sans fil peuvent être synchronisés à une source extérieure commune telle qu'une source de temps dérivée du GPS.

Pour propager le temps d'hôte, une passerelle peut accomplir une synchronisation périodique du temps dans un temps de sous-réseau D rattaché à une source externe en demandant des changements de temps par l'intermédiaire d'un DLMO.

Les convertisseurs de protocoles au sein d'une passerelle peuvent accéder à des fonctions de gestion du temps par l'intermédiaire des services de GIAP. Les convertisseurs de protocoles sont responsables d'accéder à des sources de temps extérieures et de convertir des protocoles et des formats de temps. Le temps de réseau est représenté dans le format TAI, comme décrit en 5.6.

Une DL configurée comme une base d'horloge est utilisée pour propager les informations de synchronisation du temps vers un sous-réseau D rattaché, comme décrit en 6.3.10.3. Chaque nœud contient un DMO au sein de son DMAP. Le DMO contient les attributs DL_Subnet_Clock_Master_Role et DL_Subnet_Clock_Repeater_Role qui commandent la capacité d'un nœud à être une base d'horloge. L'attribution du rôle de base d'horloge est coordonnée avec le gestionnaire de système. L'appareil enregistre sa capacité à être une source de temps au cours du processus de rattachement du sous-réseau.

Le DLMO contient un attribut appelé TaiTime qui rapporte un temps courant et un autre attribut appelé TaiAdjust pour réajuster le temps. Le DLMO est utilisé pour réajuster le temps du sous-réseau D.

Une ou plusieurs DL peuvent être associées à une passerelle. Dans une mise en œuvre, les DL sont intégrées au sein de la passerelle. Dans une autre mise en œuvre, les DL se situent au sein de routeurs dorsaux et sont séparées de la passerelle, ajoutant des retards indéterminés. Chaque mise en œuvre peut considérer les implications du retard associé à l'accès d'objets d'DL pour accomplir la synchronisation.

U.3.6 Sécurité

Des ensembles d'appareils sans fil sont reliés à un hôte étranger par l'intermédiaire d'une passerelle. La passerelle et les appareils sans fil sont censés appartenir à un groupe commun de sécurité. La sécurité pour ce groupe peut être établie par la configuration de sécurité de couche MAC et/ou de couche TL, comme décrit à l'Article 7. L'établissement des valeurs de réglage de sécurité communes est un préalable à la communication entre les points d'extrémité de communication de conversion de protocoles.

Les protocoles étrangers de bus de terrain communs n'ont pas de capacités de sécurité. Cela n'exclut pas l'extension des protocoles sécurisés vers le domaine de la présente norme. Il est de la responsabilité des convertisseurs de protocoles étrangers, tant dans les passerelles que dans les adaptateurs, d'agir comme des applications de confiance dans l'extension de la sécurité de bout en bout des protocoles étrangers. Cela peut être réalisé par l'utilisation de sécurité native ou par l'intermédiaire d'échanges tunnellisés.

U.3.7 Configuration

Pour les passerelles qui mettent en œuvre des interfaces internes telles que les interfaces GSAP exemplaires, il convient que la configuration/capacité de l'entité de passerelle soit

rendue disponible en interne à des clients internes à la passerelle. La façon dont ces attributs opérationnels internes de passerelle sont rendus disponibles relève d'une initiative locale. Des attributs exemplaires que l'entité GSAP de la passerelle peut souhaiter présenter sont décrits dans le Tableau U.41. Par souci de commodité, l'attribut décrivant les conventions utilisées sont ceux qui sont utilisés par d'autres articles de la présente norme. Voir également l'exemple d'interface G_Read_Gateway_Configuration pour un exemple de la façon dont une interface peut être utilisée pour rendre ces informations disponibles à un client interne à une passerelle.

Tableau U.41 – Exemple d'attributs de gestion de configuration de passerelle

Nom du type d'objet normalisé: non applicable

Actual_Leases	14	Nombre actuel de locations connectés à la passerelle	Type: Unsigned16 Classification: Dynamique Accessibilité: Lecture seule (Read Only)	Hausses et baisses basées sur les locations. La complexité de l'appareil déterminera le nombre de locations exigé

U.3.8 Configuration et rattachement

Une passerelle est un appareil de réseau tel que décrit dans la présente norme et elle est configurée en utilisant les méthodes génériques décrites dans la présente norme.

Une passerelle qui communique vers des sous-réseaux D par l'intermédiaire de routeurs dorsaux peut fournir une méthode pour configurer la passerelle pour communiquer vers un sous-réseau D spécifique et vers des appareils spécifiques au sein du sous-réseau D en question par l'intermédiaire d'un routeur dorsal spécifique.

NOTE 1 Rien n'exclut des mises en œuvre plus dynamiques, telles qu'un algorithme de partage de charge qui assigne des appareils au meilleur BBR trouvé, ou des passerelles et des BBR qui se découvrent l'un l'autre, ou prennent en charge la redondance qui est fournie automatiquement lorsque les sous-réseaux D se chevauchent.

Une passerelle qui communique vers un ou plusieurs sous-réseaux D par des routeurs dorsaux inclut une méthode pour configurer la passerelle pour communiquer avec au moins un gestionnaire de système, lorsque le gestionnaire de système peut résider:

- dans la passerelle;
- sur une dorsale que la passerelle peut utiliser pour la communication; ou

- au sein d'un sous-réseau D que la passerelle peut utiliser pour la communication.

Une passerelle est un appareil de réseau (contenant une AL et une adresse IPv6) tel que décrit dans la présente norme et elle rejoint le réseau à la suite des méthodes de rattachement décrites dans la présente norme.

NOTE 2 Plusieurs variantes sont possibles, par exemple: une passerelle qui se rattache en envoyant une demande interne à un gestionnaire de système corésidant, ou en envoyant une demande de rattachement par l'intermédiaire d'une PhL locale, ou qui utilise indirectement une PhL de routeur dorsal ou qui envoie la demande de rattachement à travers la dorsale vers un gestionnaire de système.

Annexe V
(informative)

Conformité avec ETSI EN 300 328 v1.8.1

NOTE 1 Avec quelques modifications (comme l'ajout adéquat de quelques "doit"), on pourrait faire de cette Annexe V la base normative pour exploitation dans la CE. Dans ce cas, l'ETSI EN 300 328 devrait être promu de la Bibliographie aux références normatives de l'Article 2.

La norme ETSI EN 300 328 est un ensemble d'exigences qui interagissent de façon complexe, ce qui requiert des déclarations spécifique de comportement de fonctionnement. Il apparaît qu'il existe plusieurs modes d'exploitation différents sous lesquels un appareil conforme à la présente norme IEC peuvent être conformes à ces exigences, qui sont généralement plus favorables pour l'exploitation de la présente norme IEC que ceux d'autres ETSI EN comme l'ETSI EN 300 440.

Les appareils conformes avec l'ETSI EN 300 328 peuvent modifier leur mode d'exploitation de façon dynamique. Il est vraisemblable que la conformité de chaque mode d'exploitation potentiel devrait être évaluée de façon indépendante.

Selon la norme ETSI EN 300 328, IEEE 802.15.4 2,4 GHz DSSS est considéré comme une modulation large bande (WBM). Tel qu'utilisé dans la présente norme IEC, il est considéré également comme une modulation à étalement de spectre à saut de fréquence (FHSSM) lorsque le programme cyclique de saut de fréquence indique au moins 15 voies.

NOTE 2 Même en cas de WBM, une certaine quantité de sauts de fréquence est nécessaire pour éviter l'évanouissement de la bande étroite qui survient fréquemment en cas de durée supérieure à quelques ms. Ainsi, le saut de fréquence se produit qu'il soit revendiqué pour un fonctionnement en mode FHSSM relatif à la conformité avec la norme ETSI EN 300 328 ou non.

NOTE 3 La norme ETSI EN 300 328:2012 v1.8.1, 4.3.1.3.2 permet de bloquer les transmissions sur certaines des voies indiquées dans le programme de saut de fréquence (mise sur liste noire) mais ne permet pas de réduire le nombre de chaînes de sauts à moins de 15. Par conséquent, l'inclusion de moins de 15 voies dans une carte de voies qui détermine le cycle de saut de fréquence des voies nominalement actives signifie que les seuls régimes de fonctionnement possibles restants sont ceux sous WBM.

Dans la présente norme IEC, les initiateurs de transactions D qui activent la détection d'activité de voie CSMA/CA "listen before talk" (LBT) avant l'envoi de chaque DPDU Data satisfait aux exigences de la norme ETSI EN 300 328 pour l'adaptivité.

NOTE 4 Ces exigences sont ETSI EN 300 328:2012 v1.8.1, 4.3.1.6.1 (FHSSM) et 4.3.2.5.2.2.1 (WBM) et le texte lié. Bien que ces exigences mentionnent "modulation adaptative", la modulation référencée elle-même est fixée, pas adaptative; c'est l'utilisation de la modulation fixée qui est adaptative. Un terme plus adapté est donc "adaptivité".

Sous ETSI EN 300 328,

- Tx-sequence-time est le temps de démarrage de l'émetteur exigé pour envoyer une DPDU Data, qui est ≤ 4,256 ms. Dans certains cas, il s'agit également du temps de démarrage de l'émetteur pour l'envoi d'une DPDU ACK/NAK, qui est ≤ 1 ms;
- Tx-gap-time est l'intervalle minimal exigé de non-émission entre la fin d'une émission et le début de la suivante par le même appareil; et
- "temps de passage" (DT) est le temps nominal pendant lequel un initiateur de transaction D utilisant FHSSM conserve son émetteur ajusté à une voie avant de changer pour une autre voie.

NOTE 5 Tx-sequence-time et Tx-gap-time sont définis dans l'ETSI EN 300 328:2012 v1.8.1, 4.3.1.2 (FHSSM) et 4.3.2.3 (WBM). Le temps de passage qui s'applique à FHSSM est défini dans une certaine mesure dans l'ETSI EN 300 328:2012 v1.8.1, 3.1 sous "étalement de spectre à saut de fréquence" et dans l'ETSI EN 300 328:2012 v1.8.1, 4.3.1.3.1. Le temps de passage est obligatoirement au moins aussi grand que Tx-sequence-time.

L'ETSI EN 300 328:2012 v1.8.1, 4.3.2.2.2 (WBM) impose une limite de densité spectrale de la puissance pour une WBM de 10 dBm/MHz EIRP. A cause du spectre de la modulation IEEE 802.15.4 2,4 GHz DSSS, cette contrainte limite l'exploitation de l'équipement sous les réglementations WBN de l'ETSI EN 300 328 v1.8.1 à une puissance de transmission maximale (total pour toutes les chaînes de transmission après un gain d'antenne et de formation de faisceau) de 20 mW (+13 dBm) EIRP.

L'ETSI EN 300 328:2012 v1.8.1, 4.3.1.1 (FHSSM) et 4.3.2.1 (WBM) limitent la puissance d'émission maximale, après un gain d'antenne ou de formation de faisceaux à 100 mW (+20 dBm) EIRP.

L'ETSI EN 300 328:2012 v1.8.1, 4.3.1.5 (FHSSM) et 4.3.2.4 (WBM) limitent la puissance d'émission moyenne des équipements non adaptatifs et adaptatifs fonctionnant en mode non adaptatif à 10 mW (+10 dBm) EIRP. L'utilisation de l'adaptativité supprime cette restriction sur la puissance d'émission moyenne.

Lorsque la WBM sans adaptativité est revendiquée, selon l'ETSI EN 300 328:2012 v1.8.1, 4.3.2.3 chacun des répondants à une transaction D dans un intervalle n'est pas autorisé à initier une transaction D dans l'intervalle qui suit immédiatement sauf si la période de non-transmission en question satisfait à l'exigence de Tx-gap-time minimal de 3,5 ms, ce qui est supérieur de manière inhérente à Tx-sequence-time pour toute DPDU ACK/NAK venant d'être envoyée.

De façon similaire, lorsque le FHSSM sans adaptativité est revendiquée, selon l'ETSI EN 300 328:2012 v1.8.1, 4.3.1.2 chacun des répondants à une transaction D dans un intervalle n'est pas autorisé à initier une transaction D dans l'intervalle qui suit immédiatement sauf si la période de non-transmission en question satisfait à l'exigence de Tx-gap-time minimal de 5 ms, ce qui est supérieur de manière inhérente à Tx-sequence-time pour toute DPDU ACK/NAK venant d'être envoyée.

Lorsque FHSSM avec adaptivité est revendiqué, les DPDU ACK/NAK qui sont envoyées par les répondants de la transaction D en tant que réponses immédiates (dans le même intervalle) aux DPDU Data envoyées par l'initiateur de la transaction D peuvent être considérés comme signalisation SCS. Alors que LBT n'est pas exigé avant l'émission de la signalisation SCS, selon l'ETSI EN 300 328:2012 v1.8.1, 4.3.1.6.3.2, la signalisation SCS ne doit pas occuper plus de 10 % du temps de passage revendiqué. Cette restriction a un impact inverse sur la durée minimale d'intervalle pour le système en exigeant que la durée de l'intervalle soit augmentée (et le débit agrégé du système diminué en fonction) par rapport à ce qui est exigé dans d'autres cas de sorte que l'occupation de la signalisation SCS (c'est-à-dire les DPDU ACK/NAK) dans les appareils revendiquant la conformité avec FHSSM ne dépasse jamais 10 % du temps de passage nominal revendiqué.

L'approche alternative recommandée pour satisfaire aux exigences de l'ETSI EN 300 328:2012 v1.8.1, 4.3.1.6.3.2 consiste à changer dynamiquement de mode pour les répondants de la transaction D pour un fonctionnement en mode non adaptatif alors qu'ils envoient leur DPDU ACK/NAK et pendant les 5 ms qui suivent (Tx-gap-time minimal exigé), temps après lequel ils reviennent au mode de fonctionnement adaptatif. Il apparaît que la seule conséquence significative d'un tel mode de fonctionnement non adaptatif temporaire est que l'appareil répondant n'est pas autorisé à initier une transaction D dans l'intervalle de temps immédiatement consécutif sauf si la période applicable de non-émission satisfait à l'exigence de Tx-gap-time minimal.

L'ETSI EN 300 328:2012 v1.8.1, 4.3.1.3.2 (FHSSM) exige que chaque séquence cyclique à saut de voie contienne un minimum de 15 voies, qu'elles soient inactives ou actives. Selon les termes de la présente norme, cette exigence signifie que seules les entrées dlmo.Ch (Tableau 160) dont la taille a une valeur supérieure à 15 sont appropriées pour une utilisation en mode FHSSM selon la norme ETSI EN 300 328 v1.8.1. Par conséquent, lorsque des séquences à saut de voie avec des longueurs de cycles inférieures à 15 sont utilisées, le

fonctionnement selon la norme ETSI EN 300 328 v1.8.1 doit obligatoirement être conforme aux réglementations WBM de la norme EN.

L'ETSI EN 300 328 v1.8.1 n'impose aucune contrainte sur le cycle de vie de l'équipement dont la puissance de transmission maximale est ≤ 10 mW (+10 dBm) EIRP.

NOTE 6 En plus de son utilisation pendant la configuration de l'appareil, pendant laquelle la configuration souhaitée de l'utilisation finale peut être définie, cette faible puissance de transmission maximale est adéquate pour les courtes distances quand des considérations spécifiques au site ne sont pas nécessaires ou ne sont pas applicables, par exemple dans un laboratoire ou sur et entre des porte-conteneurs qui composent un train en déplacement.

Il apparaît qu'un appareil conforme à la présente norme peut être conforme aux exigences de la norme ETSI EN 300 328 v1.8.1 en étant déclaré comme fonctionnant dans l'une des six catégories et en configurant ses attributs dlmo.CountryCode (9.1.15.6), en particulier les bits 11 à 14, de manière appropriée:

1) équipement WBM de faible puissance avec dlmo.CountryCode.mode=0b"x0011x"; ou
2) équipement WBM non adaptatif avec dlmo.CountryCode.mode=0b"x0011x"; ou
3) équipement WBM adaptatif avec dlmo.CountryCode.mode=0b"x0101x"; ou
4) équipement WBM de faible puissance avec dlmo.CountryCode.mode=0b"x0011x"; ou
5) équipement FHSSM non adaptatif avec dlmo.CountryCode.mode=0b"x1001x"; ou
6) équipement FHSSM adaptatif qui change temporairement de mode pour un fonctionnement non adaptatif lorsqu'il fonctionne comme répondeur de transaction D (c'est-à-dire pour envoyer une DPDU ACK/NAK) avec dlmo.CountryCode.mode=0b"x1101x".

   NOTE 7 Bien qu'il soit possible d'utiliser un équipement FHSSM adaptatif qui ne change pas temporairement de mode, les contraintes induites par le temps de passage déclaré et la durée d'intervalle minimale exigée pour fonctionner avec cet ensemble de contraintes rendent une telle catégorie hypothétique de fonctionnement inférieure à 6) en raison du débit massivement réduit du système que des intervalles extrêmement étendus induisent nécessairement.

NOTE 8 Si les régulateurs déterminent que l'équipement conforme à la présente norme ne satisfait pas à la pleine intention de réglementation pour une ou plusieurs des six catégories possibles ci-dessus, le fonctionnement dans l'un des nœuds restants est encore possible.

Chacune des combinaisons 1) à 6) impose un ensemble différent de contraintes. Certaines sont traitées automatiquement par tous les appareils sans fil qui se conforment à la présente norme IEC, alors que d'autres dépendent du mode d'exploitation demandé. Quelle que soit le mode sélectionné et configuré par l'intermédiaire de l'attribut dlmo.CountryCode de l'appareil, l'appareil fonctionne alors de telle façon et entreprend toute action exigée pour se conformer à ces contraintes.

Pour résumer ce qui précède, les contraintes réglementaires qui exigent une autosurveillance sont:

a) pour un fonctionnement dans les modes 1 et 4, limiter la puissance de sortie maximale de l'émetteur, P_{out}Max, à moins de 10 mW (+10 dBm) EIRP;
b) pour un fonctionnement dans les modes 2 et 3, limiter la puissance de sortie maximale, P_{out}Max, à 20 mW (+13 dBm) EIRP, ce qui représente une densité de 10 mW/MHz EIRP pour la signalisation de IEEE 802.15.4 2.4 GHz DSSS;
c) pour un fonctionnement dans les modes 5 et 6, limiter la puissance de sortie maximale de l'émetteur, P_{out}Max, à 100 mW (+20 dBm) EIRP;
d) pour un fonctionnement dans le mode 2, limiter le nombre total d'émissions, des DPDU Data et des DPDU ACK/NAK, de telle sorte que la puissance de sortie moyenne de l'émetteur, P_{out}Avg, est 10 mW (+10 dBm) EIRP ou moins sur tous les intervalles de mesure de 1,0 s;
e) pour un fonctionnement dans le mode 5, limiter le nombre total d'émissions, des DPDU Data et des DPDU ACK/NAK, de telle sorte que la puissance de sortie moyenne de

l'émetteur, $P_{out}Avg$, est 10 mW (+10 dBm) EIRP ou moins sur chaque intervalle de mesure de 100 fois la durée d'un intervalle de temps;

f) pour un fonctionnement dans le mode 6, limiter le nombre total d'émissions des ACK/NAK DPDU, de telle sorte que la puissance de sortie moyenne de l'émetteur, $P_{out}Avg$, utilisé pendant la transmission des ACK/NAK DPDU est 10 mW (+10 dBm) EIRP ou moins sur chaque intervalle de mesure de 100 fois la durée d'un intervalle de temps;

NOTE 9 La majorité de l'occupation de voie par des appareils fonctionnant en mode 6) se produit lors de l'envoi de DPDU Data. De telles émissions sont considérées comme de l'adaptivité selon l'ETSI EN 300 328:2012 v1.8.1, 4.3.1.5; donc, la contrainte d) ne s'applique pas à elles. Cependant, des appareils fonctionnant en catégorie 6) émettent des DPDU ACK/NAK en mode non adaptatif pour lesquelles la contrainte d) s'applique conformément à l'ETSI EN 300 328:2012 v1.8.1, 4.3.1.5. Il apparaît par conséquent que seule la totalité de telles DPDU ACK/NAK émises par un appareil fonctionnant en mode 6) est sujette à la limitation de puissance de la contrainte d). Si cette interprétation de la norme ETSI EN 300 328 v1.8.1 est correcte, alors la contrainte d) affectera principalement les routeurs dorsaux (BBR), qui, au sein d'une automatisation WISN, sont essentiellement des récepteurs de publications de valeurs et statuts de traitement et de rapports d'alertes émanant des appareils WISN de terrain. Les BBR agissant comme répondeurs de transaction dans le cas d'une transaction en duodiffusion peuvent être davantage impactés que ceux qui ne reçoivent la duodiffusion.

g) pour un fonctionnement en mode 2 et 5, satisfaire à l'exigence d'intervalle Tx-gap-time de non-émission après l'émission d'une DPDU Data;

NOTE 10 Cette contrainte est satisfaite automatiquement lorsque la durée est ≥ 8,508 ms en mode 2, ou ≥ 9,256 ms en mode 5).

h) pour un fonctionnement en mode 2, 5 et 6, satisfaire à l'exigence d'intervalle Tx-gap-time de non-émission après l'émission d'une DPDU ACK/NAK.

Pour d), e), f), g) et h), l'équipement contrôle dynamiquement son activité récente pour éviter d'émettre lorsque cela constitue une violation de l'une de ces contraintes.

NOTE 11 Alors qu'un gestionnaire de système peut programmer l'activité d'appareil pour satisfaire aux exigences de d), e), f), g) et h), il est de la propre responsabilité de l'appareil de surveiller son activité récente et d'empêcher l'émission lorsque celle-ci constituerait une violation des contraintes de réglementation. Ainsi, la responsabilité ultime pour le fonctionnement d'un ensemble d'appareils repose sur les appareils individuels eux-mêmes, et non sur quelque gestionnaire distant qui pourrait être corrompu par une cyberattaque réussie sur un seul appareil.
